The constant C as used above is taken from Peele's "Mining Engineers' Handbook."

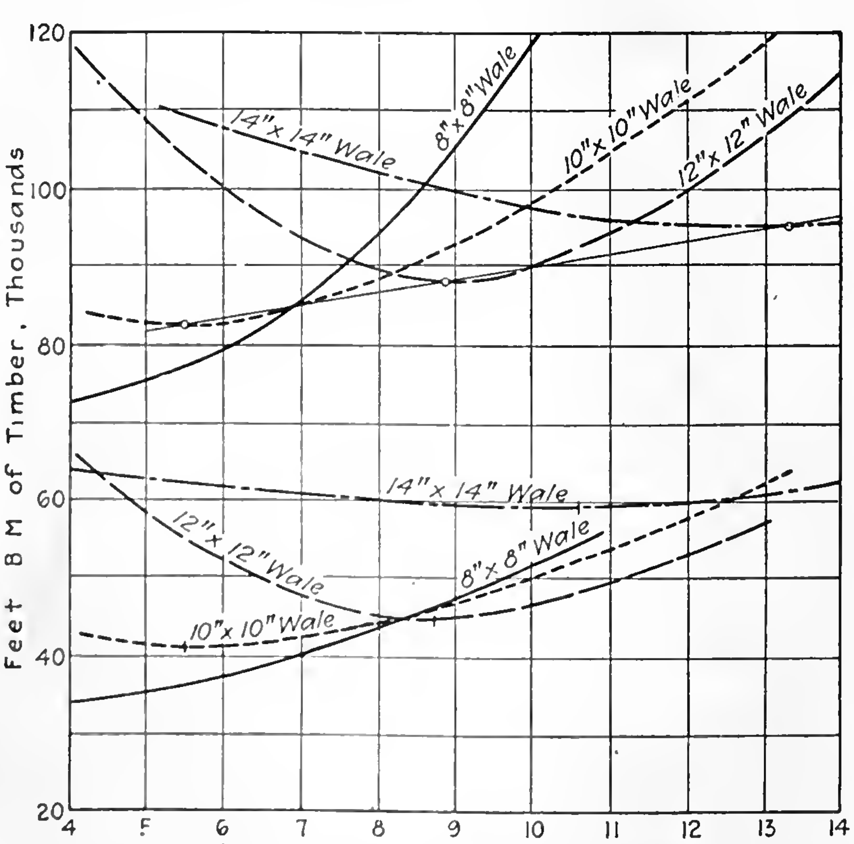

FIG. 3. CURVES SHOWING AMOUNT OF TIMBER REQUIRED FOR VARIABLE WALE CONDITIONS

sheeting. It is well to call attention to the fact that the sheeting thickness or strength will be fixed by the span between the first and second wales from the surface—not counting the one at the surface—and not the span from the surface to the first set. The reason for this is that the load upon the sheeting in the top span, as shown in Fig. 1, is just one-half that in the others; thus, the limiting size will be found in the diagram opposite the second wale, as stated before.

The size of the bracing is determined by practical considerations rather than theoretical. If we take the case of a 12 x 12-in. wale on a 10-ft. span, for the conditions in the diagram, we find that the allowable load on the wale will be 28,800 lb., which would call for about 40 sq.in. in the brace. This gives an absurdly small stick, and so, from the fact that the braces are subjected to heavy blows from one source or another, as well as from the necessity of providing sufficient area for end bearing of the wales and to satisfy numerous other construction requirements, it has been the custom to make the braces the same size as the wales or slightly smaller. This, however, does not affect the validity of our conclusions concerning economic conditions.

In conclusion, it should be pointed out that the foregoing results are based upon timber quantities and not upon the cost of the timber, the reason for this being obvious. We are here concerned with basic relations rather than local ones, which, when applied to concrete cases in connection with local conditions, will produce the most economical results for the general solution.

Blanket Lake Bottom To Stop Leaks From Water Reservoir

Dyke Also Built To Cut Off Bay From Which Loss Was Heaviest—Gage Observations Show Plan Successful

LEAKAGE from Bull Run Lake, which is a natural reservoir utilized for the water-supply of Portland, Ore., has been checked by blanketing the bottom and building a dyke to cut off a bay where much of the leakage was concentrated. There is no natural surface outlet or overflow, but the water passed out through an underground channel and emerged in the form of springs. A dam was built above this outlet to raise the water level. Leakage was discovered, however. through the boulders and shattered basaltic rock which appear to form the greater part of the lake bottom and the interstices of which have become filled with silt.

Clay containing some fine gravel is used for the blanketing, this material being obtained principally on the east side of the lake, about ½ mile from the work. It is transported on an improvised raft made of cedar logs, and equipped with a gasoline engine and propeller and a wooden 5-yd. hopper. The material is dumped from the raft in amounts depending upon the nature of the leaks. Where these occur among large boulders the blanket may have to be several feet in thickness, but where the bottom is of shattered rock a thickness of about a foot is usually sufficient.

The dyke is an earth fill, backed with large boulders on the outer slope. Material is deposited by means of skips run on wire cables and by the raft mentioned above, but after the fill nears the water surface it is finished by means of the skips alone. Care is exercised to deposit selected clay on the face of the embankment.

When the fill has been brought to the proper grade its inner face is riprapped to high-water level to prevent wash by wave action. Blanketing is carried out into the lake some distance beyond the toe of the dyke. No serious troubles have been encountered, the worst difficulty being found in obtaining suitable material for the dyke and for blanketing, as the formation is mostly loose rock and boulders, and a large quantity of waste material must be handled. All machinery and supplies for the work have to be hauled 20 miles in wagons from the nearest railway and then packed on horses for 11 miles over a mountain trail to the lake. The equipment, therefore, is necessarily light, and the work is more expensive than if it were accessible by wagon road.

To check the results of the work, observations were made by means of gages placed in the lake at various points, by the receding of the water in the bay outside the dyke, and by means of weirs at the points where Bull Run River emerges from the ground. As soon as the dyke was carried across this bay, where most of the leaks occurred, there was a noticeable decrease in the subsidence of the water in the lake as shown by the gages. There was also a marked decrease in the flow of the water over the weirs at points one mile and one and one-half miles from the lake. F. M. Randlett, engineer of the Bureau of Water-Works, who supplied the information here given, states that the larger part of the leakage is under control, although there are a few small and widely separated leaks that are to be located and stopped.

Control of Fires in Cinder Fills

Isolation appears to be the most satisfactory treatment of fires in cinder fills and culm banks. Such fires are a source of trouble on many railways using this material in fills for track and for building sites. According to report, the application of water usually has the effect of spreading the fire and even increasing its intensity, rather than extinguishing it. A method employed with success in many cases is to dig trenches to isolate the fire, which is then left to burn itself out. These trenches may be filled with clay or sand, while sand may be used also to bring the surface of the fill to grade as settlement occurs. One railway has had to dig out fires in cinder fills along its roadbed, using earth to replace the burning material. Trestles were burned on another road as the result of the practice of dumping cinders on the ends of the approach fills. Dumping at such places is now prohibited. On some roads, also, it is considered undesirable to use cinders as fills where buildings are to be erected, owing to the likelihood of trouble occurring from fires in the material.

Professional Organization in England

Abstract of an Analysis by Sidney and Beatrice Webb of the Motives, Methods and Results of Such Organization, Including That of Engineers

Many of the problems which are under active discussion among engineers in this country are keenly analyzed and discussed in the report from which the following abstract has been made. In many of its aspects the discussion covers with startling exactness the very conditions we find in this country, though the actual studies were on English professional organization. Among the topics touched upon are such pressing questions as division among professional societies, the strong centralized society versus the federation of societies, the cleavage between the leaders of the profession and the rank and file, professional responsibility to the community, the good points and the weaknesses of professional codes of ethics, and registration (or, as we call it here, licensing).

The report was made by Sidney and Beatrice Webb, the well-known English Socialist economists, for the Fabian Society, a Socialistic body, as a contribution to that organization's study of the control of industry. It appeared originally as a supplement to the "New Statesman," Apr. 21 and 28, 1917.

The full report takes up in separate chapters the professional organizations of lawyers, medical men, teachers, technicians (including engineers, architects, surveyors and chemists), of those engaged in literature and the fine arts, of those engaged in banking and various office activities, and of managers and superintendents. With this part of the report the following abstract does not deal. It does take up, however, the salient features of the two final chapters, which discuss the success, shortcomings and limitations of professional organization, and also the authors' conclusions.

The abstract is one largely made by Robert A. Cummings, consulting engineer of Pittsburgh, elaborated by additions from the original text.

Where italics are used in the abstract they are those of the editor of this journal.—EDITOR.

MOTIVES FOR ORGANIZATION

Three separate motives may be traced for the establishment of professional associations.

The first of these, and one which is usually placed in the forefront among the ostensible objects of the association, is the creative impulse—the intention and the wish to advance the knowledge and perfect the art of the vocation. This motive has not only resulted in the development of vigorous scientific societies but in genuine scientific work and intellectual comradeship. Moreover, the creative impulse is responsible for the professional code in one of its aspects, when it seeks to mark off the professional man from the profit-maker by a higher sense of honor, not only in his relations to fellow professionals, but also in those in which he stands to the community.

The second motive for professional association is that of fellowship among one's own kind, whether merely comradeship and social intercourse, or a willingness to befriend one's fellows; passing insensibly into an appreciation of the advantages of mutual assistance, and from that to mutual protection. The movement toward professional self-government is largely a development of this fellowship influence, which creates a desire to be judged or controlled by fellow members; that is, by persons who realize the conditions under which they work, and share their grievances and aspirations, rather than by persons with different social antecedents and outlook.

The third motive is the possessive impulse, the desire to secure for the members of the group all the remuneration and status which the community can be induced to accord for the performance of a particular service. The possessive impulse makes professional organization hostile to unqualified persons and even to those having a different technique. Obvious shortcomings of successful organization are the danger of an attempt to exact a higher remuneration or easier conditions of employment than are required to maintain the service in efficiency, and the objection to public regulation and to disciplinary inspection. The possessive impulse, however, is not always harmful. Without some protective development there is always a danger of any group being so crushed down as to be incapable of rendering its full service to the community. Without adequate security of a sufficient livelihood and a large measure of personal freedom in the execution of their tasks, neither the exercise of the creative impulse nor the maintenance of professional honor becomes possible.

The exercise of these three motives leads to a mutual development of each.

The professional mind is apt to be biased against new kinds of knowledge, against research which seems to lead into the domain of other vocations, and against innovations in technique which involve a change of outlook or a training different from that possessed by the existing practitioners. It is for this reason that we see arising "subject associations," confining themselves exclusively to the manifestations of the creative impulse; that is to say, the disinterested development of the science and art of the vocation; and protected against too much "professional egoism" by their inclusion not only of amateurs of the subject and men of other professions, but also of expert representatives of the "community of consumers." An instance of this is the Engineering Standards Committee.

CONDITIONS FAVORING GROWTH

It appears that the greatest reaction against vocational or professional organization was at the period when the functions of government were most limited. When state activity in a given line of service increases, we find corresponding professional organizations growing in membership and power. In fact, as the national and local governments have grown in scope and complexity of operations, they have been steadily making more and more use of, and therefore extending the influence and the power of, the professional organizations of brain workers, as a corrective to that development of bureaucracy which the collective control and conduct of public affairs inevitably necessitates.

Another set of circumstances has favored vocational organization. As long as industry is carried on by small

working masters, combining the functions of capitalist, undertaker, and business manager, and themselves using such scientific technique as was available, there was no professional organization. It was the growth of these business enterprises in size and complexity, and the consequent coming into existence of specialized classes of brain workers, divorced from participation in the profits, that led to the formation of the several professional associations. The rise of these associations in numerical strength and social power has been concurrent with the continual increase in the magnitude of the industrial enterprises with which their professional activities are concerned, and with the progressive elimination of the little working master.

Contributory to these two main causes of development is the continual elaboration and differentiation of professional technique. Without a sufficiently defined demarkation between the professional and the ordinary cultivated layman, no organization of a profession is possible. What happens is, first, the development of technique from its earliest germs and then the encouragement of the growth of technique by a professional organization.

Professional Ethics

Professional self-government has developed specialized rules of conduct. These rules can be classified under two heads, those relating to the conduct between professionals and those between professionals and the community.

The first set of rules forbids competition and criticism and prevents self-praise and advertisement. These rules discourage members of a profession from adopting unorthodox views and from associating with unqualified persons. They tend to good feeling and maintain a high standard of honor between professionals, but they may militate against innovations which make for progress, and they sometimes protect inefficiency and professional negligence.

In the most highly organized professions, an effort is made also to standardize the conduct of members of the profession toward the public. The most universal of these requirements is the distinction set up between what is permitted to a professional and what to a business man. According to the accepted canons of political economy, business men are permitted and even encouraged to compete with each other in price and quality, and to use the arts of advertisement to promote the sale of their wares. Moreover, they are assumed to make their profit by exploiting the labor of mind or body of their subordinates. They are also allowed or assumed to enter into secret understandings with other business men, with regard to sharing the profits of common undertakings. Above all, it is taken for granted that a business man will keep for his own profit any new invention or discovery that he makes, or of which he obtains control; and that he will attempt, whether by secrecy, by trademark, or by patent, to prevent anyone else from making use of it for the service of the public. All this is prohibited by professional ethics to the members of the most highly organized brain-working professions. The professional man is forbidden to take contracts in which the labor of other people is exploited for his own profit. He is always assumed to gain his livelihood solely by the use of his own faculties. He is prohibited from having any pecuniary interest, direct or indirect, in the materials, plants, processes or institutions which he recommends to his clients. So long as he is professionally engaged, he is required to think only of the advantage of his client and not of his own interest. In the higher ranges of professional ethics, he is expected to risk, and even to sacrifice, his health and his life in the performance of his professional duty, an expectation which never exists in business.

The weakest side of the ethics as elaborated by professional associations is the irresponsibility manifested with regard to the needs of the community. What the professional associations have always sought to protect is the interest of the practitioner, and the interest of the well-to-do client on whom he depends. This is true of all the learned professions, including engineers, who have been too eager to patent their own inventions to encourage their professional associations to concern themselves about how to make these inventions serviceable to the community.

If professional organization demands greater powers of government over the work of its members, and claims to decide how each profession shall be organized and conducted, it must give more attention to the requirements of the community as a whole, not merely for those persons who can pay the fees desired but for the whole population.

On the whole, the development of professional ethics has been one of the finest results of professional organization. But it has its dangerous aspects. It may be used to prevent the upgrowth of a new technique or a new method of organizing the profession in the public interest.

Militant Methods

All the devices by which trade unions attain their ends have been practiced by professional associations. For instance, there are restrictive devices requiring prolonged apprenticeship, limitation of the number of apprentices, the exclusion of women, the refusal to cooperate professionally with unlawful or recalcitrant practitioners, and the rejection of novel methods of performing the service which the public might desire.

So long as practitioners worked entirely for a succession of individual clients, the method of collective bargaining and the refusal to accept service under unfair employers were not open. As soon as professionals began to be employed at salaries, they took to collective bargaining and insisted upon a standard minimum of remuneration, refusing to accept employment, resorting to the boycott and even the strike. This is particularly true of the teachers and doctors, and in one or two cases their associations have been registered as trades unions. Professional associations have practiced militant action by resorting to political pressure, and this has become an important feature of the modern association.

Registration of Qualified Persons

In all brain-working vocations which have developed professional organizations there has arisen among the bulk of the practitioners a demand for statutory or otherwise authoritative registration of legally qualified practitioners. This demand has always been accompanied by insistence that the determination of this qualification, and, therefore, the keeping of the register, should be entrusted to an existing body of practitioners who consider themselves qualified. This identification of a register by legally qualified persons with professional self-government is, it is needless to say, neither logically nor practically necessary, and has, in

fact, often not accompanied statutory registration. In England today, where vocational organization is, on the whole, stronger than in any other country, the authoritative registration of legally qualified persons is nowhere accompanied by complete democratic vocational self-government. In many cases appointments to the governig body are made by "oligarchical corporations," such as the Colleges of Physicians and Surgeons.

The keeping of the register has resulted in prolonged controversy, the most remarkable feature of which has been not the divergence of interest between the vocation as a whole and the community as a whole, but the embittered quarrels over policy between the aristocracy and the rank and file of each profession. The agitations which have recently arisen for the statutory registration of architects and accountants, and, in a lesser degree, of engineers, are hampered by the internal dissensions within each of these vocations. The leading members of each profession see no advantage in a statutory register of qualified practitioners. What they prefer to seek are clauses in statutes and administrative orders compelling particular authorities to employ only the members of the dominant professional association. Moreover, even when the leaders of a profession give a perfunctory support to any movement for registration, they always insist that the authority controlling the register shall be predominantly made up, not of representatives of the rank and file of the profession, but of its superior grades.

The great institutions of engineers have latterly come to exercise great influence in favor of a monopoly for their own members in the appointment to important engineering posts, while during the war the recognition by the Government of these great institutions in the selection of men for commissions in the Army and places in munitions works is virtually handing over to members associates and students of these institutions the monopoly of certain grades of engineering. These indirect ways of establishing a register of persons qualified to hold remunerative posts of a public character may, in fact, be a more effective, because a more secret, way of securing for a certain group of persons a monopoly of employment. Even the growth of public opinion in favor of professional representation on royal commissions and departmental committees inevitably leads to the recognition of the membership of the principal professional association concerned as the only source from which representatives of the profession can be drawn.

Unit of Organization

In so far as professional association is based on the voluntary principle, the unit of organization seems strictly limited by the condition that all the persons to be included must have essentially identical interests on the main questions of policy. This is the fundamental cause of the variegated character of the voluntary associations of brain workers, which are always tending, with the increase in the size and diversity of the profession, to break up into new units corresponding to new group interests. It is to this cause that we ascribe the characteristic impermanence of voluntary organization among brain workers—the constant supersession of one association by another, and the perpetual shifting in relative importance of the different associations in the profession.

Nor is this tendency to a breaking up into separate societies, each pursuing its own policy, confined to differentiation of technique. We see it manifesting itself when some members of a profession, among whom are represented various types of technique, find themselves marked off from the bulk of their profession by some peculiarity of employment. The engineers working for local authorities, whether on drainage, electricity, bridges, road making, or the construction of buildings—not satisfied with the various specialized institutions of their profession—have united in a powerful organization of County and Municipal Engineers.

What determines the basis of these perpetual regroupings seems, therefore, to be not only the development of a common technique, but also the opportunity for social intercourse, the sense of a common interest, and especially the existence of common enemies, whether these are other sections of the same profession or a particular type of employer. Where a general organization includes within its scope divergent sections of one vocation, having mutually conflicting interests, differences of technique or different methods of remuneration and conditions of service, it tends either to become inert, or else to develop within itself separate associations or groups which act as caucuses pushing the divergent interests. These caucuses may end by making the association more of a battlefield than a platform for common action. Hence, one of the problems of professional organization is whether the greatest measure of common action can be obtained, where such diversity of interests exists, by *an amalgamated association* with common funds, a common policy, and a common government, or by *a loose federation of separate associations, delegating to the federal body only such powers as can be exercised with the consent of all the sections concerned.* Thus, for one or other reason, with every increase of professional organization in influence and membership, there seems to be—if the organization is on a voluntary basis—an increase in the number of separate associations, and an intensification of the diversity of their several policies.

What Is a Vocation?

When any demand is made for statutory powers of self-government, what are to be the outer limits of the vocation? Does the profession consist of all those who "habitually and for gain" coöperate in the rendering of the service or the provision of the commodity? Must we include all the indispensable contributors to the service, such as craftsmen, skilled and unskilled?

It is needless to say that no voluntary association coinciding with a vocation in this wide sense has ever arisen, or shows any sign of arising. Professional association if left to itself is always limited by the requirement for its membership of a common technique, practical opportunities for social intercourse, and a certain identity of pecuniary interest as against other classes. But when it is proposed to delegate to a profession any powers of government, the limits of the vocation to be subjected to these powers have necessarily to be defined.

Where statutory authority has been conferred, it has always been of wider scope than the membership of any one association. What has been conferred on professional association has been only the power to regulate the qualifications and conduct of certain grades of practitioners. The reason for this limitation of a unit is that the needs of a vocation can be properly understood and appreciated only by those habitually dealing with

its technique. Each service includes many techniques and a good deal of unspecialized work. *It is thus identity of training and technique, not coöperation in the service, which furnishes the boundaries of any statutory organization.*

Government of Professional Organization

Growth of self-goverment within a profession always brings about a more or less embittered dispute between the advocates of government by a select class and those of government by the rank and file. This dispute is largely responsible for the multiplication of voluntary organizations.

Is the aristocrat of the profession—the person who has enjoyed a longer and more extensive training than the ordinary practitioner, or who has developed a specialism involving a difference in technique, or who has acquired the hallmark of superior academic distinction—to be endowed with greater rights than the members of the profession having only the statutory minimum qualification? It is interesting to note that the limitation of government to a superior grade of the profession in choosing the governing council or in declaring the policy of the organization has been adopted by many of the principal voluntary organizations. Where an oligarchical constitution of this kind has not been adopted, there is a tendency for the superior grades of the profession either to abstain from joining, or at any rate from taking any active part in its affairs; or, on the other hand, for separate organizations of the superior grades to spring up either independently or within the main association, forming a powerful caucus for the promotion of sectional interest. When united action of the profession as a whole becomes indispensable, we see these various associations coming together in more or less permanent federation; and in such cases the rule is for the several associations to meet on equal terms, with equal representation, irrespective alike of gradations of rank or numerical membership—thus preserving the rights of the numerically smaller upper grades.

Whenever it is found necessary to bring in any statutory authority all these questions become acute. The main body of practitioners always desires to have the council elected by the profession as a whole, voting in equal geographical districts; but this procedure would involve the swamping, by the great numerical superiority of the rank and file, not only of the leaders of the profession, and, indeed, of the whole of the higher grades, but, what is no less important also of the various small minorities of specialists or practitioners of particular technique. There is thus a tug-of-war between the more select classes and the rank and file of the profession, the first using their political influence with the statesmen and the heads of the bureaucracy, by whom their professional superiority is appreciated, and the second appealing through the popular electorate to the members of Parliament. In the extremely important Engineering Standards Committee, which did not "come into the limelight," the influence of the superior grades has been paramount.

The question whether the professional organization shall be governed by the rank and file, or by the members of its superior grades is more important to the public than may at first sight appear. If the influence of the rank and file is decisive, the tendency is towards (1) maintaining only one ungraded qualification, so that there shall be no claims to superiority of status; (2) upholding a policy of "sharing out" the work, which leads to the objection to salaried service; (3) a preference for "rotation of office" or promotion by seniority; (4) keeping the qualification for public appointments low, so that they may be within the reach of all; (5) objecting to any requirement of a particular training, experience or academic attainment. On the other hand, in associations in which the influence of the superior grades is dominant we find (1) a desire for a graded profession, in which each grade has its own qualifications for entry; (2) a bias in favor of reducing the intellectual qualifications required for the lowest grade, in order to widen the gulf separating it from the higher grades; (3) a policy of restricting public appointments and honors of the profession exclusively to the members of the highest grade, irrespective of the special talents or special experience of exceptional members of the lower grades. It must not be taken for granted that either of these policies is necessarily good or bad. What is bad is that they are constantly being pressed heedless of the interest of the community which the profession has to serve.

Results of Professional Organization

The results of professional organization have been of a very mixed kind.

Effective organization, in the way of beneficial effects, raises the standard of professional honor, improves the education of its members, increases the opportunity for their professional training, disseminates improvements in professional technique, and promotes the scientific study of its subject matter. In all these ways professional organization has for its result an improvement of the service which the profession has to render the community; and it is not a matter for complaint if, coincidentally, there is also a raising of the status of the profession in public consideration, and even an increase in its aggregate emoluments and privileges.

There are, however, other results which are more invidious. Professional organization seems never to escape a tendency to exclusiveness. Whenever it controls or influences the entry into the profession, it tends through educational qualifications, apprenticeship and high fees, to confine the recruiting of the profession to the small social class which alone can afford for its children a long and expensive schooling of the conventional type. These onerous and restrictive conditions of entry are often justified by the importance of securing in the profession persons of cultivation and superior attainments.

No less serious is the influence of professional organization in refusing to recognize any but the science and art that were current in the generation that is passing away. This reluctance to admit the new knowledge or the new processes is seen at its worst when what is knocking at the door is some revolution which would shift the boundaries of the profession, transfer some of its service to another set of practitioners, or consign to the scrap heap some of the processes by which its members have gained a living.

Sphere of Professional Organization

Professional organization has shown itself to be of the greatest use to the community where it has been inspired by the creative impulse, with which the fellowship impulse is often associated. It is, in the main, to

the individual and collective activities of the existing body of practitioners—these activities being heightened by professional association—that the community owes most of the continuous advance in the science and art of a profession; because these practitioners alone enjoy that combination of knowledge, training, and daily opportunities for discovery upon which progress normally, although by no means invariably, depends.

Professional organization is, moreover, indispensable as a defensive force. Experience demonstrates that it is required for protection, alike of the individual practitioner against the economic oppression and lay tyranny to which he may otherwise be subjected, and of the profession itself against conditions and restrictions which would withhold from it the necessary means of training and improvement, deny to its rank-and-file members an appropriate standard of life, and prevent the most efficient service.

But professional organization has also an important part to play in the government both of the profession itself and of the service which it renders, and, therefore, in the government of the community. The very specialization of the professions renders it both difficult, and in the public interest undesirable, for the government of the professions to be carried on exclusively and autocratically by a lay authority, even if it represents the consumers, or by a bureaucracy trained only to administration.

On the other hand, it is undesirable to give to professional organization undivided control over the conditions of entry to the profession, the training required, the power of expulsion from a statutory register, the organization of the service, the terms of public employment, the technique to be encouraged or prescribed, and the treatment to be meted out to "unqualified practitioners." What is required is some sort of composite authority, such as the Engineering Standards Committee, in which there can be represented, not only the knowledge and desires of the profession, but also the interests of the consumers or users of the particular service, the larger and more enduring interests of the state, and even the knowledge and desires of other professions which may be indirectly concerned. The first function of professional organization is to supply duly authorized representatives of the profession to such composite authority.

The second function of professional organization in connection with the government of its service, and the most important of all, is one which has so far scarcely been claimed by professional associations. This is the function of independent, authoritative criticism of the government of the state, alike in its central and in its local administration, and of responsible advice, both to the legislature and the executive on matters in which the profession has special competence. One of the gravest drawbacks of the bureaucratic administration which is involved in all enterprise on a large scale is the immunity from expert criticism which is now secured by official secretiveness and departmental discipline, and the practical monopoly of access to the mind of the minister or governing committee possessed by the departmental chiefs. We know of no effective organ of criticism except that which might be afforded by professional organization.

Perhaps the most important of all of the aspects of this criticism and advice which it is the duty of professional organization to supply to the state is one which has hitherto been entirely neglected. It should be a matter of professional honor for the collective organization of each profession to see to it, *not merely that its members are well qualified and properly remunerated, but also that the service of the profession is supplied in adequate quantity for the needs of the community, not only the rich but also the poor.*

The Unsolved Problem

The most intractable problem of professional organization, and one for which this report offers no complete solution, is how to discover, in each profession and in each branch of a profession, the most effective unit of organization, and the most appropriate method of formulating a general will, alike as an organ of expression and criticism, and as an instrument for supplying representatives to composite authorities. The simple solution of asking all the registered or recognized practitioners to elect a council representing the entire profession has two capital drawbacks. It submerges all the expert specialists, and all the newer and smaller sections, in the undistinguished mass of the rank and file pursuing the old routine. Moreover, even when provision is made for enabling these minorities to have a share in any pronouncements of the council, the result is blurred and ineffective; in the compromise between the different elements the specialization of knowledge and intensity of emotional experience, or just what is most valuable in vocational association, is inevitably lost.

Finally, the characteristic impermanence of professional associations, which results naturally from the constant shiftings of a progressive technique and a changing social environment, makes it difficult, without an objectionable stereotyping of that which is in its nature variable, to base upon these voluntary associations any formally constituted professional council which is intended to be permanent. *The only inference we can draw is that the constitution of any professional council, whether statutory or voluntary, must necessarily be complicated, ought always to be elastic, and will need to be perpetually revised.* A solution may perhaps be found in an elaboration of what may be called "stratified democracy," in which the affairs of each grade or special section are dealt with separately by that grade or section, with an independent and uncensored right of expression, as well as by the profession as a whole.

Status of Government Motor-Vehicle Equipment

Delivered and uncancelled contracts for motor vehicles of all types for the Government Army service covered 254,626 units, by recent report. Of these 223,871 have been delivered and 30,755 are still under contract. Motor trucks of all kinds total 115,137, of which 96,551 have been delivered and 18,586 are still under contract. Motor cars, ambulances, motorcycles, trailers and bicycles to the number of 139,489 have been contracted for; 127,320 have been delivered and 12,169 are still to be delivered. These figures do not include 4847 Ordnance Department trailers which were purchased. Of the total number of motor vehicles, 126,111 are overseas, while 97,760, which number includes those still under contract, are in the United States. It is reported that large numbers of these trucks will be transferred to the Postoffice Department for the transportation of mail and parcel-post matter.

Long-Distance Motor-Truck Haulage Costs in Ohio

Routes Between Akron, Youngstown and Cleveland Investigated—Present Rates Too Low—Operate for 52 Cents per Truck Mile

An investigation made of one of the long-distance motor-trucking companies, operating between Akron, Cleveland and Youngstown and covering a 12-months' period, has recently been completed by Melvin W. Boyle for the Packard Motor Car Co. The results of the investigation show that freight rates which have heretofore been charged are much too low—not giving a reasonable profit to the truck operator. The cost of running a 3½-ton truck averaged \$28.89 per day when covering an average distance of 55 miles, or about 52c. per mile. The investigation was made to determine what rates should be charged, as indicated by the actual cost of doing business. The following is an abstract from the report covering the investigation:

Freight shipments between Cleveland and Akron were found to be much greater than those between Cleveland and Youngstown. The amount hauled between the former places was 80% of the total. However, the cost per mile on the haulage of the 20% transported between Cleveland and Youngstown showed the same cost per mile. The investigation covered a company operating twelve 3½-ton trucks. The amount of freight from Cleveland to Akron was just about double that from Akron to Cleveland; the average loads being 8500 and 4300 lb., respectively. Thus, the trucks generally ran one way only half loaded. If this could be remedied the indicated rate would be cut considerably.

One of the largest factors tending to increase the cost of operation was found to be the condition of the roads. Breaks in the surfacing requiring detours, failure to remove snow, etc., all caused costs to jump. At times it took trucks from two to three days to make a return trip between Cleveland and Akron. Trucks were blocked in the snow, requiring gangs of men to dig them out, and often an extra truck had to be sent to assist. After every heavy snowstorm the trucks had to break their own way, not only being delayed thereby but having excessive repair charges due to the wear and tear. The extra expenses for drivers, gangs of men, etc., mounted when bad conditions were encountered. During the spring months the road was impassable in many stretches, which required long detours over poor roads in which deep ruts and holes were formed, often causing breakage of springs, injury to differentials and other damage.

Mileage Figured

The average number of miles covered per truck per day was 55, or 16,500 miles per year of 300 days. This mileage allows for truck repairing, overhauling, time lost in loading and unloading, and various other delays. Thus, although the actual speed in operation was much greater, the average was cut down by this loss of time. The development of the pneumatic tire will undoubtedly increase mileage and thereby lower the cost; however, this tire has not yet been put on the market for the larger trucks, and cannot be an immediate remedy.

Referring to the accompanying table, some of the items need explanation. Item 5, driver's expense, covers meals and room rent when out of town. Item 10 covers the expense of a repair gang which is necessary in long-distance motor trucking. This gang must consist of men competent to repair trucks, and it must be ready to work night or day when trucks are broken down. The records show that two mechanics were necessary to keep 12 trucks moving. Item 11 covers one complete overhauling per truck per year, which has also been found necessary. Item 13 covers warehouse charges, salaries, office expense, traveling expenses, etc., for the three cities on the route.

OPERATING COST FOR LONG-DISTANCE TRUCKING, BASED ON 55 MILES PER DAY AND 300 DAYS PER YEAR

Item	Cost Per Year	Cost Per Day	Cost Per Mile
1. Interest on \$5,000 at 6% on depreciated value	\$180.00	\$0.60	\$0.0109
2. Insurance, complete protection	450.00	1.50	.0272
3. Depreciation at 20% per year	1,000.00	3.33	.06
4. Driver at \$5.00 per day	1,500.00	5.00	.0909
5. Driver's expense	300.00	1.00	.018
6. Helper, part time	100.00	.33	.006
7. Gasoline, 3.2 miles per gallon at 25c.	1,288.65	4.29	.0781
8. Lubricants, 78 miles per gallon at 58c. and 10c. per day for grease, etc	155.10	.51	.0094
9. Tires, 36 x 5, dual rears at \$448.00, less 10%	952.05	3.17	.0577
10. Repair men, 1 at \$1,900 per year; 1 at 1,500 per year; \$3,400 ÷ 12 trucks.	283.33	.94	.0171
11. Repairs—Overhaul	600.00	2.00	.0363
12. Garage	225.00	.75	.0136
13. Overhead, \$1,600 per year each truck	1,600.00	5.33	.0969
Totals	\$8,634.13	28.75	\$0.5221
14. Claims ½%	43.17	.14	.0026
Complete total	\$8,677.30	\$28.89	\$0.5247

Computation of Necessary Freight Rates

In a trip from Akron to Cleveland and return the distance covered averaged 100 miles. This was due to a certain mileage covered in each city, in delivery and pick-up. Using the cost per mile as shown in the table, the cost per trip would be \$52.47. The average tonnage, as stated before, was one-half load up and a full load back, or an efficiency of 75%. On a basis of 8500 lb. for a full load, the costs and the indicated freight rates are as follows for various efficiencies:

For 75% efficiency, the combined load would be 12,750 lb., transported at a cost of \$52.47, or \$0.4115 per hundredweight. With a profit of 20%, the indicated freight rate would be \$0.4938.

At 83% efficiency or two-thirds loaded one way and a full load the other way, the combined load would be 14,168 lb., or an average cost per hundredweight of \$0.37, which with a profit of 20% added would give an indicated freight rate of \$0.444.

With a 100% efficiency, or a combined load of 17,000 lb., the indicated freight rate per hundredweight would be \$0.369. The records showed practically no difference in operation cost for loaded and empty trucks.

Present rates are far below these indicated rates, principally because the operators had to make a tentative rate until the limiting costs had been determined. Furthermore, the established trucking companies are put at a disadvantage by the man owning a single truck who is willing to use it for a day or two in good weather to keep his truck busy. To run a legitimate trucking business, the operator must work summer and winter and in all kinds of weather, and if manufacturers want this service they must pick a dependable concern and pay a profit; otherwise, the trucking companies will have to go out of business.

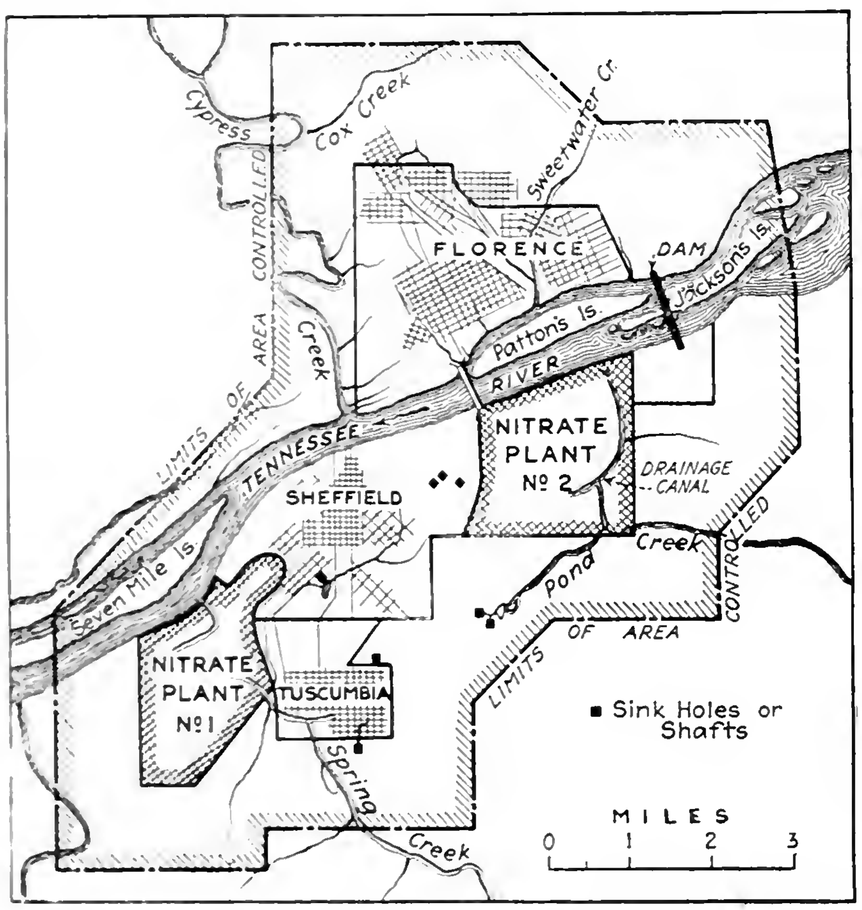
It may be interesting to know that of at least 20 companies, many small and a few of good size, which have operated between Akron and Cleveland, there are only two still in business which have operated over one year.

Malaria Control at Nitrate Plant

Mosquito Eradication by Clearing, Drainage and Oiling Water Surfaces Reduces Disease 95 Per Cent in Alabama District

By W. G. Stromquist
Sanitary Engineer, United States Public Health Service, Florence, Ala.

To safeguard the health and increase the efficiency of the 20,000 employees building the two nitrate plants at Sheffield, Ala., the United States Public Health Service in March, 1918, by request of the Alabama State Board of Health, organized the Muscle Shoals sanitary district, including the nitrate plants, the construction camp of the Tennessee River dam and the cities of Florence, Sheffield and Tuscumbia. Malaria being prevalent and the plants drawing a large proportion of labor from malarial sections, measures for control of this disease were an important feature of the activities. An area of approximately 60 square miles was included in districts where the mosquito-eradication work was done.



MOSQUITO EXTERMINATION DISTRICT INCLUDES CITIES AND NITRATE PLANTS

North of the Tennessee River the topography is hilly, with level bottom lands along the river. Except for sloughs in the bottoms, the drainage is good. The larger islands contain swampy areas. A high bluff cut by steep and narrow gullies borders the south bank, beyond which the land is level to rolling. A number of drainage areas have no surface outlet, so that there are many ponds. In general, the soil is loam and clay overlying limestone, which outcrops in many places. Sink holes in the limestone region provide outlets for the surface water of some of the isolated drainage areas.

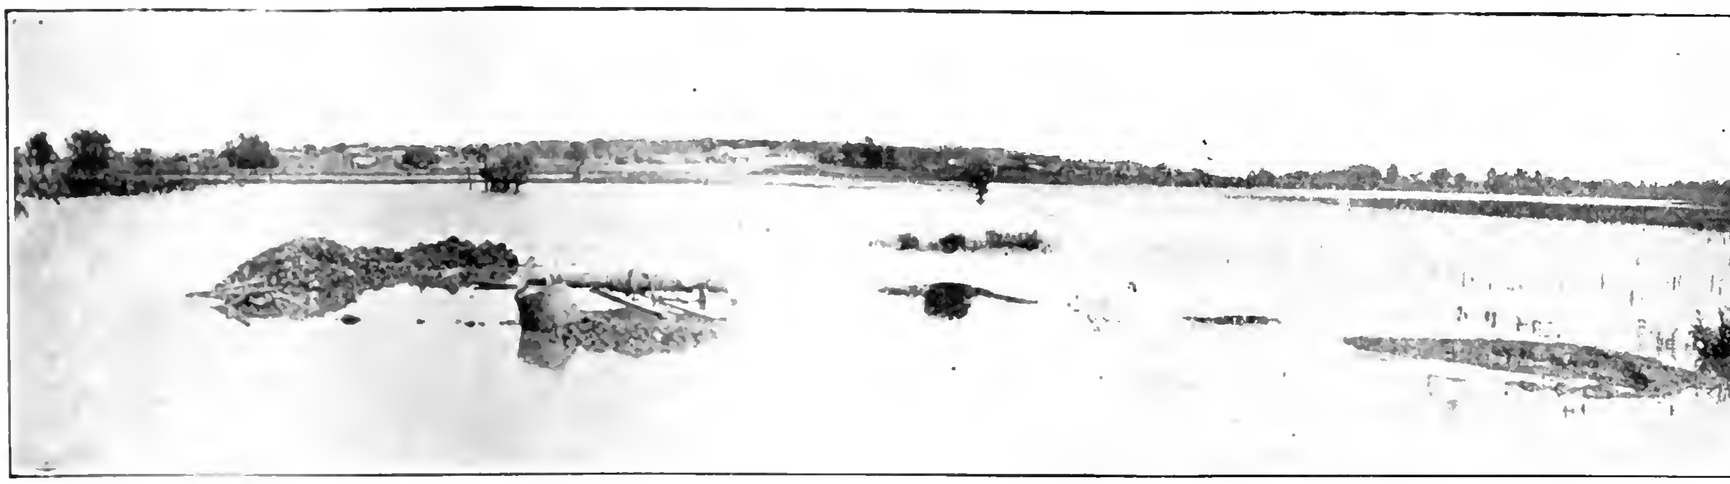
As malaria-carrying mosquitoes may fly one mile from their breeding places, all water surfaces within that distance of the area to be protected were considered a menace. A hurried survey determined the five most important problems, which are shown by the map: The Pond Creek area; Spring Creek; sloughs on Patton's Island and in Florence; sloughs in the river bottoms west of Cypress Creek, and, finally, a large number of ponds.

Drainage was the prominent feature of the work, in order to eliminate breeding places. Ditches were dug or improved, new channels cut and old channels cleared of brush and drift, all this being supplemented by oiling. Some of the heaviest work was on Patton's Island. Conditions there before and after drainage are shown in the accompanying views. A canal built to carry waste water from Plant 2 to the river provides drainage for a swampy area, and a lateral from this intercepts part of the flow of Pond Creek. Vertical drainage by natural sink holes and vertical shafts was a feature of the work. Two sink holes forming the only natural outlet of Pond Creek were enlarged, a timber crib 10 ft. square and 30 ft. deep being sunk in one of these. A 40-acre pond near the business section of Sheffield was drained by a shaft 40 ft. deep, with results shown in two of the views, printed on the next page.

Approximately 30 miles of streams were cleared, 12 miles of new ditches dug and 12 miles of old ditches improved. Ditches require frequent attention, to prevent obstruction by vegetation and drift. Very little maintenance was done last season, however, owing to the greater necessity of completing the drainage work, but as the season was unusually dry there were no ill effects.

Mosquito breeding was controlled in all water surfaces by oiling with a 1:2 mixture of black oil and kerosene. The oil was delivered in barrels and distributed so as to be readily accessible for the oilers, who carried 5-gal. knapsack sprayers. Each man cov-

CONDITIONS ON PATTON'S ISLAND BEFORE AND AFTER MOSQUITO WORK
This slough is within mosquito flight distance of Nitrate Plant 2 and Florence.



A POND OF MORE THAN 40 ACRES AT SHEFFIELD, ALABAMA, WAS DRAINED BY 41-FOOT VERTICAL SHAFT INDICATED BY WINDLASS

This pond covered "city lots" near business center of city. Conditions before and after drainage are shown by the two views.

ered a district of 5 to 6 square miles. Drip cans used on the smaller streams were 5-gal. galvanized cans with a ¼-in. air cock near the bottom. These were placed in boxes and suspended about 5 ft. above the water, being adjusted to drop 15 to 20 drops per minute. This treatment was supplemented by spraying.

Medical students were employed to inspect the oiling and to look for mosquito breeding, each inspector covering two or three oiling districts. Numbered signs at ponds and along streams and ditches facilitated the daily reports of oilers and inspectors. Oilers reported all ponds visited, and whether oiled or found dry. Inspectors reported as follows: Oiled, needs oil, or dry; mosquito larvæ present or not found. In general, oiling and inspection were done once a week. About 55 miles of streams and ditches and 300 ponds were oiled, using 14,500 gallons.

Labor shortage was one difficulty. With an eight-hour day as a basis the men worked 10 hours, receiving time and a half for overtime. At first laborers were paid 25c. per hour, which was soon increased to 30c. and then to 35c. near the end of the season. Foremen were paid $5.50 and $6.60 per day. High wages and a poor grade of labor greatly increased the cost. On the drainage work, from three to eight gangs were maintained throughout the season. These varied from six to 30 men, according to the nature of the work, but in general it was found best to have 12 to 15 men in each gang. The fact that some of the foremen were familiar with local conditions and took personal interest in the work was an important factor in its success.

Five medical students were employed as oiling inspectors from about June 1 to early in September. An engineering student made surveys and kept cost records. A maximum of nine laborers were used as oilers. The maximum force was 140 men. Federal funds bore the expense of supervision, labor, the purchase and upkeep of two trucks, gasoline and oil for the trucks and for cars used in supervision of the work. Funds appropriated by the two counties and the three cities were used to buy tools and other equipment.

Cost records were kept, with actual man-hours, the foremen making daily progress reports. The cost of drainage and maintenance work was divided into labor, foreman, transportation and incidentals. The cost of oiling included labor, inspection, transportation and oil. The transportation charges consisted of the truck drivers' wages. The total cost was approximately $60,000. With 50 square miles controlled, exclusive of

COST OF MOSQUITO ELIMINATION, PER SQUARE MILE

Supervision	$80
Labor:	
Drainage	800
Maintenance	25
Oiling (including inspection)	100
Transportation:	
Cost and upkeep of trucks and automobiles	85
Tools and supplies	60
Oil	50
Total	$1200

the plant reservations, the cost per square mile was $1200, distributed approximately as shown in the accompanying table. With the most difficult and expensive work completed, and the probability of lower wages, it is thought that the mosquito breeding could be controlled during the coming season at about one-third the cost for the first season. It is expected that the local authorities will appropriate funds and that supervision will be maintained by the United States Public Health Service.

Malaria has been reduced 90 to 95%, according to local physicians, but there are no records of the number of cases in previous years. The absence of mosquitoes is a subject of favorable comment by residents.

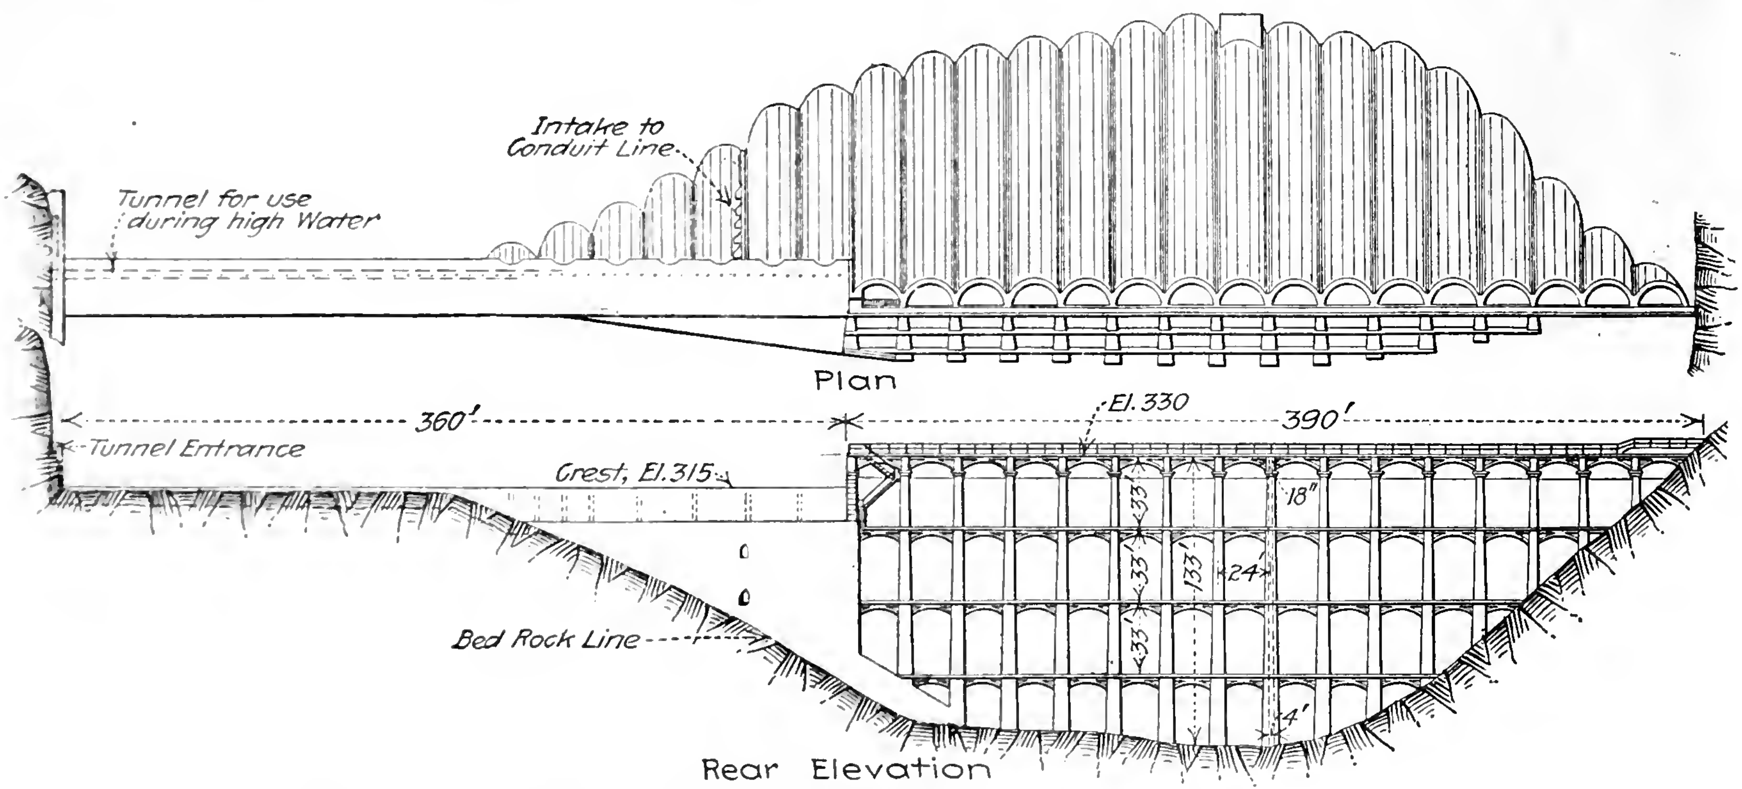
The mosquito-eradication work in this and other dis-

tricts has been under the supervision of J. A. A. Le Prince, senior sanitary engineer. R. E. Tarbett, sanitary engineer, organized the work in the Muscle Shoals sanitary district. The general activities were organized by Surgeon L. L. Lumsden, with Assistant Surgeon H. S. Mustard, and later Assistant Surgeon Thomas Parran, Jr., as medical officer in charge. The writer was in immediate charge of the mosquito-eradication work, assisted by H. R. Fullerton, assistant sanitary engineer.

Record Height Concrete Multiple-Arch Dam Completed

Dam Forming Lake Hodges in Irrigation District Near San Diego Is 136 Feet from Crest to Low Point in Valley

A MULTIPLE-ARCH reinforced-concrete dam just completed by the San Dieguito Mutual Water Co. in southern California has an overall height of 136 ft., which makes it the highest structure of this type on record. It is located on the San Dieguito River about 30 miles from San Diego, and will have a storage capacity of 38,000 acre-ft., which is to be used for irrigating lands in the valley below.



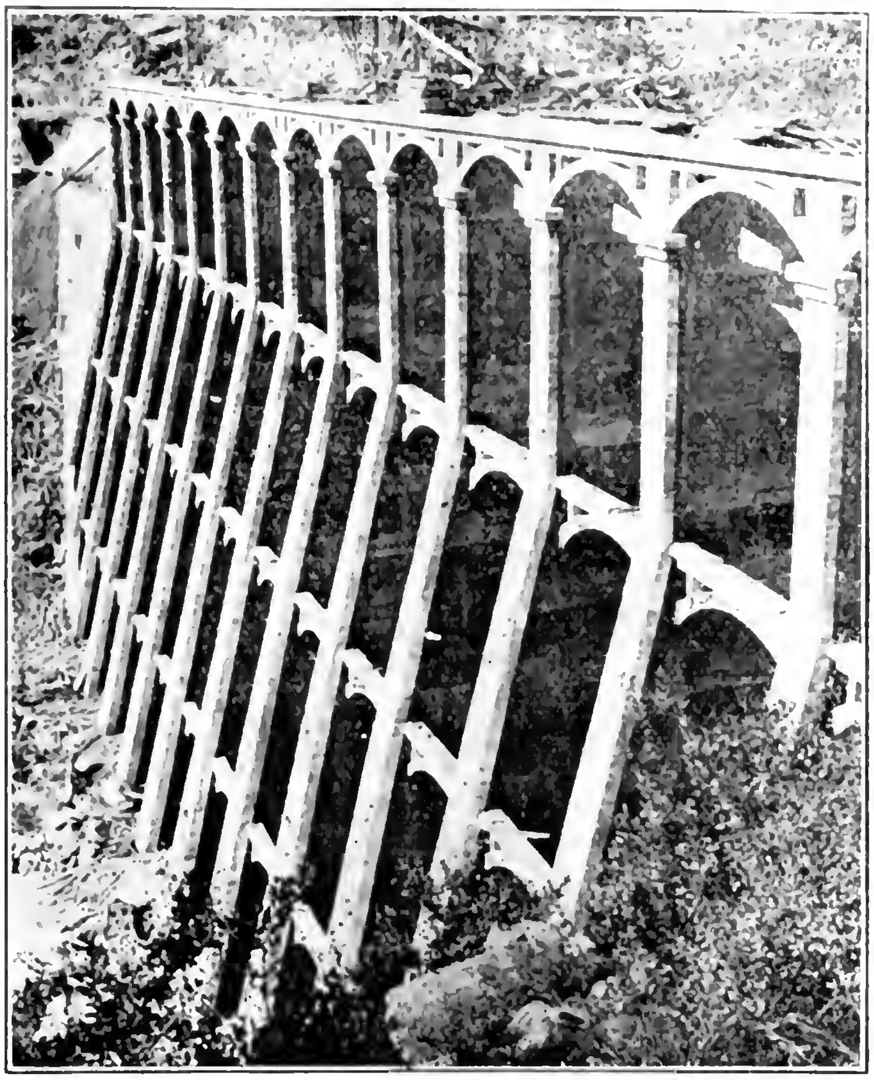
LAKE HODGES DAM FOR SAN DIEGUITO MUTUAL WATER COMPANY, CALIFORNIA

The length of the concrete structure across the gorge is 558 ft., the balance of 192 ft. being a wide bench at the north end of the dam excavated in the solid rock in order to provide a spillway of 70,000 sec.-ft. capacity. This capacity was required by the State Engineer's office, as the maximum stream flow on record at this point is 72,100 sec.-ft. The total length of the spillway provided is 360 ft., of which 192 ft. is excavated from the mountain side, and 168 ft. is in the form of a rollway over the top of the concrete structure at its north abutment. The storage capacity in the 15-ft. rise between the spillway level and the top of the dam would be 38,000 acre-feet; that is, equal to the net capacity below spillway level. In order to avoid obstructing the spillway with piers supporting an overhead bridge, access to the valves under the dam is maintained during high water by means of 4 x 6½-ft. concrete-lined tunnel built under the spillway for a distance of 192 ft., connecting at this point with a series of concrete foot bridges extending under the dam through the buttresses and from which the blowoff and service gates can be reached.

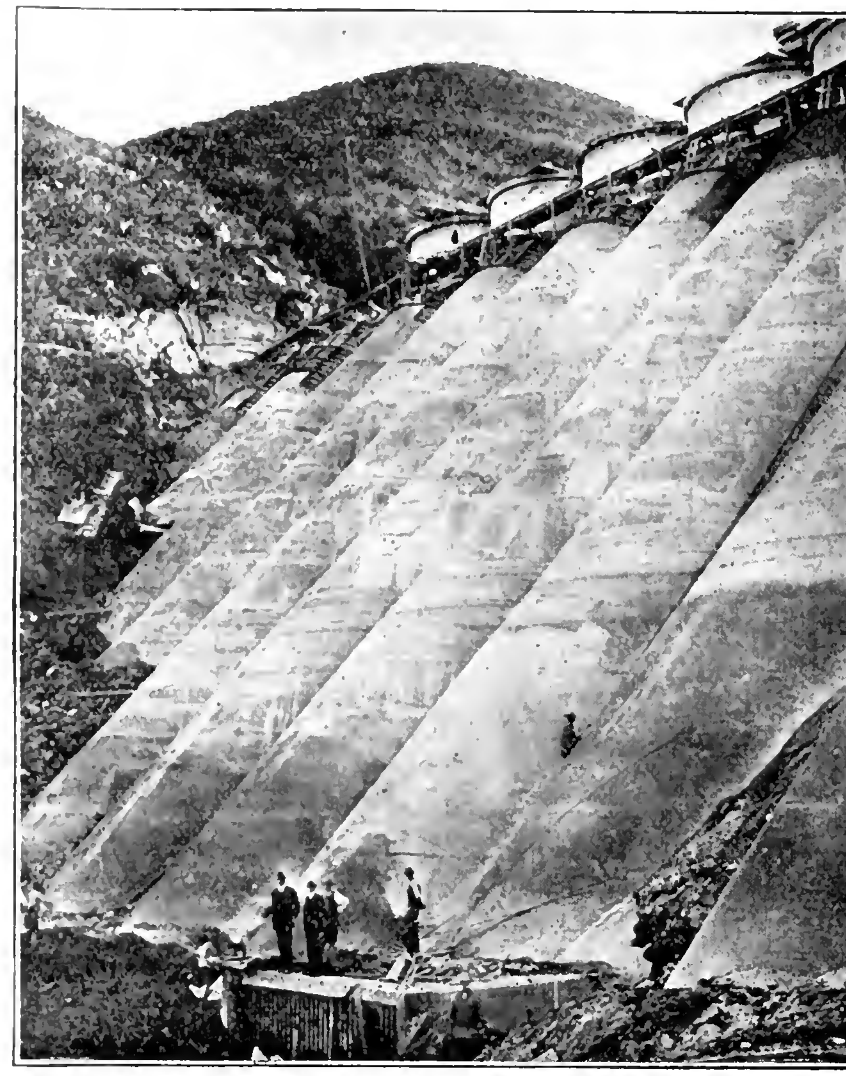
During low-water periods, operators have access by a more convenient entry, through the downstream face of the spillway, into the chamber where the valves admitting the water to the irrigation conduit are located. These consist of six 20-in. outlet gates set so as to draw water off at 10-ft. lifts. Each gate has its screen and connecting pipe to the conduit, which through the structure and beyond, is a heavily reinforced-concrete tube tied to the buttress at one side and laid on bedrock throughout. There are also four 24-in. blowoff valves at the lowest point of the dam. The latter are reached from a suspended concrete stairway running down from one of the concrete footwalks mentioned before.

The buttresses, which rest on bedrock, have no reinforcement except where arches, strut-beams and foot walks are tied in. They are spaced 24 ft. on centers and vary in thickness from 4 ft. at the bottom of the tallest buttress to 1½ ft. at a point 47 ft. below the top of the structure, and above this point this thickness is maintained. Each buttress has a showing face 2 ft. thick and increasing in width from 4 ft. at the top to 8 ft. at the bottom.

The arches vary in thickness from 2 ft. 7¼ in. at the lowest point to 1 ft. at a point 50 ft. below the top of the dam, and maintain this thickness of 1 ft. to the crest, the extreme crest, however, being stiffened by means of a coping 2½ ft. wide by 1 ft. deep. The crown slope of the arches is 45°. The radius of the extrados of the slanting arches is 13 ft. 10¼ in., and the radius of the intrados is variable. The reinforcement is shown on the drawing.

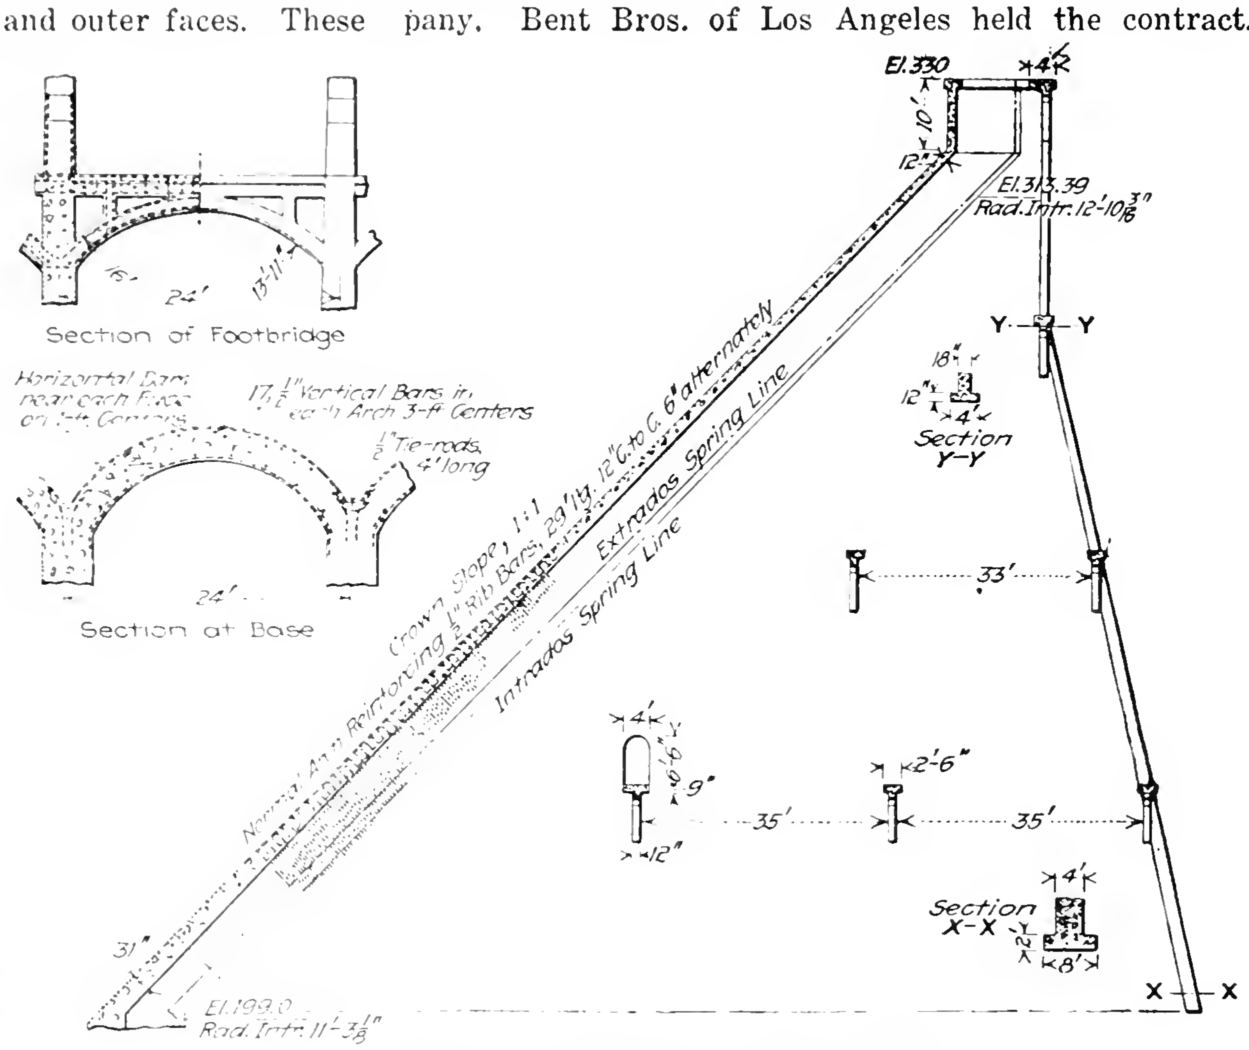


DOWNSTREAM FACE OF HIGHEST MULTIPLE-ARCH DAM HAS ARCHITECTURAL PRETENSION



UPSTREAM FACE OF MULTIPLE ARCHES ARE FINISHED WITH THE CEMENT GUN

The greater part of the reinforcing steel is composed of ½-in. deformed bars. Part of the reinforcing in the spillway roll top and in the strut beams is of ¼-in. deformed bars. In the arches the ½-in. bars are spaced 12 in. on centers on both inner and outer faces. These reinforcing bars are so alternated that the vertical space between bars in the two faces does not exceed 6 in. The arches are also reinforced with vertical rods 2 ft. on centers alternately near inner and outer faces thus giving vertical reinforcement 12 in. on centers. All steel was kept 2½ in. from the surfaces. The concrete mix in the arches was 1 : 2 : 4. The cement gun was used for putting a finishing coat on the upstream face, and has given a very satisfactory finish. The 50-ft. head of water thus far stored behind the dam did not cause any leakage through the structure. During February, 1918, a sudden flood passed through the partly finished dam over an arch that had been left about 25 ft. below the tops of the other arches. The low arch was overtopped to a depth of about 20 ft., the flow falling between the two buttresses for several days without damage. The dam was designed by John S. Eastwood, who served as consulting engineer for the company. E. A. Case was the chief engineer in charge of construction for the water company. Bent Bros. of Los Angeles held the contract.



DETAILS OF THE LAKE HODGES DAM

How Should a Federal Department of Public Works Be Organized?

Need for Clear Determination of What Bureaus Should Be Included, and How Personnel Should Be Protected and Built Up

By Charles Whiting Baker
Consulting Editor, "Engineering News-Record"

A NATIONAL convention of engineers has been called by the Engineering Council to meet in Chicago, Apr. 23-25, to formulate plans for the organization of a Federal Department of Public Works and for a campaign that will secure its creation by Congress.

That the engineering profession is undertaking a very large and difficult task, anyone who realizes the huge inertia which retards all Governmental action will agree. Even on matters of great public importance, to which there is no opposition, it is often very difficult to obtain action by Congress. If the project for a Federal Department of Public Works is to have any chance of success, it must be presented in such form that a powerful body of public sentiment can be enlisted in its support and that opposition will be aroused from as few sources as possible.

For more than forty years there has been discussion in the engineering profession as to the desirability of a Federal Department of Public Works, manned by a permanent body of civilian engineers. Seldom, however, has the discussion included the details of how such a Government department should be organized.

It is evident that if the profession desires now to carry this important reform to success, these detail questions must receive careful study. If a delegation of engineers were to appear before committees of Congress, merely to recommend that a Department of Public Works should be created, they would be assailed at once by questions: What would be the field of such a department? Which present bureaus should it take over? Would this change mean adding a new member to the Cabinet? How will the proposition affect the urgent demands which are being made by other influential interests for changes in the Federal Government organization?

The engineering profession, if it is to succeed in its ambitious task, must be prepared to answer all these and similar questions, and give convincing reasons for its answers. In the coming convention such questions as these are to be threshed out. In preparation for the discussion there, the Engineering Council has sent a prospectus to each engineering society invited to participate, in which various questions are stated, and the society is urged to consider and vote upon them.

Such general discussion by engineers is highly desirable; for, if this great reform is to be carried through engineers all over the country must be able to inform and arouse public opinion in its support.

Care is needed at the outset in defining the field which the proposed department should cover. In earlier discussions of the question it was urged that such a department should take over all the engineering work carried on by the Government. Today, however, engineering is a much more comprehensive term than it was a quarter century ago. A large part of the work done by both the Navy Department and the War Department—the construction of ships, docks, fortifications, ordnance—is engineering work of a very high order; but no one would advocate transferring such military functions to a Department of Public Works.

Again, there is a strong movement, backed by the executive heads of the railway companies, for the organization of a Federal Department of Transportation. If created, such a department would probably take over the functions of the Interstate Commerce Commission, and such other supervision over the railways as the Government may continue to exercise; the Government work in merchant shipbuilding and ship operation; perhaps also the Bureau of Navigation and the Steamboat Inspection Service, now under the Department of Commerce.

A great deal of this work is engineering work, and the Department of Transportation, if organized, should be largely conducted by engineers; but none of these functions seems properly included in a Department of Public Works. Furthermore, those promoting the establishment of a Department of Public Works may well enlist the coöperation of the influential interests backing the proposed Department of Transportation. It may be easier to bring about the systematic reorganization of the Government's business which the establishment of these two departments would involve, than to establish either department separately.

The proper field for the proposed Department of Public Works appears to be the Federal Government's operations in civil engineering construction together with the functions of those scientific bureaus which are chiefly carried on by engineers and whose work is chiefly useful as a foundation for engineering work.

In the prospectus of the Chicago conference there is given the following list of engineering bureaus scattered through various departments, with a request for an opinion as to whether each should or should not be included in the proposed Department of Public Works:

- Treasury Department:
  - Public Health Service
  - Supervising Architect
- Department of War:
  - Public Buildings and Grounds
  - Construction Division of the Army
  - Rivers and Harbors
  - Mississippi River Commission
  - California Débris Commission
- Department of the Interior:
  - General Land Office
  - Indian Affairs
  - Geological Survey
  - Reclamation Service
  - Bureau of Mines
  - National Park Service
  - Alaskan Engineering Commission
- Department of Agriculture:
  - Forest Service
  - Weather Bureau
  - Public Roads
- Department of Commerce:
  - Bureau of Standards
  - Bureau of Lighthouses
  - Coast and Geodetic Survey
- Unattached Functions:
  - The Panama Canal

That the sanitary engineers who carry on the Public Health Service, and the architects and engineers who construct public buildings, should be under an engineering department rather than the Treasury is too obvious to need argument, and the transfer of these bureaus should arise little opposition.

When it comes to the transfer to the new department of the river and harbor and other civil engineering work now carried on under the War Department by the Army engineers, no such easy success is likely. The arguments for the transfer of these works from military engineers to civil have often been presented and are familiar to most engineers. As was pointed out in discussing the question in *Engineering News-Record* of Feb. 20, p. 359, one of the strongest of these arguments is that river and harbor work, under the nominal control of the Corps of Engineers—though the policy is dictated by Congress—has become a national disgrace. This is so well known that public support should be readily enlisted in favor of the transfer of this work to the control of civilian engineers organized under a Cabinet officer who would have the authority and initiative to plan and carry out public works for the national welfare instead of merely distributing Federal expenditures in certain Congressional districts.

In the discussion of this question among engineers, first place has often been given to the position of the engineers in Government service. In pushing the reform before the public, first place must be given to the national benefit which will result from the substitution of intelligent planning by able engineers in carrying out all classes of Federal works, in place of the haphazard spending of money that has hitherto prevailed.

At the close of a war in which engineering has played so large a part, the public will look with greater favor than ever before on the proposition that the Army engineers should devote their time to military engineering work in the interest of national preparedness. To keep them busy on civil engineering work, as has been done hitherto, inevitably results in neglect of their own proper duties.

Bureaus Under Agriculture, Commerce and the Interior Departments

Of the three bureaus in the Department of Agriculture above noted, the one destined to be most important in the future is probably the Bureau of Public Roads. Already it has supervision over the heavy expenditure of the Federal Government in aid of state road construction; and much more extensive work on the nation's highways is probable. Little argument is needed to demonstrate that this should be under a Department of Public Works rather than Agriculture.

A valid reason for the inclusion of the Forest Service in the proposed department is its jurisdiction over the work of water-power development which is in prospect. It will be recalled that the Federal water-power bill, which came so near passage in the late Congress and for which success is expected in the coming session, created a Water-Power Commission made up of the Secretaries of the Interior and Agriculture Departments and of War, because the bureaus concerned with water-power were scattered through these three departments. If these bureaus are brought together in a Department of Public Works, the need for such a cumbrous administrative organization will disappear.

Perhaps the Agricultural Department will seek to retain the Weather Bureau; but its relation to the engineer's work for flood control, water-supply and irrigation is close enough to ground an argument for its inclusion in the Public Works Department.

Of the three bureaus under the Commerce Department listed above, the building of lighthouses and the work of the Coast and Geodetic Survey would surely be generally recognized as civil engineering functions. As for the Bureau of Standards, its work is so largely carried on by engineers and for engineers that the proper place for it would seem to be in the department which will be presumably the engineering department of the Government.

Under the Interior Department, seven bureaus are listed above for possible transfer to the Department of Public Works. In answer to the objection that this would practically destroy the Department, leaving it only patents, pensions and education, the National Service Committee of the Engineering Council has made the interesting suggestion that the Department of Public Works could most easily be started by merely changing the name of the Interior Department, the latter a name which has no longer any significance. This would obviate also the creation of a new Cabinet office.

Of the seven bureaus in the Interior Department listed above, the Reclamation Service of course belongs in a Department of Public Works and so does the work of building the Alaskan railroads. The Geological Survey should be under the same head as the Coast and Geodetic Survey, and as the Bureau of Mines. The care of the national parks should be in the same department as the care of the national forest reserves. The Land Office and the Indian Bureau have such close relations with the other bureaus just named that they should be retained.

Organization of Department

Turning now to the organization of the proposed department: The profession will surely agree that the engineers in such a department should be given a permanent status. These men, on whose independent judgment the conduct of the department will depend, must be safeguarded from dismissal through political or personal influence. If the Government's work is to be carried on with economy and efficiency, unprejudiced engineering judgment is a first essential. Some reasonable tenure of position for engineers in the department is necessary for this reason, and it is also necessary in order that engineers of the requisite ability and character may be obtained. If engineers must exert political influence to obtain positions in the service and hold them after obtaining them, there is little chance that the Government would be able to secure for its great tasks such engineers as have built up the railway systems of the country or created its great industrial establishments.

Hardly less essential in planning the personnel of the proposed department is provision for regular promotion and for retirement on partial pay on reaching a certain age limit on becoming disabled in the service. It is hardly to be exected that Congress can be persuaded to increase the salaries for technical and professional men in the service of the Government to the scale common in private business. There is a fair prospect, however, that Congress will, eventually, in view of the urgent necessities of the departments at Washington,

provide a retiring allowance for Government employees at a certain age limit. With secure provision for old age or disability, men will be better content to work at the low scale of salaries common in the Government service.

It may be argued that such a corps of civilian engineers as is here proposed, with a fixed tenure of office, definite provision for promotion and retiring allowances on reaching the age limit, would to some extent duplicate the organization of the present Corps of Engineers. It has, nevertheless, great advantages over that organization in its freedom from military control and military methods. It would be recruited, also, from men trained in the engineering schools and probably also by some years in the school of practical experience, instead of being brought into the work fresh from West Point.

It needs only a glance, too, at the varied kinds of work which this great department would have to execute to see how necessary in such an organization would be engineers of a great variety of experience, experts in their respective fields. It is only by enlisting the service of such men that the Government can hope to have its great works carried out efficiently.

But, in carrying out any great reform, it is well not to attempt too much at the start. Fundamental though the internal organization of such a department may seem to be to its success, those who have planned the Chicago conference give warning of difficulties in the way. The various bureaus which it is proposed to bring together in that new department each have their own organizations, methods, and personnel which have been built up through a course of years, and to a considerable extent are covered by special laws. If it were attempted now to make a sweeping reorganization of these bureaus, as well as transfer them to a new department, strong opposition would certainly be encountered. Moreover, the bill to create the new department would have to be a very long and complex statute repealing a large number of existing laws and enacting other provisions in their place. It is easy to foresee that such a law would be carried through Congress with great difficulty, if at all.

If the proposed Department of Public Works is to become a reality, therefore, the wisest plan would appear to be merely to bring together intact such bureaus as manifestly belong under such a department, with practically no change in their present organization and personnel. The working out of the relations between these bureaus and of the general organization of the department could be left for the future.

Upkeep High on Disconnected Road System

MAINTENANCE of the 700 miles of state-aid roads of Illinois is difficult and expensive, because the system is so disconnected. The longest continuous stretch of improved road is 15 miles, and the average length is less than two miles. About 300 miles are earth road and the remainder are principally of brick and concrete. The costs per year per mile, including work on the shoulders and ditches, average: Brick, \$56.56; concrete, \$81.45; earth, \$102.20; gravel, \$162.20; macadam, \$564.20 (including surface oiling). Maintenance work on brick and concrete paving consists mainly in filling cracks and building up the earth shoulders; on macadam paving it is mainly surface treatment, while on earth and gravel roads it consists of dragging and filling depressions with new material. In addition, there are the cutting of weeds, the clearing of ditches and the dressing of the shoulders. Where the gang system of maintenance is used, each gang, composed of two to five men in charge of a foreman, takes care of the work in from 10 to 15 counties and has about 75 miles of road under its charge.

The equipment used consists of a small motor truck, heating kettles and the necessary tools and accessories. Only in Vermilion County has the patrol system been introduced, this being made practicable by the fact that there are 90 miles of hard road, the greatest mileage in any one county.

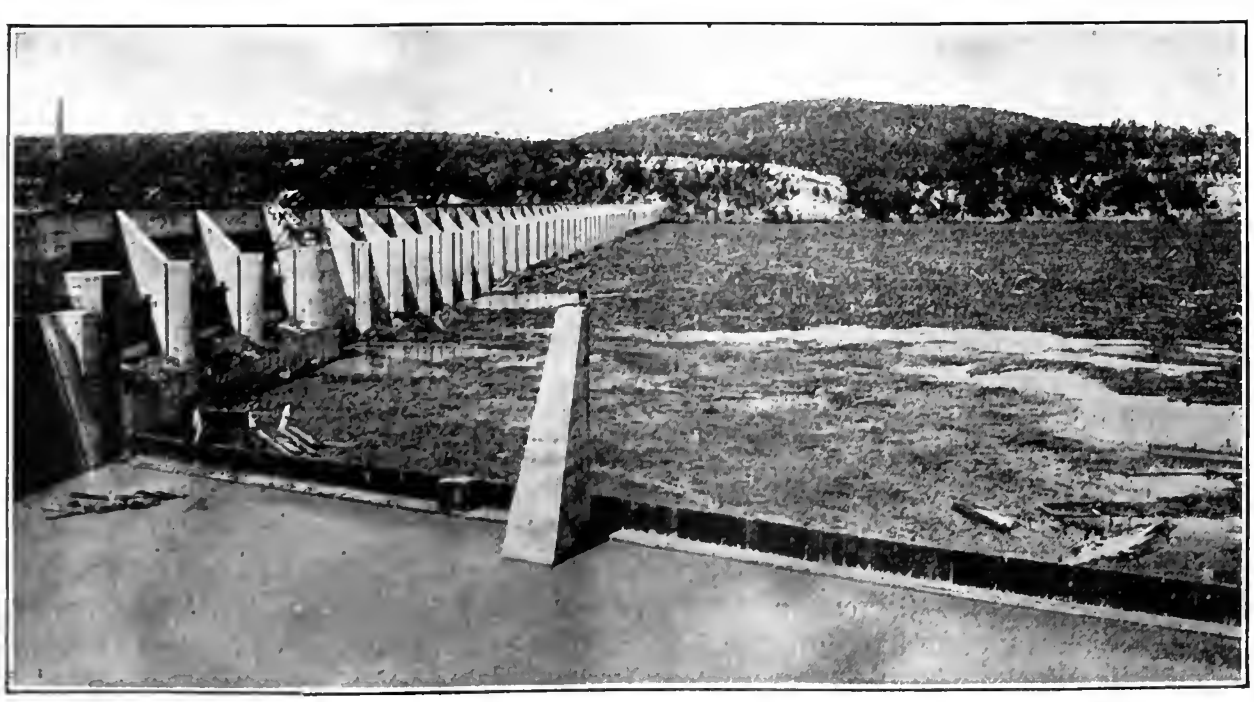
Drift on the Colorado River Held Back by Austin Dam

Passes Over the Rounded Top of Old Dam, But Is Caught by the Present Structure—All Sorts and Sizes of Débris

BY T. U. TAYLOR
University of Texas, Austin

ENGINEERS unacquainted with the Colorado River, Texas, do not appreciate the seriousness of the drift problem in its relation to the Austin dam. The accompanying view, showing drift conditions in the spring of the year, will help them understand what has to be contended with, besides emphasizing the importance of designing a dam to meet local conditions.

The drainage area above the dam at Austin, Tex., is 37,000 square miles. There is an immense amount of drift that comes down the Colorado River, and this



NEW AUSTIN DAM CATCHES VAST QUANTITIES OF DRIFT

drift will be stopped by, passed over or around any dam across the stream.

During the existence of the old dam the drift passed over the rounded crest with no practical difficulty. In 1911, when the City of Austin was considering the present style of dam, it was warned of the futility of depending on it to pass the drift. This warning was ignored, and the contract was let for an open-work dam with a crest in the new part at El. 51 ft., with gates 14 ft. high between buttresses which were supposed to raise the water to El. 65 ft. above the toe of the old dam. There were 28 of these gates, and the first drift flood that came after they were installed destroyed 24 of them and clogged up the gateways with drift.

The accompanying view was taken by the writer when the lake level was 54 ft. above the toe of the dam. It was taken from the east end of the dam, looking toward the west. From the lone buttress or pier in the foreground to the west bluff is practically 1200 ft. The small patches of water seen in the foreground are the result of pulling drift out of the east gate sections. The drift ranges in size from mere trash to logs 3 ft. in diameter, and 60 ft. long.

It should be remarked that there is another dam at Marble Falls, about 120 miles, by river, above the Austin dam, and that the Marble Falls dam partially obstructs the channel and stops considerable drift.

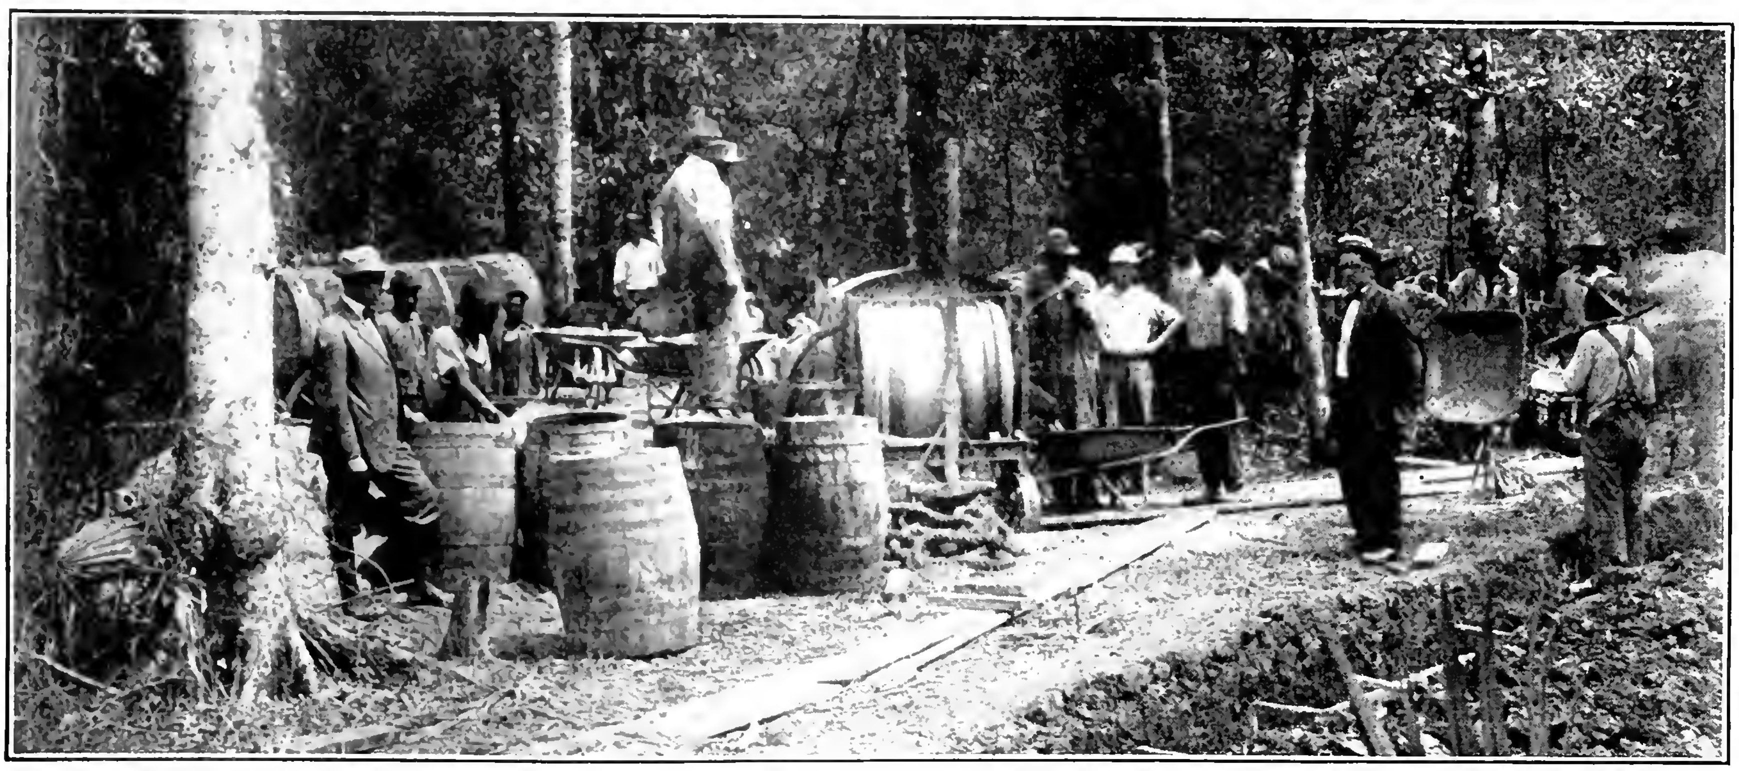
Planning Work Expedites Casing of Pipe Line With Concrete

In Repairing Oil Line Different Foremen Directed Materials Supply, Plant Repairs and Principal Construction Operations

PLANT mobility and precise scheduling of operations have enabled the construction forces of the Standard Oil Co. to obtain notable speed in casing a steel pipe line with concrete. Working 131 men in a gang, 280 miles of 8-in. line in Louisiana have been concreted at an average speed of one-third mile per gang per day. The gangs were divided into crews under foremen and subforemen, and each crew performed a specified set of operations in step with the other crews. Easily shifted tent camps kept the gangs close to their work. All equipment was portable, and certain units less movable than the others were provided in duplicate, so that one unit could be moved ahead and set up ready for work while the other unit was busy on the preceding section. Materials delivery was timed exactly with the work.

Corrosion of the six-year-old oil pipe line between Ida, La., and North Baton Rouge, La., made concrete casing necessary. The terrain traversed by the line is generally low and flat, with a large percentage of marsh land and swamps and some rolling hills. Chlorine salts and other acidulated solutions in the soil had pitted the pipe; in places the pitting was severe. The work to be done involved more than simply placing a concrete casing. It was necessary to uncover the lines, hoist and hold the pipe above the trench bottom, pound, scrape, brush and otherwise clean the pipe, and then to lower and encase the pipe and backfill the trench. All these operations had, moreover, to be performed while the pipe was carrying oil under pressures of from 100 to 600 pounds.

At times one superintendent directed the field operations of as many as four gangs. Each gang consisted of 125 laborers and six foremen. The laborers were apportioned about as follows: Forty men uncovering, handling and backfilling pipe line; 20 men cleaning pipe; 50 men concreting; 10 men handling materials and equipment, and five utility men. Subdivision of the duties of the foremen was carefully planned. There were two materials foremen, three ditching foremen and two concreting foremen, each having a set schedule.



CONCRETE WAS WHEELED FIFTY FEET EACH WAY FROM LOCATION OF THE MIXER

The direction of materials supply was kept separate from the direction of construction operations. A materials foreman, generally one for every two gangs, designated the distribution points, investigated roads, and routed and placed materials and supplies along the work. On the work an assistant foreman, one for each gang, directed the unloading, looked after the housing of cement and the salvage of cement sacks, and saw generally that all things were done which were necessary

PIPE-LINE CREW SHIFTING HORSES AND SETTING FORMS

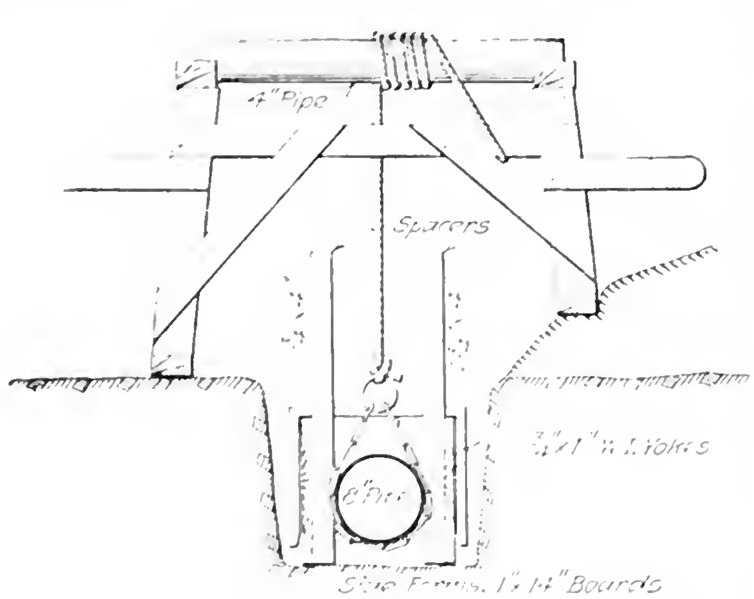
to keep the construction foremen promptly supplied with materials, supplies and equipment.

The transportation of materials was somewhat simplified by the fact that the pipe-line work paralleled railways to a considerable degree. Sand, cement, lumber and equipment were shipped by railway in carload lots to stations nearest the work, and from these points were hauled to and distributed along the work by teams. Water-supply was a more complex task. The amount of water required for concrete mixing and for drinking and cooking was quite large. This water was hauled in tank wagons from convenient bayous, creeks and wells from which it was pumped by portable diaphragm pumps. Horizontal, galvanized-iron, 5- and 10-bbl. tanks were used, the larger or the smaller being employed according to the character of the roads. Cross baffle plates in the tanks prevented the surge of the water when the roads were rough. The tank wagons discharged into barrels located were the water was wanted.

The preparation of the pipe line for the concreting operations was in charge of a general foreman and two assistant foremen. The general foreman directed the operations of uncovering and of raising and lowering the pipe. One assistant supervised the pipe cleaning and the other directed the backfilling and the finishing up of work of various kinds.

After being uncovered, from 200 to 300 ft. of pipe at a time was hoisted by means of windlass horses to a height which permitted the leveling of the trench bottom and the thorough cleaning of the pipe. When cleaned, the pipe was lowered to a position 2 in. above the trench bottom, and concreting was begun.

Cement mortar, nominally of 1:3 mixture, was used for the casing. However, the purpose was to insure a mixture in which the volume of cement was always great enough to fill the sand voids, so the nominal proportions were changed whenever tests, which were constantly made, indicated material variation in the void contents of the sand. Experience has shown this mixture to be practically waterproof. The thickness of the casing was 2 in. under the pipe bottom, 1¾ in. on each side, and 1 in. over the top, which was shaped to a flat crown. No bottom forms were used except where the bottom was boggy or where there was a small water crossing. This practice greatly reduced the amount of lumber left in the trench. The side forms were 1 x 14 in. x 16-ft. boards, cleated across at the middle and at each end to prevent splitting. They were set on edge on the trench bottom and were held in position by wrought-iron clamps spaced about 4 ft., and by timber spacers which blocked them away from the pipe. This arrangement, as shown by the drawing, insured the proper thickness of covering and the exact centering of the



WINDLASS HORSES HELD PIPE LINE SUSPENDED WHILE BEING CONCRETED

INCASED PIPE LEFT IN FORMS OVER NIGHT TO HARDEN

pipe in the forms. The butt joints in the side forms were banked outside with clay to prevent leakage of mortar.

The concrete was machine-mixed and was placed with wheelbarrows having side spouts to facilitate pouring into forms. Stock piles were placed at every tenth joint of the pipe line, or 100 ft. apart, so that the maximum wheelbarrow haul of concrete was 50 ft. ahead and 50 ft. to the rear. Wheel-mounted, $\frac{1}{2}$-cu.yd., power-driven mixers were used. They were hauled by four-mule teams. Two mixers were provided for each gang, one being in use while the other was being hauled ahead and set up ready for use as the work advanced.

Concrete was placed with the pipe suspended, as shown by the sketch. Careful puddling was necessary to fill solidly under the pipe, but otherwise the work presented no special difficulties. When a 100-ft. length of pipe had been concreted and the corresponding length ahead had been suspended in position for concreting, the slings holding the concreted length were released, letting the pipe "float" in the green concrete. No squeezing up or settlement of the concrete resulted from this procedure. The holes left by removing the slings and spacers were filled, and each morning the side forms were removed from the previous day's work.

A construction foreman and a machinery foreman directed the concreting operations. All work of lining up the steel pipe, moving and placing forms and mixing and placing concrete was in charge of the construction foreman. His assistant attended to the upkeep and repairs of mixers, motors and other equipment, and saw to the shifting and setting up of the extra mixer.

All construction was under the direction of the pipeline department of the Standard Oil Co. of Louisiana. Information for this article was furnished by F. Ray McGrew, assistant superintendent.

Piecework Faster Than Day Labor On Hand Excavation

Greater Yardage per Man Recorded in California on Both Road and Irrigation Work—Station Gangs Used on Piecework

By Everett N. Bryan

Chief Engineer, Waterford Irrigation District, Waterford, Calif.

YARDAGE output per man in excavating for road construction in California was 10.9 cu.yd. and 14.3 cu.yd. by piecework, compared with 6.8 cu.yd. and 10.9 cu.yd. by force account. On excavation for irrigation structures, the piecework output per man was 7.2 cu.yd., as compared with a best record of 6.3 cu.yd. by force account. In both comparisons the conditions favored more rapid excavation on the force-account jobs.

The road excavation amounted to 59,027 cu.yd. of loam, "dobe" and cemented gravel, containing in places large percentages of loose rock. Loosening by blasting was necessary to get the best results. All excavation was pick and shovel work, and the material was loaded into cars.

The force-account excavation amounted to 12,283 cu.yd. One cut of 9000 cu.yd. had a maximum depth of 25 ft. This was handled by driving a center drift at the bottom and trapping as much as possible of the mate-bottom and trapping as much as possible of the material into cars. The excavation in the smaller cuts was shoveled. Competent foremen were in charge in all cases. The average output, including drilling, blasting, drifting, mucking, transporting and dumping was 6.8 cu.yd. per man per day. Counting labor in drifting and mucking alone, the output per man per day was 10.9 cubic yards.

Nine station gangs excavated the remaining 46,744 cu.yd. Part of the material was trapped into cars in center drifts at the bottoms of the deeper excavations, part was trapped into cars beneath lean-to platforms against the faces of the excavation, but the larger part was shoveled directly into the cars. Generally, the conditions were not so favorable to rapid progress as they were in the 12,280 cu.yd. of excavation that was done by force account.

The output per man per day for the nine gangs was, however, 10.9 cu.yd., including all operations, and 14.3 cu.yd., including only labor in drifting and mucking.

In excavating for irrigation structures the force-account operations were divided into two parts. About 1339 cu.yd. of excavation was for 28 canal structures and was contained in pits not over 30 in. wide, which were shallow enough to be dug without reshoveling. There was some hardpan in the pit bottoms and the top soil had to be loosened by picking. Very little blasting was necessary. The average output was 3.94 cu.yd. per man per day. The second part of the force-account excavation consisted of trenches for five inverted siphons, and amounted to 1019 cu.yd. The material was not inconvenient to handle, there being very little cemented gravel requiring blasting. The output was 6.3 cu.yd. per man per day.

Piecework Contracts for Trenching Siphons

On another part of the work piecework contracts were let for the trenching for three more inverted siphons. The excavation amounted to 2469 cu.yd., of which 2218 cu.yd. were in one trench $4\frac{1}{2}$ ft. wide and averaging $5\frac{1}{2}$ ft. deep. The other two trenches were of smaller cross-section, the smallest one being 2.25 ft. wide and averaging 3.2 ft. in depth. The smallest trench was very hard at one end and required blasting; the middle-sized trench was handled entirely without powder, and the largest trench required the use of powder throughout. An average of 0.69 lb. of powder per cubic yard was used, and the bottom was carefully trimmed with picks to leave a smooth surface on which to lay the concrete pipe. The average progress per man per day, including drilling, shooting, picking, shoveling, and forge work, was 7.8 cubic yards.

In some cases it is not practicable to compensate an entire gang on a piece-rate basis, but it is often possible to engage one or more of the men to undertake the work on such a basis, if the employer will pay wages to the other men and deduct the cost thereof from the total sum earned by the gang. This plan is applicable to many lines of work where the total cost is not sufficient to justify an attempt to let contracts in the usual way. The work requires less watching than when done by day labor, and is generally accomplished with greater satisfaction to both employer and employee.

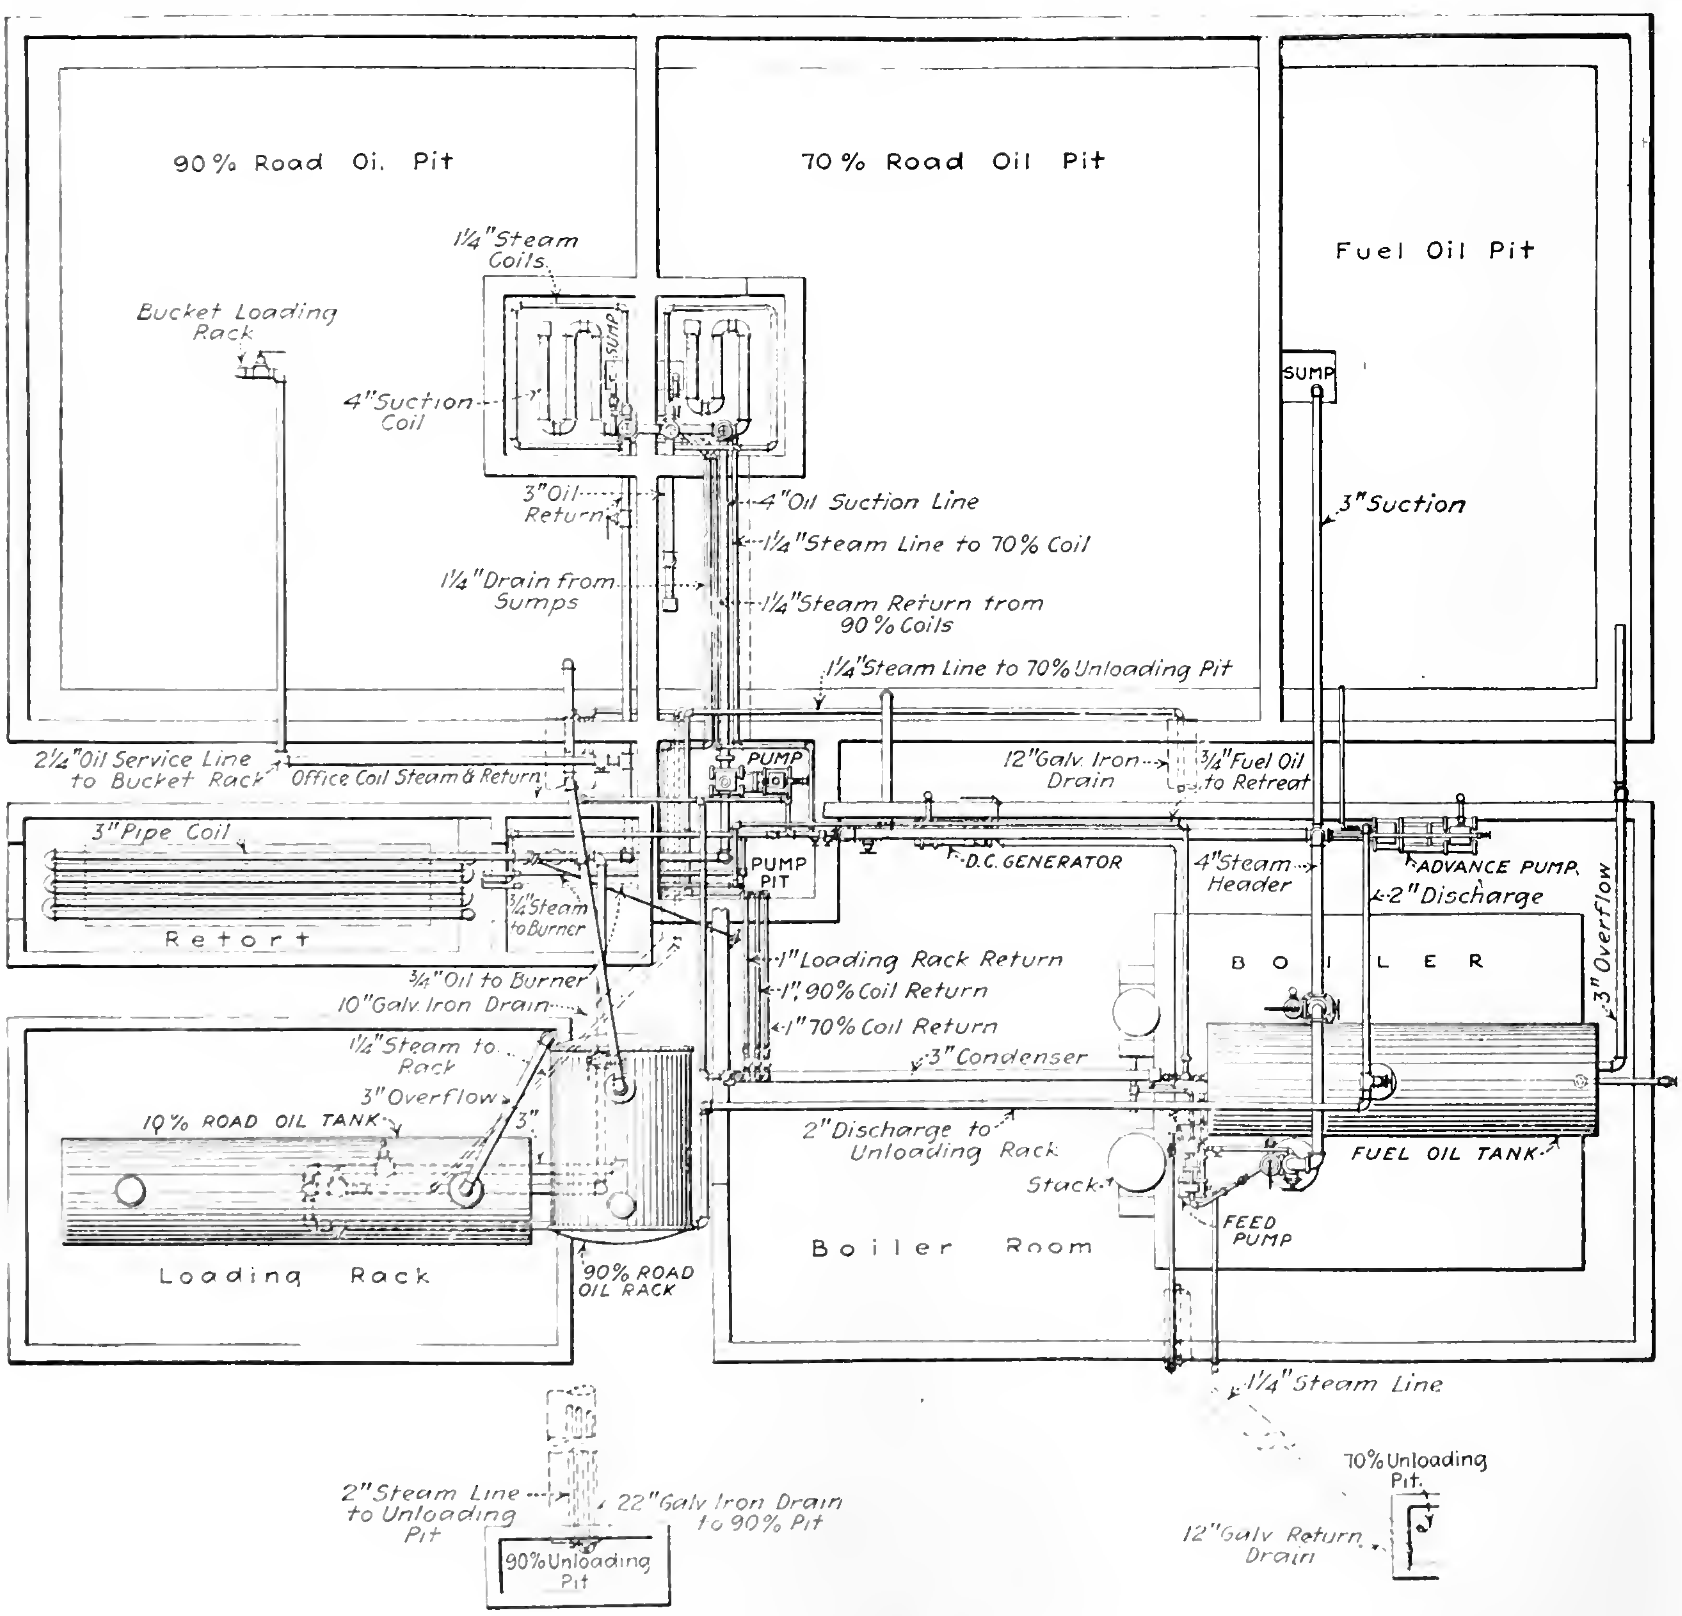
Road-Oil Heating Plant of Los Angeles County

Road Department Builds Plant from Old Equipment in Stock—Installation Saves County $20 per 1000-Gallon Tank

By E. Earl Glass
Monrovia, Calif.

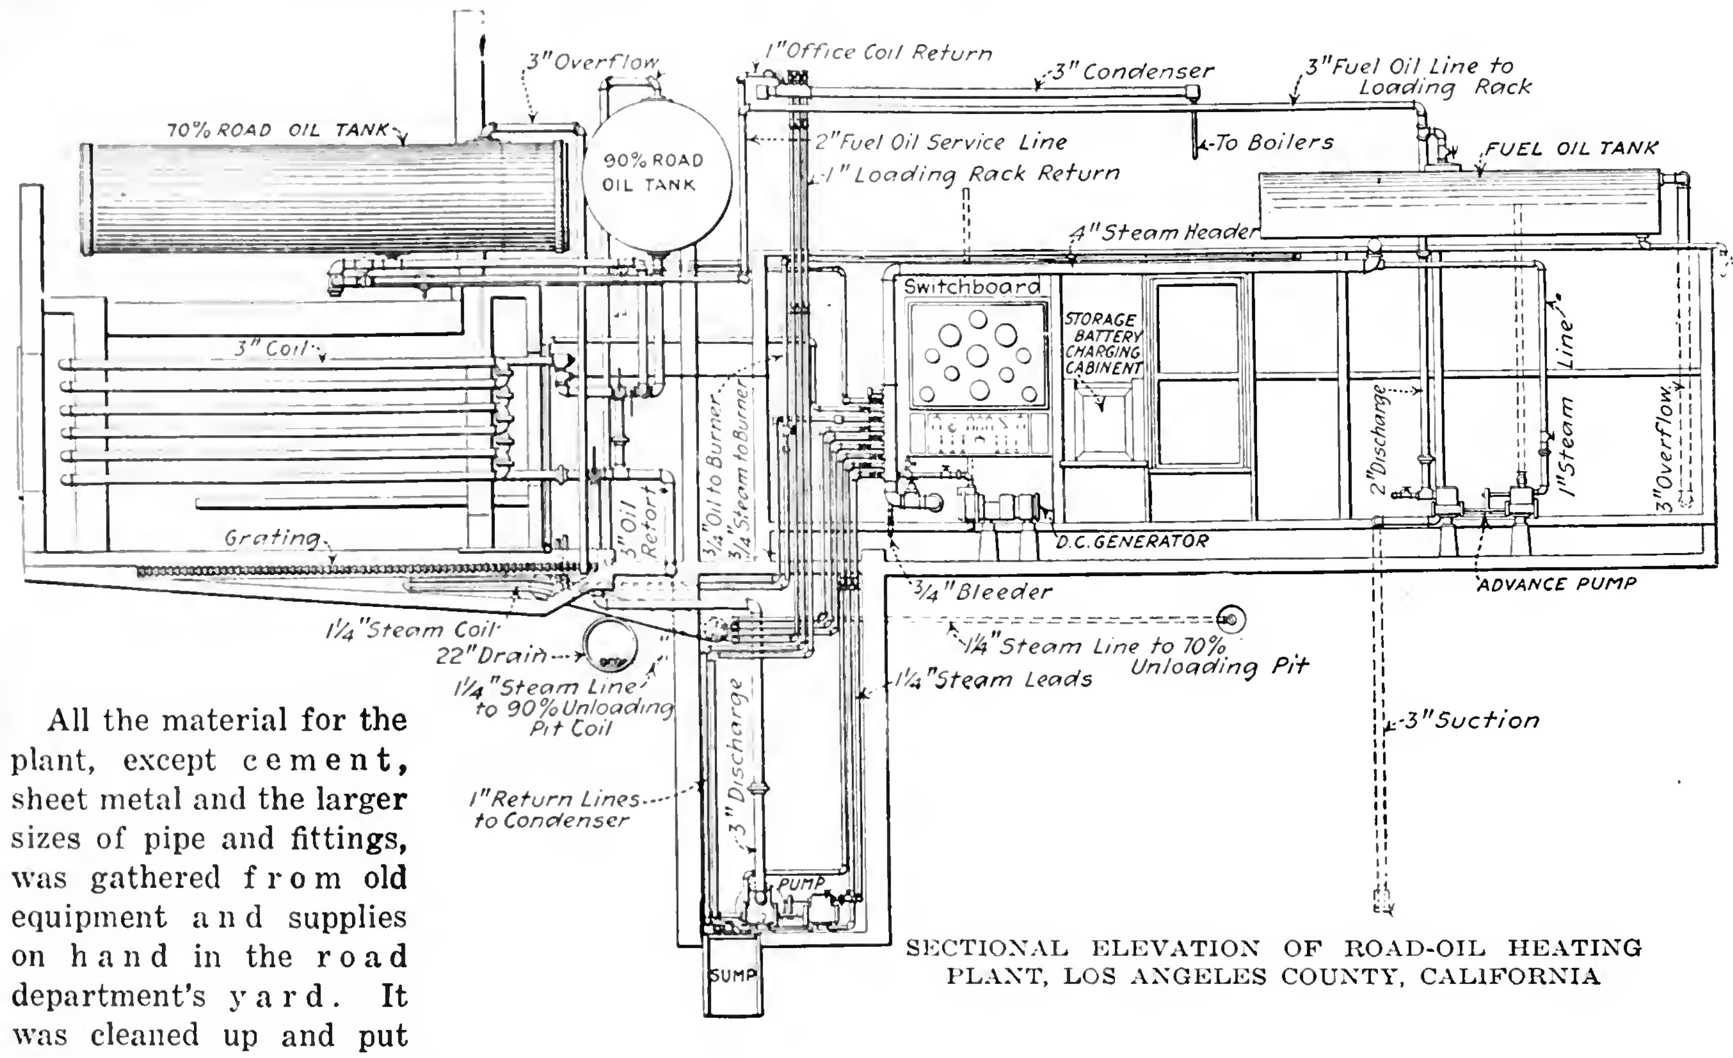
A ROAD-OIL heating plant built from old equipment in the stock of the Los Angeles County road department has been very successful. A saving of $16.66 in delivery and of $1.32 in heating and loading per 1000-gal. tank, as compared with the rates of private companies, has been effected by the installation. The cost per barrel-mile of spreading on the road has been reduced from 3.5c. to 1.68c.—a net saving of 1.82c. From 8000 to 10,000 gal. of oil per day, depending upon its gravity, can be handled, and when operating at capacity the cost averages $1.35 per 1000 gallons.

Large quantities of natural asphalt oil are used in the construction of roads in California, and the county officials found they could effect a considerable saving by handling the oil themselves. The new plant was located, centrally, in the eastern part of the county, at the Baldwin Park warehouse, which is distant 25 miles from the old source of supply. A 20-mile delivery trip, on the average, for each tank of oil used in the district, was thus eliminated. Since the private companies charge 3½c. per barrel-mile (one-way charge) for delivering and spreading, the road department saves $16.66 on each 1000-gal. tank of oil. A further saving is also effected in delivering and spreading, as shown by actual operations. A county truck can average 66 miles per eight-hour day, or 33 miles one way. With a truck driver at $4 per day, a truck helper at $3.50 per day, gasoline and oil at $2.50 per day and interest, depreciation and repair at $3 per day, this gives a total of $13 per eight-hour day, or 1.68c. per barrel-mile, as compared with the commercial rate of 3½ cents.



PLAN

ROAD-OIL HEATING PLANT BUILT FROM EQUIPMENT IN STOCK AT A COST OF $6000



SECTIONAL ELEVATION OF ROAD-OIL HEATING PLANT, LOS ANGELES COUNTY, CALIFORNIA

All the material for the plant, except cement, sheet metal and the larger sizes of pipe and fittings, was gathered from old equipment and supplies on hand in the road department's yard. It was cleaned up and put in good order, so that the finished plant does not show its origin in either performance or appearance. Plans and elevation are shown in the accompanying drawings.

Excavation for the pits required the removal of about 1500 cu.yd. of clean gravel, which was used to level the warehouse ground, the select gravel being used as a natural aggregate for the concrete of the pit floor and walls. The plant has three oil compartments in the storage pit, two of three-car capacity for the heavy 90% and medium 70% oils, and one of two-car capacity for fuel oil. They are filled by gravity, from railroad tank cars, through 22-in., 12-in. and 6-in. drains, running from the three unloading pits, which are situated between the rails on the siding and are spaced 45 ft. on centers. A flowing temperature is maintained in the two large drains and their track pits by means of the steam-pipe coils with which they are fitted. The track pits are 2 x 6 x 2½ ft. deep, with 6-in. concrete walls and floors.

At normal temperature, the 90% oil has about the consistency of slightly warm tar, while the 70% oil is somewhat more fluid. The former is used for the construction of bituminous macadam roads, for the wearing coat on concrete highways and for all patching and repairs on these roads. The 70% oil is used almost exclusively by the road foremen for the construction and repair of the oiled-earth roads, which include most of the secondary roads in southern California.

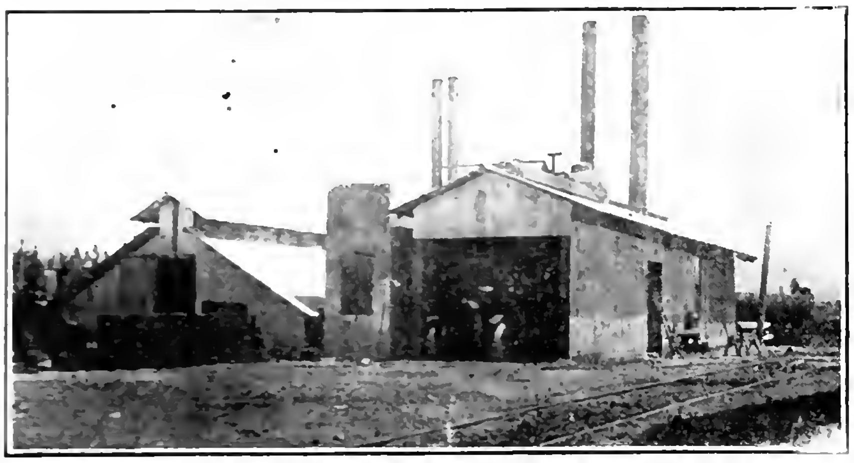
A 12,000-gal. car of the heavy oil is unloaded in seven to ten hours, depending on the time which has elapsed since the car was loaded hot. Two hours' time is required to empty a car of 70% oil. Steam for the car coils, track pits and drains is furnished by two boilers of 35 and 50 hp., the 13-way manifold on the steam header being made in the warehouse shop with an acetylene welding outfit. The boilers also supply steam for operating the pumps, oil burners, heating pit coils and heating system for the warehouse office. Either boiler is capable of running the plant at capacity. Compressed air from the warehouse is used to start the oil burners under the boilers. A 1-kw. steam-turbine direct-current generator unit supplies the current for charging the storage batteries for the trucks and automobiles. A drop-leg condenser automatically returns the condensed steam to the boilers.

A sawdust mixture was used successfully for covering the steampipes, but was not suitable for the oil lines, as it takes fire at high temperatures. In making this mixture 2 lb. of wheat starch and 1 lb. of rye starch were cooked to make 5 gal. of paste, and enough sawdust was stirred in to make 10 gal. of mixture. This was spread on canvas strips and wound on the pipe, and then heated to dryness by turning on the steam. When a coat of boiler paint is applied, this treatment gives good results and a fair appearance.

The retort is entirely inclosed by a 6-in. concrete fire wall, carried well above the surrounding buildings and kept out of contact with the brickwork of the retort by a thin plaster of mud, to allow for expansion of the brick. The firebox is lined with firebrick and heated by an oil burner. The 3-in. retort coil has 430 sq. ft. of heating surface, and all the return fittings are readily accessible for the removal of burned pipes. The coil pipes, 2 in. in diameter, extend through pipe sleeves in the end walls of the firebox into the return chamber, and the coil supports are kept fully air-cooled, resisting the high temperatures by passing through 4-in. casings extending through both side walls.

The loading room has a floor of 2 x 4-in. pine grating over a shallow concrete pit which drains through a coil-heated pipe to the 70% compartment. The delivery trucks back upon this rack and are loaded from above through a universal nozzle. Any one of the three grades of oil may be drawn from its overhead storage tank by

the operation of one of the three valves on the service lines at the nozzle. The entrance to the loading rack is closed by a roller door made by nailing narrow Oregon pine ceiling to three pieces of canvas belt. The oil pit is roofed and the other buildings are sided with galvanized sheet metal. The illustration shows a truck loading in the shed.



LOADING TRUCKS AT ROAD-OIL HEATING PLANT

In operation the asphalt oil is admitted to the 5 x 6-ft. cell, and rises to the depth of 6 ft. This cell has the capacity of a 1000-gal. truck. The 1¼-in. pipe steam coils raise this from normal temperature to 150° F. in about one hour. It is now fluid and is raised through the retort to its overhead tank by the duplex steam pump in the pit below the boiler room. The 4-in. suction pipes in the heating pits are jointed and balanced, so that the hot oil may be drawn from the surface. The efficiency of the heating pits is being further increased by the laying of flat steam coils on their floors.

A 1-in. metallic hose is connected to the line between the 90% pit and the retort and is used to fill 4-gal. steel buckets with heavy oil. Highway maintenance crews use these to carry patching oil on their tool trucks. As more than 200 of these buckets are used each day, this method is much more effective than carrying the buckets from a fixed filling pipe, as was done in the past. All oil pipes drain back when not in use to prevent setting of the asphaltic oil in the cold pipes. Each of the overhead storage tanks is fitted with an overflow pipe returning to its proper pit.

Fuel oil (27 gravity) is pumped directly from its pit to the 550-gal. supply tank over the boilers, whence it flows to the burners of the retort and boilers and to the service nozzle over the loading rack. This oil is delivered to the county road rollers, steam shovels and piledrivers by truck tanks or trailer tenders.

Oil temperatures are indicated by an electric pyrometer, calibrated from 0 to 800° F. Five thermo-couples are fixed at the following points: One in each heating pit, one in each road oil tank and one in the retort coil. These lead through a selective switch to the indicator. Regulation of the circulation of the oil through the retort, and thereby of the temperature of the road oil, is controlled by a gate valve which is operated from the switchboard by an extension stem and hand wheel. This gives a practically centralized control of the plant and makes one-man operation possible. The cost of operation is $7.50 for fuel, lubricant and water, and $4.50 for the operator, or $12 per eight-hour day. Ten 1000-gal. tanks of 70% oil at 300° F. or eight 1000-gal. tanks of 90% oil at 350° F., can be loaded in eight hours.

The full capacity of the plant will seldom be called upon, but an average of five truckloads per day may be expected. This will give a cost of about $2.25 each, for heating and loading. The cost of the plant was about $6000. It is being operated under the supervision of F. H. Joyner, county road commissioner.

Inclined Railway to Deliver Materials on Hetch Hetchy Project

DELIVERING materials and equipment to the Early intake portal of the 18-mile tunnel on the Hetch Hetchy water-supply project required special consideration because the intake is in a narrow cañon about 1700 ft. below the Hetch Hetchy Railroad. The method decided upon was the use of an inclined tramway 3000 ft. long with a maximum incline of 70%. This tramway was built in 1917.

1700-FOOT INCLINE TO EARLY INTAKE PORTAL

To prevent creeping anchorages were put in as close together as the outcropping of rock afforded suitable foundation. These anchorages consisted each of an extra large tie, usually a 14 x 14-in. timber, cut as long as necessary to develop the strength of the anchorage. Where the rails crossed these anchor ties the flanges were notched so that the spikes could prevent creeping of the rails over the tie. Twenty-pound rails were used.

No measurements have been made of the lengthening that has occurred in this rail line since it was installed a year and a half ago, but the resident engineer asserts this has amounted to as much as 6 or 8 in. An interesting point is that the resultant movement is downward, whether caused by contraction or expansion.

When the incline is ready for operation a 25-hp. electric winch will handle the cars. In the meantime, the only access to the bottom of the cañon is by means of a wagon road built on a uniform 10% grade, and about 3½ miles long.

Midway in the line (near the top of the accompanying view) there is a turnout. Three rails instead of two were used on the incline to insure against derailments at the turnout, which, experience proves, are of frequent occurrence where only two rails are used.

This work is being carried out by the City of San Francisco under the direction of M. M. O'Shaughnessy, city engineer.

More Water Laboratories in Kansas

Water-works managers in a number of the smaller Kansas cities are fitting up small chemical and bacterial laboratories. The practice is being promoted by the State Board of Health, which will supplement the work of these small laboratories by more extensive analyses made periodically in its main laboratory.

Water Consumption Cut More Than Half at Newark, Ohio

Contract for Water-Waste Survey Reduced Underground Leakage and Located Illegal Use of Water

BY F. H. WARING
Assistant Engineer, Ohio State Department of Health, Columbus, Ohio

WATER-WASTE surveys cut waste and consumption at Newark, Ohio, more than half, or from 131 to 61.5 gal., in 1918. Much of the excessive consumption was due to the illegal use of water, and much to underground leakage. The curtailment was effected by professional water savers, working under contracts in coöperation with the city water department.

The population of Newark in 1918 was estimated at 30,000. The water-supply is pumped from infiltration systems in the bed of the north fork of the Licking River, supplemented from the river direct. Liquid chlorine disinfection is used. Up to Mar. 1, 1918, the city water-works was conducted under the immediate supervision of the director of public service, J. Edward Wilson, who then appointed Taylor Kussmaul superintendent. The latter had been engineer at the pumping station and later assistant in the office of the water-works department.

The water consumption at Newark averaged about 3,000,000 gal. a day for the four-year period up to January, 1917. Subsequent steady increase in water consumption took place, until in the spring and summer of 1918 it had reached the estimated figure of 4,100,000 gal. per day. On Mar. 1, 1918, 6700 of the 7000 services were metered.

In attempting to account for water consumed, the superintendent observed: (1) That the water consumption estimate of 137 gal. per capita was excessive for a city of the size and character of Newark; (2) that he could account for but a small percentage of the total water consumed by checking up the 96% of services that were metered; (3) that an average daily pumpage of over 4,000,000 gal. placed a burden on the pumping station which would soon have to be met by the installation of a new pump at a considerable expense to the city. It was the superintendent's purpose, therefore, to find out if the purchase of such an additional pump was necessary.

On July 1, 1918, every service had been metered, and still the large quantity of water consumed was unaccounted for. On Aug. 1 a water-waste survey company was employed to make a survey of the distributing system. At the suggestion of the superintendent the employment of the comapny was not made generally public.

CONTRACT FOR WASTE SURVEY MADE

The survey experts contracted to test (1) the existing pumps; (2) all meters larger than 3 in. (3) the distribution system, for underground leakage. It was agreed that the leaks, as located, would be repaired and that tests would be made at industrial plants to detect any illegal use of water.

The company furnished one engineer and three pitometers; the city furnished shelter boxes for the instruments, a foreman and three laborers for line work, necessary transportation and incidentals. The company guaranteed to save the cost of the survey to the city by accounting for and stopping leakage of water which would be figured for one year at 3c. per 1000 gal. The city agreed to pay one-third of the contract price when the guarantee was fulfilled, one-third when the field work was completed, and one-third when the report was filed and accepted. The contract price to the city under the above conditions was $2600. It is estimated that the city incurred expenses connected with the survey amounting to $2600 more.

Pump tests indicated slippage as high as 14½% when the pumps were drawing water direct from the Licking River. Repairs were made and the second test indicated 10% slippage. Further repairs were undertaken, but the exact amount of slippage then prevailing was not determined before the survey was finished. Having installed measurement devices for the total quantity of water pumped, the average daily consumption in August was found to be 120 gal. per capita. This figure was far in excess of what it should be for a totally metered city of 30,000.

The city was then divided into districts, and the water consumed in each district was measured for a 24-hour period. If comparison of the day and night rates showed the latter to be a high proportion, indicating waste, the district was subdivided and the same 24-hour study was made. In this way leakages were narrowed down and located, and the necessary repairs were made at once.

ILLEGAL USE OF NEARLY 1,000,000 GALLONS FOUND

In the course of the survey the experts located an illegal use of water by the American Bottle Co. amounting to about 895,000 gal. per day. This water was being taken through an unauthorized connection to a fire line which entered the property from a 12-in. city main. The connection was uncovered and photographs of it were obtained. The company disclaimed any knowledge of the connection, although water had been drawn through it regularly for cooling purposes in its factory. This and other evidence enabled the city to bring charges against the bottle company. A bill for $49,000, estimated to cover the amount due the city for 1918, was rendered. On refusal to pay the bill the city threatened to shut off the bottle company's entire supply, and the company brought suit to enjoin the city from carrying out its threat. The company offered to settle for $6700, representing that the evidence at hand proved only the definite illegal use for a short time preceding the survey. The trial court sustained the company and gave the city judgment for $6700. The city has taken the case to a higher court.

During August, after the shut-off of the illegal connection at the American Bottle Co., the average daily quantity of water accounted for by the meters from which revenue is received amounted to 909,700 gal. Other consumption was: Flat-rate services for commercial use, 379,000 gal daily; public watering troughs, 99,000; hydrant leakage, which could be stopped after repairs had been made, amounted to 82,000 gal. A total of 1,469,700 gal. a day was accounted for.

At this time a remeasurement showed that 1,845,000 gal. was being pumped to the city. Of the difference, amounting to 375,300 gal., 243,000 gal. was attributed to unavoidable leakage, or 3000 gal. per mile for the 81 miles of main in the city. The remainder, 132,300 gal., was assumed to be consumption by the city building and fire houses and the city hospital. The second as-

sumption was thought to be too low, but, nevertheless, showed forcibly the fact that the main leakage had been reduced to a minimum.

Recapitulation of the average daily consumption shows the following comparative totals:

	Gallons
Before the survey	3,932,000
After the survey	1,845,000
Decrease	2,087,000
Leakage located and stopped	552,000
American Bottle Co. illegal use stopped	895,000
Decrease unaccounted for	640,000

Of the decrease unaccounted for, about 140,000 gal. were attributed to two leaks that were subsequently discovered and repaired by the city on the supply main, leaving 500,000 gal. unaccounted for.

It is felt by the survey experts and by the city officials engaged on the work that this item represents a large consumer taking water illegally from the mains, but whose connection could not be located following the exposure of the American Bottle Co. In other words, the large consumer became aware that investigations were being made and discontinued taking this amount of water just before the survey was finished.

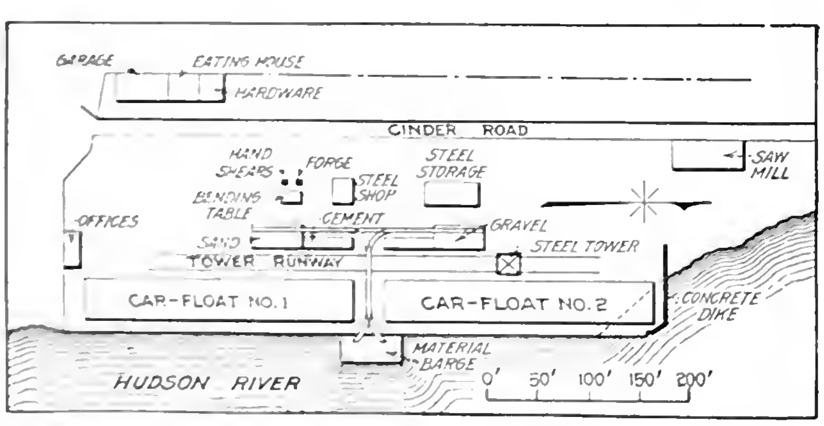
The water-waste survey at Newark revealed the fact that before the survey the average daily per capita consumption amounted to about 131 gal. After the survey, and after leakages had been repaired and illegal use of water stopped, the per capita consumption fell to 61.5 gal. The leakage amounted to 23.1 gal. and the illegal use to 29.8 gal.; unaccounted for but stopped, and thought to be additional illegal use of water, 16.6 gal. per capita. In other words, the City of Newark has accomplished a reduction in water used, and for which previously no revenue had been derived, corresponding to 53% of the total water pumped before the survey. It is needless to add that an additional pump was therefore found to be unnecessary. Furthermore, the plans of the city for a filtration plant will be considerably modified by the accurate data on water consumption obtained. The water-works department is now upon a sound financial basis.

Hudson River Shipyard Layout To Build Concrete Car Floats

Concrete Placed for 1600-Ton Vessels From Stiffleg Chute Tower—Will Launch Sideways From Jacked-Up Ways

By H. W. Eldridge
Engineer, Technical Department, Atlas Portland Cement Company, New York

CONCRETE car floats, having a finished weight of approximately 1600 tons, which makes them the largest concrete towboats now under construction, are being built in a yard specially designed for them, at Athens, N. Y., on the Hudson River, about 120 miles above New York City. Distinctive features of the yard are the launching method and the provision for

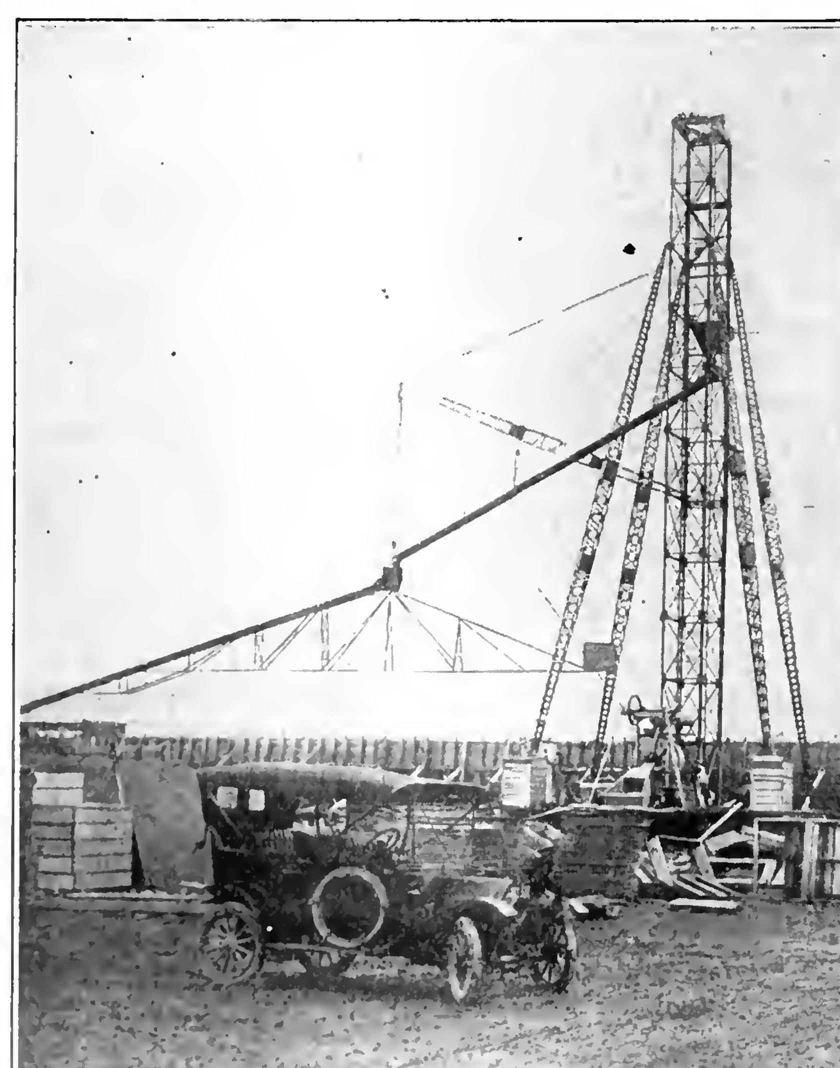


CONCRETE SHIPYARD AT ATHENS, N. Y., WHERE CAR FLOATS ARE BEING BUILT

concreting from a stiffleg tower with chute which will control half of the long boat at one set-up and which can be moved on rollers to control the other half. Six of the floats are being built at this yard for the Embarkation Division of the War Department.

The boats are each 265.9 ft. long, of 38 ft. 2 in. beam, and are 11 ft. 3 in. deep. They are of the general form common to wood and steel floats and provide for three lines of standard-gage railroad track with a capacity of seventeen 50-ton loaded cars. Provision is made at the yards to build two of these floats at a time on side-launching ways and to command the concreting operations from a tower running on tracks paralleling the ways. Details of the layout are shown in one of the drawings.

The river at this point has a depth of 25 ft. and a tidal range of 5 ft. The construction materials are



TOWER CHUTE HAS NO GUYS AND IS MOVED ON ROLLERS UNDER PLATFORM

delivered by barge to a trestle running into the yard between the car floats and the cement sheds and extending the full length of the concreting yard. This trestle supports a 24-in.-gage industrial track. The rise and fall of the tide are taken care of by a hinged joint in the trestle 30 ft. from the end. The material is loaded into 1½-yd. industrial dump cars which are hauled on

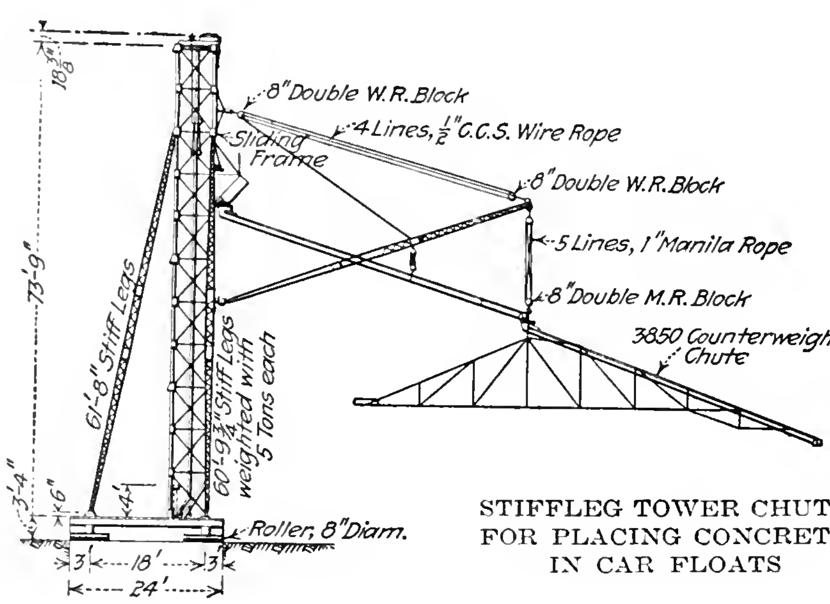
SEVENTEEN-CAR CONCRETE FLOAT ON WAYS JUST BEFORE LAUNCHING

the trestle by a line running through a snatch block to a motor truck on the ground alongside.

The remainder of the yard comprises a modern sawmill 28 x 72 ft. in plan, a steel storage yard, a steel fabricating building 20 x 24 ft., bending tables, forge and shears. A power punch is being used for the spacing angles detailed to hold the reinforcement. The remaining buildings are the garage, eating house, hardware store and small tool shack and the office building.

The concrete aggregates are graded Hudson River gravel, and are being delivered by barge from a point south of Newburgh, on the river, and the cement is delivered from Hudson, N. Y., directly opposite Athens.

The plan for handling the concrete was worked out by the engineers of the shipbuilding company and the Insley Manufacturing Co. A steel tower 80 ft. high with a ⅝-yd. mixer and chutes having a radius of 114 ft. are mounted on a specially designed platform. The tower was made portable by the use of a timber runway and 22 hardwood rollers 6 ft. long and 8 in. in diameter. The details of this steel tower are shown in one of the drawings. From one set-up of the tower it is possible to place concrete a total distance of 196 ft. It is, therefore, necessary to make only two tower set-ups for the concreting of each car float. The 50-hp. motor which furnishes power for the operation of the elevator bucket and concrete mixer is also used for moving the tower, by using a cable fastened to an anchor post or deadman. The tower and chutes are thus a complete portable unit. No guy wires are necessary, as the entire plant is perfectly balanced. There are four stifflegs fastened to the corners of the tower at a point about 10 ft. below the top, and to the tower foundation. The two on the side of the tower, opposite the chutes and boom, are weighted down each with a 5-ton sand box, which is sufficient to resist the overturning moment. The tower is very rigid, and no

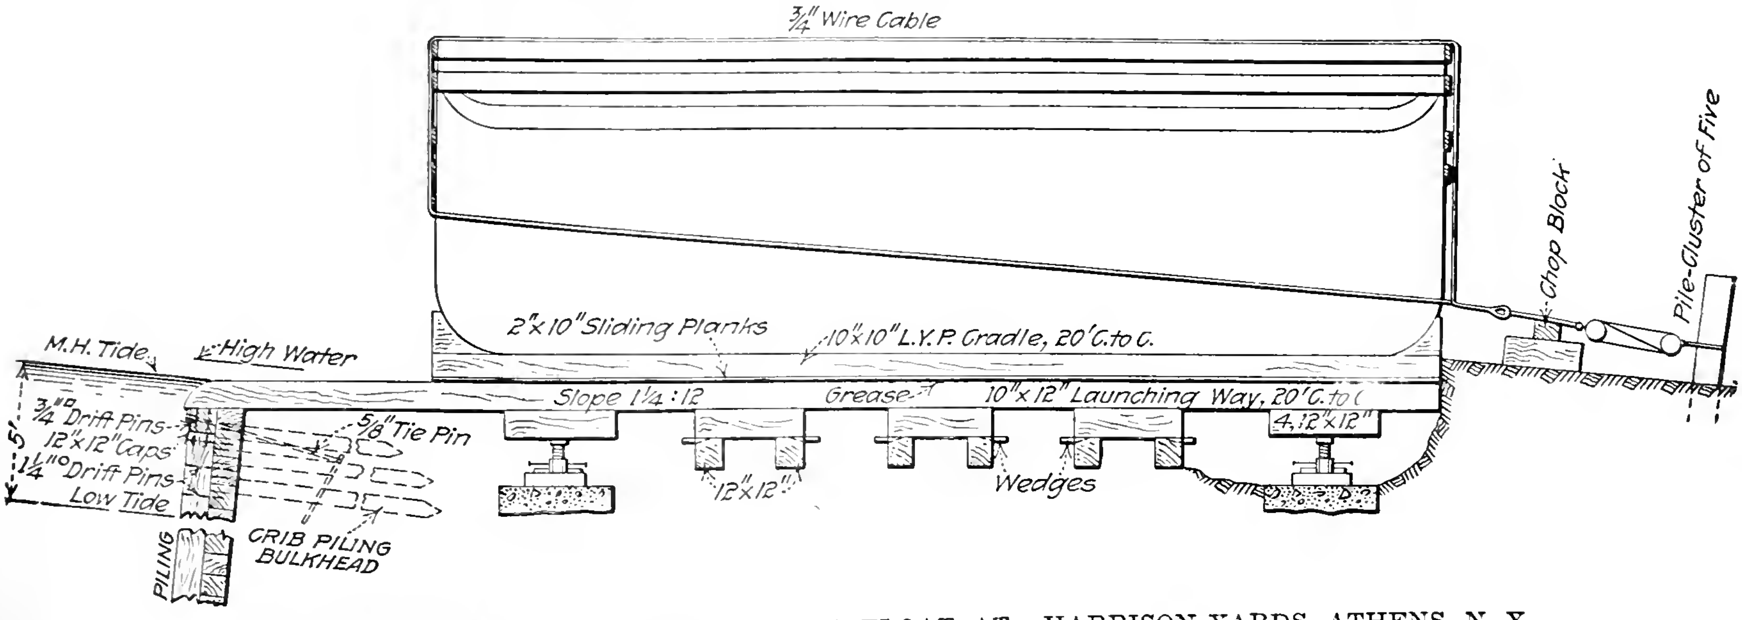


STIFFLEG TOWER CHUTE FOR PLACING CONCRETE IN CAR FLOATS

trouble has been experienced in maintaining the elevator bucket in true alignment.

The chutes consist of one 50-ft. boom chute and one 50-ft. counter-weight chute, and extension chutes. A complete electric lighting system has been installed.

Continuous placing of concrete is required for this work, and the tower is accomplishing this wonderfully well. The side forms for one of the floats have a total



LAUNCHING DETAILS OF CONCRETE CAR FLOAT AT HARRISON YARDS, ATHENS, N. Y.

distance of about 610 lin.ft. To place the concrete continuously, a complete circuit of this distance must be made before the initial set of the concrete already placed has been obtained. This is being done, and readily demonstrates the flexibility of the plant.

In preparing the site for the construction and launching ways the ground is evenly graded on a slope of $1\frac{1}{4}$-in. to 1 ft. Timbers made up of 12 x 12-in. logs slabbed on two sides are placed on 6-ft. centers on this grade with the top face flush with the ground level. During construction the entire weight of the vessel is supported by these timbers. Two launching timbers and a series of jacks are then placed at intervals of 20 ft. The jacks are supported by a concrete footing and capped by a 12 x 12-in. block 4 ft. long. The two 10 x 12-in. launching timbers are supported by two jacks and at the water end by the bulkhead piling, and also by 12 x 12-in. blocking and wedges between the jacks. The two 10 x 10-in. timbers which make the saddle are yellow pine. It was impossible to, secure hardwood timbers, and therefore, as it was necessary to obtain a hardwood finish to the underside of the saddle timbers, two 2 x 10-in. hardwood planks are used for this purpose.

When the vessel is ready for launching a $\frac{3}{4}$-in. steel cable is to be passed around the ends, as shown in a drawing, and anchored to a cluster of five piles. When the forms are being built, provisions are being made for removal above the saddle timbers. This part of the form is to be first stripped and the saddle timbers placed. The jacks are then to be started, raising gradually and uniformly over the entire length, thus transferring the weight of the vessel from the timber ways to the launching timbers. As the vessel is jacked the remainder of the forms are stripped and removed. The 12 x 12-in. blocking is wedged up as the jacking progressses, so that the weight is evenly distributed. This performance continues until the desired slope has been obtained. The lines are then simultaneously cut at the chop blocks, and the vessel starts down the ways. It is expected to launch at a slope of 4 ft. and at the high stage of the river. The launching design was made by William Jones, chief engineer of the company.

The contract is being executed by the Louis B. Harrison Shipyards, Inc., of 141 Broadway, New York City, under the direction and supervision of the Embarkation Division of the War Department. Mr. Jones, the chief engineer, is in responsible charge of the yard, and the War Department is represented by G. E. P. Bradley.

One vessel is ready for launching, and a second one has forms in place and steel installed and is practically ready for the placing of concrete.

Ohio Uses Cost-Plus-Lump-Sum Contract for Highway Maintenance

DURING the past year a modified form of the cost-plus-lump-sum contract has been used for resurfacing work by the Bureau of Maintenance and Repair of the Ohio State Highway Department. The new form is reported to have worked well, having encouraged the contractors to prosecute the work actively. Under the modified plan the state furnished all materials, thus relieving the contractor of the risk of rising prices.

The following example illustrates the form of procedure. The work was the reconstruction of a bituminous macadam top on an old macadam road. Selected contractors were asked to bid on the items given in the accompanying tabulation, which also gives the accepted bid prices. All labor, teams and equipment not specified in the contract were provided and paid for by the department.

In planning this contract, the objects sought were: Reduction of risk to the contractor; inducement to the contractor to push the work, and assurance that the contractor would do good work. By taking unit bids on items which are more or less uncertain, the contractor's risk is reduced. Also, since the state buys and furnishes all materials, the contractor is relieved of all risk of price advances and of delays in obtaining materials. Active prosecution of work is encouraged by the fact that the contractor's equipment and personal time are tied up until the job is finished. Finally, the contractor is assured a reasonable profit, though he has no chance of making one that is unusually large.

Maintenance work is directed in the field by patrolmen, foremen and superintendents. These men work under the supervision of a resident engineer, representing the county. The resident engineers work under the direction of division or maintenance engineers, who have charge of several counties each and who are responsible to the deputy highway commissioner.

Clinton Cowen is state highway commissioner of Ohio, and A. H. Hinkle is deputy highway commissioner in charge of the bureau of maintenance and repair.

SCHEDULE OF BIDS ON OHIO COST-PLUS-LUMP-SUM CONTRACT FOR ROAD RECONSTRUCTION

Approximate Estimated Quantity	Item	Contractor's Bid	Total
90 days	1 10-ton road roller	$6 40	$576
Lump sum	1 heavy road grader	100.00	100
Lump sum	1 contractor's plow	30 00	30
Lump sum	1 harrow	25 00	25
Lump sum	1 tank wagon	100 00	100
Lump sum	1 stone unloader	250 00	250
Lump sum	6 slip scrapers	8.00	48
Lump sum	3 wheel scrapers	30 00	90
1,000 days	Teams with dump wagon (not including driver)	4.50	4,500
Lump sum	All picks, shovels and other small tools	150 00	150
Lump sum	Moving outfit on job	200 00	200
200 days	Foremen (2)	4 00	800
Lump sum	General supervision*	1,400 00	1,400
Totals			$8,269

*Contractor must be on the work at least half the time.

Prohibition and Water Revenues at Cincinnati

Based on information supplied by the Water-Works Department, William F. Von Hoene, comptroller of Cincinnati, estimates that the loss in water-works revenues that will follow putting prohibition into effect will exceed $100,000. It is stated that in 1915 Cincinnati breweries used 65,611,000 cu.ft. of water; distilleries, 8,993,500 cu.ft.; manufacturers of accessories, 5,956,400 cu.ft. This makes a total of 80,560,900 cu.ft., said to be the normal yearly water consumption for these industries. The value of this water in terms of revenue is placed at $80,561. In addition, it is estimated that each of the 850 saloons in Cincinnati paid an average of $30 a year for water, making $25,500 and thus bringing the total loss up to a little over $100,000. This is gross loss. No allowance is included for water consumed in substituted manufacturing plants or by tenants for the quarters previously used for saloons.

Tamped Concrete Specified For Illinois Roads

Requirements Controlling Quality of Workmanship Made More Rigid—Increase in Machine Operations Encouraged

CONCRETE so dry that it must be compacted by tamping is specified for 1919 state-aid road work in Illinois. Machine tamping is encouraged, but is not required. Other new clauses tighten up the requirements for quality of construction, but they call for no radical changes in plant and methods previously employed. An outline of the new provisions which are of most significance to the contractor follows:

Consistency is rigidly defined. Broadly, it is to be "such that a conical pile of the concrete having a 45° slope will neither tend to flatten nor to run at the edges." It is to be such that the concrete will require "considerable tamping." It is required that precision of consistency be established by the following test: "A cylinder 6 in. in diameter and 12 in. in length shall be filled with concrete which shall be tamped until all voids are filled and a slight film of mortar appears on the surface. The cylinder shall then be removed and the vertical settlement or slump of the concrete noted. This settlement shall not exceed 2 in. when the mechanical finishing machine is to be used and shall not exceed 4 in. when the finishing is to be done by other methods permitted in the specifications."

Concrete is to be deposited the full depth of the slab and across the road in successive batches and then "it shall be leveled off and tamped mechanically with a machine approved by the engineers, until all voids are removed and the concrete is thoroughly compacted. The mechanical tamper shall go over each area of the pavement at least five times and at such intervals as will give the desired result." Hand tamping may be substituted for machine tamping, "providing at least four men are engaged at the exclusive work of tamping."

When machine tamping is employed the surface will be finished by two beltings, one given just after tamping and another just before initial set occurs. If hand-tamped, the slab is to be rolled once across and back and then a move forward of one-half the width of the roller, and then it is to be belted as with machine tamping. Specifications for belts and rollers and for their operation are the same as they have been previously.

Special Preparation of Subgrade

Special preparation of the subgrade is required for concrete roads. "The rolling and thorough compaction of the subgrade shall extend for a width of at least 12 in. beyond the edges of the pavement, and no backfill of any material excepting concrete will be permitted when re-rolling." In detail the accuracy of subgrade is to be determined as follows: "Immediately before any concrete is placed upon the subgrade it shall be tested for elevation by the use of a templet riding on the side forms behind the mixer. In the lower edge of the templet there shall be driven nails 6 in. apart and to such depths that their heads will just come to the true position of the subgrade when the templet is riding on the forms. Testing the elevation of the subgrade shall be done by moving the templet back and forth on the forms. On those areas of the subgrade found to be too high by as much as ⅛ in., additional excavation shall be made until the required depth is reached, and the excavated material shall be deposited on the shoulders. Those areas below the true elevation shall be filled with concrete making an integral part of the slab proper; all expense for this extra concrete including both labor and material shall be borne by the contractor."

Minor changes affecting equipment or construction methods are: Hauling over subgrade for greater distances than 500 ft. is prohibited. When tamping machines are used the side forms must be steel. Removal of side forms after 12 hours is permitted. Mixers shall be equipped with automatic locks or time-recording devices which will prevent emptying until the batch has been mixed for the minimum time required.

Except as noted, requirements for concrete construction remain substantially as in previous specifications. Clifford Older is chief engineer, Division of Highways, Department of Public Works and Buildings, Springfield, Ill.

New Illinois Road Specifications Work No Hardships on Contractors

By Clifford Older
Chief Highway Engineer, Division of Highways, Springfield, Ill.

ABSOLUTELY no reason exists why contractors should be alarmed over the new provisions in the specifications which have just been issued by the Division of Highways of Illinois, for concrete roads.

There will be no difficulty whatever in handling in the ordinary contractor's mixer concrete of the consistency specified, except that possibly chutes may be found unsatisfactory for distributing the material. Several of the best contractors last season placed, without any trouble, concrete of a consistency only slightly wetter than is now specified. The present mixer equipment owned by contractors will handle this concrete as economically as heretofore, except possibly in the case of mixers equipped with chutes. Except as to chutes, no mixer equipment that is in good condition and that has heretofore been acceptable will need to be scrapped.

Mechanical subgraders will not be required, nor is it anticipated that they will be needed. The new specifications for subgrading merely emphasize a little more strongly the results we have heretofore expected to secure. The only additional provision is that backfilling with loose material of any kind will not be permitted after the final rolling. This means that where depressions or ruts occur in the subgrade the high places must be cut off and the low places filled with concrete. This will work no hardship on any contractor who uses reasonable care in the preparation of the subgrade and avoids rutting or cutting it up by hauling long distances over it, after the rolling is completed.

Machine tampers are not required, although they are encouraged. Hand tamping is permitted. However, there are mechanical tampers on the market which, there is every reason to believe, will spread, tamp and finish concrete of the consistency required with less labor than has been heretofore used. The use of such a machine in St. Clair County, Illinois, resulted, without question, in a saving in cost to the contractor. At the same time, better results were secured, since the concrete could be laid without an excess of water. The machine cost about $1200, and would finish three or four times as much road in a day as the mixer could handle and only one man was needed to operate it.

LETTERS TO THE EDITOR

Comment on Matters of Interest to Engineers and Contractors Will Be Welcome

Old Impact Formula Preferred

Sir—I have read very carefully your editorial of Mar. 6, p. 454, on railway-bridge impact allowances, and I beg to say that I am in thorough accord with your criticism of the proposed new impact formula. An impact formula, to be of any value, should cover other things beside impacts, especially in articulated structures where members do not always take equal stress and there are other minor defects which impair the accuracy of any calculations which can be made. These defects generally appear in the lighter members near the center of the bridge and the old impact formulas take care of these parts to a certain extent, but they are not taken care of by the new formulas. I regard the old formula as a practical one and it has demonstrated its sufficiency by long use.

The new formula, although it is the result of many tests, will not give us the results which our experience justifies us in believing more satisfactory. The new formula would make no distinction between the impacts for a single-track and a double-track bridge—or a four-track bridge, for that matter—but the old formula takes care of this in a satisfactory manner. On the whole I regard the results of the tests made by Professor Turneaure as a satisfactory check on the formula which has been used in this country for a long time, rather than something new to be introduced into our specifications.

Compensation in Minor Engineering Positions

Sir—I dislike very much to attempt to measure verbal swords with an engineer of the eminence of John M. Goodell, but it seems to me that that gentleman, in his letter in *Engineering News-Record* of Mar. 6, 1919, p. 482, is laboring under two misapprehensions. The first is that the salaries now paid in engineering work are in any way commensurate with present wage and salary scales in other occupations, and the second, that limiting the education of men engaged in the minor engineering occupations, such as surveying and drafting, would make them satisfied with their present salaries.

As to the first, it would be obvious to everyone that the general level of wages has risen so enormously in recent years that all people on paid salaries have suffered a decrease in income none the less real because it is measured in purchasing power and not in dollars. In all occupations, where the individual is employed by others, and where the requirements of the job partake of the mental rather than of the manual, there have been no salary increases in recent years which are in any manner proportional to the great increases in the wages of manual laborers and artisans. It is from such conditions that the engineer is suffering today, and he feels it all the more keenly because he is thrown into such close contact with people of the manual-labor class.

There are undoubtedly many engineers in minor positions who are not capable of rising above their present limitations. But it does not follow that they should not, under present economic conditions, receive any increase in salary. The rise in the wages of manual laborers and artisans has not, in general, been due to any increase in their skill or to any greater value or quantity of the work produced by them. It has been due to the coercive power of organized labor in times of public stress. It is fairly easy in a manual trade to establish arbitrary scales of wages, and to insist, through the power of organization, that these scales be paid, but the man who performs his work primarily by his own individual ability, initiative and education is not so organized, and by the nature of his work cannot use the coercive power of organization to increase his salary. Such increases as he gets are usually due to an actual increase in the value of the work done by him, and have but slight reference to changes in the cost of living.

As to the second misapprehension, I know of no surer way to increase the wages of transitmen and draftsmen than to limit their education to that which might be obtained in a mere trade school. For, if the transitman or draftsman were possessed only of such education and ability that he had no opportunity or aspiration of attaining to a higher engineering position, it is certain that he would, in due course, become a labor union man, and use the power of union labor to secure a greatly increased wage for himself. Surely the transitman's or draftsman's manual skill is at least as great as that of the carpenter or the bricklayer, and the work which he accomplishes is at least of as great a value. Why should he not, therefore, receive as high a wage? The main reason why he does not is because he feels that he has a certain amount of ability and education which may in the future enable him to rise to a position requiring real engineering knowledge, and it is that hope and expectation that lead him to reject the simpler and surer method of wage increase through organization, coercion and strikes.

The "under dog" in engineering today is not, as Mr. Goodell asserts, kicking at his salary because he thinks that he should receive more money simply because he has an expensive education. He is kicking because other men, who have no special education, and are doing work requiring no greater manual skill and not so much mental ability as his own work calls for, can now afford to sport limousines on their recently greatly increased wages, while the purchasing power of his own salary has become less and less. He knows that the value of his services has not decreased, and that the value of the artisan's services has not increased. He knows that if his services were worth more than the skilled laborer's ten years ago they are still worth just as much more. He knows that something is wrong, and that he is made to suffer, through no fault of his own, in the general readjustment of economic conditions. Therefore, when he goes to his employer and as one man to another, without threat or intimidation, asks for a raise in salary, the employer should be the first to recognize these conditions. Yet, because this same employer is himself suffering from economic conditions, and perhaps has been forced to pay higher wages to his manually skilled employees, he often adopts the

"penny wise and pound foolish" policy of refusing the request because he is not forced to grant it.

It might be expected that where the employer is himself an engineer he would be the more ready to recognize the value of the services of his subordinate engineers. Yet how many of your readers are familiar with that type of employing engineer, perhaps a member of the Am. Soc. C. E., who, when approached by a subordinate for a raise, regales him with stories of how, when he was young, he worked for $50 or $60 a month on difficult and responsible work, and believes that all engineers should go through the same mill. To the suggestion that $50 or $60 a month in those days was as good as $100 a month today he turns a deaf ear.

There are, however, some employing engineers who are beginning to see the light, and who realize that the profession can never be maintained upon a high plane by the practice of paying lower wages to subordinate engineers than to mechanics, and some of the more enlightened of these men have associated themselves with other engineers, some of them representatives of the "under dogs," in an earnest endeavor to raise the whole scale of engineering salaries to a plane more nearly representative of present economic conditions. I refer to the American Association of Engineers, which is the only national organization of engineers that concerns itself with the bettering of the economic condition of the technical engineer, and seeks to do this through methods compatible with the dignity of a useful and learned profession. I hope that ere long all engineers will see the light. If not, the future of the profession is dark indeed.

Washington, D. C. KENNETH P. ARMSTRONG.

Boston Engineers' Trade Union Dinner

Sir—What is perhaps a significant sign of the times is furnished by a dinner of Boston engineers, held at the City Club on Mar. 25. The dinner was given by the Civil Engineers' Association of Boston and was its third annual banquet. This organization is made up of men working for the City of Boston and the State of Massachusetts, and is affiliated with the American Federation of Labor. Also present at the dinner were the members of the Civil Engineers' and Inspectors' Union No. 16,347, which is likewise affiliated with the American Federation of Labor, but is made up of men working for private employers. A number of men engaged in private engineering practice were among the guests. One of the after-dinner speakers was Maj. Gen. Clarence R. Edwards, who described the work of the Army engineers of the 26th Division.

The keynote of a number of the other speeches was advocacy of the organization of professional as well as trade workers to protect the rights of the individual. The president of the association said that while some members had resigned as a result of the association becoming affiliated with the American Federation of Labor, a much larger number had been induced through this move to join the association.

The dinner was certainly an enthusiastic one, and showed that those present looked forward with confidence to an increase in their salaries as a result of their alliance with the American Federation of Labor. It appeared that benefit to engineers had already been gained by the support of the federation before the State Civil Service Commission. It seemed to be the general opinion of those present that no question of professional ethics is involved by affiliation with organized labor and that this is not in conflict with the objects of the professional engineering societies. These societies, it was held, had concerned themselves essentially with the scientific and intellectual needs of the profession rather than with the business welfare of their members. Some speakers pointed out that legal and medical associations do not hesitate to take action to protect the business interests of their members.

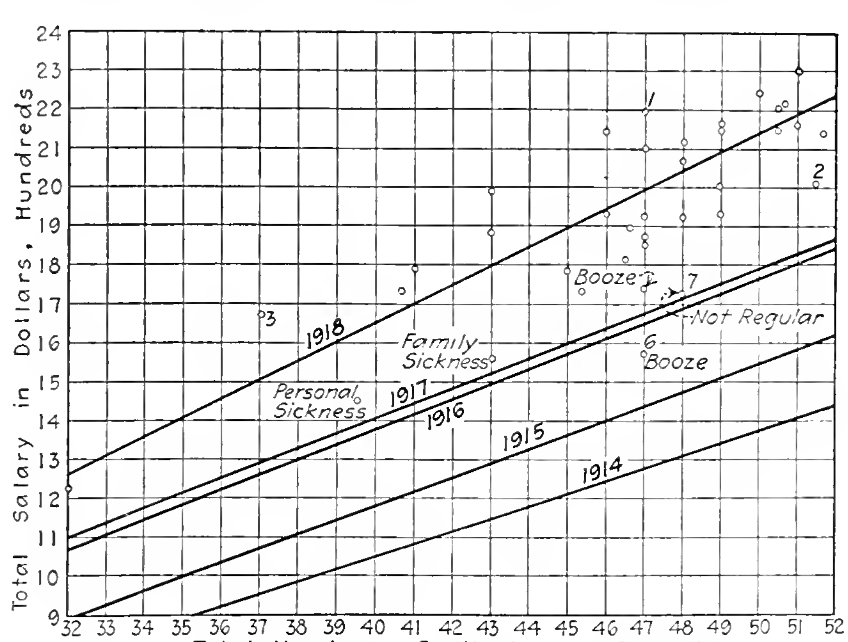
Whatever opinions one may hold for or against the trade-unionizing of the engineering profession, it is well for all of us to face fairly and understandingly the conditions that confront us today. This public dinner and the prevalent sentiment which it voiced seems to reveal a condition more widespread than many engineers realize. OBSERVER.

Boston, Mass.

What Carpenters Earn with One Contractor

Sir—With the present agitation for higher wages in the building trades, due to increased cost of living, a study of actual earnings by carpenters in the New England district during the year 1918 gives interesting results.

In a recent War Labor Board hearing in New York City Dr. William F. Ogburn, statistician for the board, stated that "budgets arrived at scientifically, based on the actual expenditures of over 600 families, consisting of five members, father, mother and three children, two of whom were of school age" would amount, at the present time, to $1500 for the "bare sustenance level," $1800 for the "minimum comfort level" and approximately $2100 for the "security and citizenship level." He further stated that in his opinion the smallest in-



CURVES SHOW ACTUAL EARNINGS OF CARPENTERS EMPLOYED BY ONE LARGE CORPORATION

Average curves for each year are based on actual earnings of a number of men for that year, the small circles showing earnings in year 1918. Wages were as follows:

1914, 50c. per hour to June 1; 55c. per hour remainder of year; 10-hour day, straight time for overtime.
1915, 55c. per hour whole year; 10-hour day, straight time for over time.
1916, 55c. per hour to June 1; 60c. per hour remainder of year; 10-hour day, straight time for overtime.
1917, 60c. per hour to June 1; 65c. per hour remainder of year; 10-hour day, straight time for overtime to Sept. 13, then 8-hour day, 1½ time or double time for overtime.
1918, 65c. per hour to June 1; 70c. to Sept. 1, 75c. remainder of year; 8-hour day; 1½ time or double time for overtime.

come on which such a family with present living costs could live and enjoy health and comfort was $1800.

The attached chart shows the average earnings for a group of approximately forty carpenters employed by our company over a period of five years. For example, a carpenter working at the rates and hours noted, if on the payroll for 52 weeks or the entire year, should have earned the following amounts: In 1914, $1440; 1915, $1620; 1916, $1845; 1917, $1870; 1918, $2240.

How did the men whose actual 1918 earnings are represented by the circles fare during that year? Our employment records show that for this group of men the average family included mother, father and one and one-half children. Using the minimum comfort budget of $1800 as a basis, and allowing $250 per child, the budget for this family calls for $1375 per year. The father, however, on an average had to spend about six months of the year away from home to get work. This would add, over normal expenses, approximately $10 per week, or $260 for the six months. The family budget then becomes $1635 for the year. Referring to the chart, we see our "average-family" carpenter would have received that amount in 39.5 weeks. We also see that every man in the group with the exception of three received well over this amount.

Why did some of the men earn so much more than others?

Referring to the chart again, specific cases are interesting.

No. 1. A very steady man; quit his out-of-town job the minute overtime was cut out. Had he worked five weeks longer, and rounded out the year, he would have received $2360 for his year's work.

No. 2. The star worker of the group. For the years 1914-1917, inclusive, his earnings ranged from $50 to $150 above the average. During 1918 he did not care to work Sundays and took a day off now and then. He was satisfied and reported to the writer he had saved "about $500." His family consists of himself and wife.

No. 3. A widower with four children. He is an "overtime chaser"; "works for any company having overtime work." He left at the end of the thirty-seventh week and went to a shipyard building wooden ships. His reported earnings for the remaining portion of the year would indicate that he received at least $2500 for his year's work.

Nos. 4 and 5. Owing to personal and family sickness these men cannot leave Boston and must therefore take what work comes along in that city.

Nos. 6 and 7. One of our foremen reported that two of his men were going "to the dogs." One "boozed," the other had a habit of leaving on Friday night and showing up for work Tuesday morning. The wage record seems to prove that the foreman is correct.

Earnings for 1919 will probably not approach those of 1918 by a considerable amount. The building trades at the present time are flat, thus causing considerable unemployment. Prospective builders are waiting for a drop in material and labor prices. Owners who have started building insist there shall be no overtime; the "straight" eight-hour day and not the "basic" eight-hour day shall prevail. Labor leaders demand a 44-hour week (in Boston the 40-hour week is already in effect in a few of the trades); they insist there shall be no reduction in rates; in fact, owing to the constantly increased cost of living (?), there seems to be a universal demand for greatly increased hourly rates.

The wage situation in the building trades certainly warrants a close study. Unless all parties concerned "lay their cards on the table, face up," and *coöperate,* the coming summer will have a deluge of squabbles, with consequent strikes.

Employment Manager, Aberthaw Construction Company,
Boston, Mass.

The Pioneer National Society to Adopt the Cleveland Plan

Sir—May I call the attention of your readers to an oversight that occurred in *Engineering News-Record* of Mar. 6, 1919, pp. 454 and 495? The first national society to adopt the Cleveland plan of joint membership was not the American Society of Mechanical Engineers, in 1919, but the American Association of Engineers, in 1918.

Joint membership is not a panacea; it is but one step toward closer relations among all engineers. The next step might by the adoption of this plan, as modified by experience, by all the national societies in unison and in addition requiring, as recommended by the Intersociety Relations Committee of the Cleveland Engineering Society, and as approved by the American Association of Engineers and the Association of Ohio Technical Societies, that applicants for membership in national societies shall show as a prerequsite for membership that they are members of an accredited local society.

C. E. DRAYER,
Secretary, American Association of Engineers.
Chicago.

Why Not Engineers for Federal Rural Health-Protective Work?

Sir—I have noted the comments of H. C. Hodgkins, in *Engineering News-Record,* Mar. 13, p. 535, on the above-named subject. Having been employed by the United States Public Health Service, I am familiar with its attitude toward the sanitary engineers employed on public-health work, such as drainage for "mosquito eradication." I can say from experience that such engineers have been allowed very little responsibility. While this may be due to the nature of the work given them and to the reputed lack of executive ability among engineers, there is no question that the medical officers in charge are jealous of their position and authority and prone to consider as an instrusion the exercise of authority by any nonmedical officer.

The opinion has been widely held that only medical men are fitted to supervise matters of public health. This fallacy has long ago been dispelled, for there is a large and growing number of nonmedical, though specially trained, health officers who are making their influence felt, to the discomfiture perhaps of the medical profession. My attitude has always been that the sanitary engineer is the proper person to direct public-health work as the problems are primarily engineering problems and the medical phases are, largely, purely incidental. This view is gradually gaining ground, I believe. Efforts have been made in the Public Health Service to obtain for the sanitary engineers wider

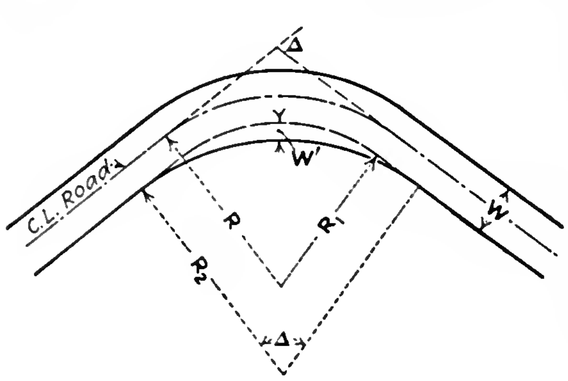
responsibility and higher standing, but all efforts have been vetoed, due to the predominance of medical men in the service. As a result, the medical officers have been giving more time to engineering problems, such as labor questions, pay rolls, and field drainage details, than to the duties for which they are fitted. In my own experience, I found that the medical officer in charge of my station was more interested in the wages paid my laborers than in the health of the laborers themselves, for while he was interfering with the field work one of the workmen was ill for three weeks with spinal meningitis, a communicable disease. In another case, the medical officer spent a large part of his valuable time in writing out checks to cover a large payroll for labor on work which was under the supervision of the sanitary engineer.

The sanitary engineer has charge generally of important phases of sanitation and general public-health work, and he should have responsibility in keeping with the nature of the work performed. Engineers must take the stand that they are as important factors in respect to the public welfare as doctors of medicine—they surely are as high-grade men, on the average.

E. G. SHEIBLEY,
Hydraulic and Sanitary Engineer.
Riverside, Calif.

To Compute Added Area on Highway Curves

Sir—The following simplified formula for computing the extra area in pavement due to widening at curves may be of some interest to highway engineers. In all cases which I have met, slide-rule computation is accurate to tenths of a square yard, and may be used to save time.



With the notation shown on the diagram, it can be shown:

$$R_1 = R - W/2$$

$$R_2 = R_1 + \frac{W'}{exscc\ \Delta/2}$$

Area added $= (R_2^2 - R_1^2)\ (tan\ \Delta/2 - \Delta/2\ radians)$

W. W. CRAWFORD,
Division No. 1, Wisconsin Highway Commission.
Madison, Wis.

The Duluth Way of Meeting Cost of Water-Main Extensions

Sir—The two editorial notes in your issue of Mar. 20, "Meeting the Cost of Water-Main Extensions" and "Assessment of Benefits Deserves More Attention," lead me to send you a copy of a paper on the general subject that I wrote a few years ago (see *Jour.* Am. W. W. Assoc., December, 1915, p. 612).

The criticisms in your articles are to the point and are vital. Since the adoption of our method of making extensions in Duluth there has been but little criticism, with no attempts to change the system. If the extension is designed to boom real estate the plan throws the burden upon the property. If bona-fide consumers exist or build along the line of the extension afterward, the property is gradually relieved, so that eventually the consumers pay for the entire expense of the service.

Under this method no vacant property escapes where contributions are necessary in order to evade a losing proposition so far as the Water Department is concerned.

D. A. REED,
Manager Water and Light Department.
Duluth, Minn.

[Under the Duluth plan, 8% of the first cost of a 6-in. water main is charged annually against abutting property, for 15 years, on the basis of 5% interest and 3% sinking fund, or the charge may be paid in one installment, at 25% discount. Against this charge is credited one-half of the water revenue paid by the occupant of any premises. The other half is allowed for operating expense. Vacant property bears the entire 8%. The charge is based on frontage, with no debit for the second side of a corner lot. The same plan is followed for gas (the city owning the gas works) except that a 4-in. main is the base and only one-third the gas rates paid are credited against the charge.

Strictly speaking, this is not an assessment for benefit, but rather a uniform and, so far as appears, an arbitrary annual charge in lieu of rates for 15 years, with a penalty for letting property remain vacant. It is virtually a guarantee of 8% on the cost of a minimum-sized main, but the guarantee terminates in 15 years, regardless of how few water consumers there may be on the street. It is much fairer than the apparently common practice of letting one or a few willing persons bear the entire guarantee of revenue, or even put up the entire first cost of an extension, with no means of compelling other property owners to do more than pay ordinary water rents when they become consumers.—EDITOR.]

Colorado River Flood Control by Storage Promising

Sir—Mr. LaRue's article in *Engineering News-Record* of Mar. 6, 1919, p. 456, on the control of the Colorado River by storage offers a promising solution to a situation growing more precarious every year.

Here is a river which menaces the most intensively productive region in the world, the Imperial Valley. Head-water storage on the Colorado will have its full effect in flood prevention in this valley, a thousand miles below the source of floods and the reservoirs proposed to prevent them. This situation, then, is unique, in problems of flood control by storage, in that herein is contained every promise of ultimate success. Examine the figures given for the 1917 flood and imagine what would have happened if the Grand River peak had been delayed a week. The Yuma peak instead of 143,000 sec.-ft. might have reached 165,000, and the levees might have been overtopped at all points.

Immunity from flood damage in the lower Colorado hangs by too slender a thread not to begin at once a comprehensive study of the possibilities of permanently removing this menace by storage. The data which Mr. LaRue points out as necessary cost an altogether insignificant sum, considering the important purposes they will serve. The study should be begun without further delay.

J. C. STEVENS.
Portland, Ore.

HINTS FOR THE CONTRACTOR

DETAILS WHICH SAVE TIME AND LABOR ON CONSTRUCTION WORK

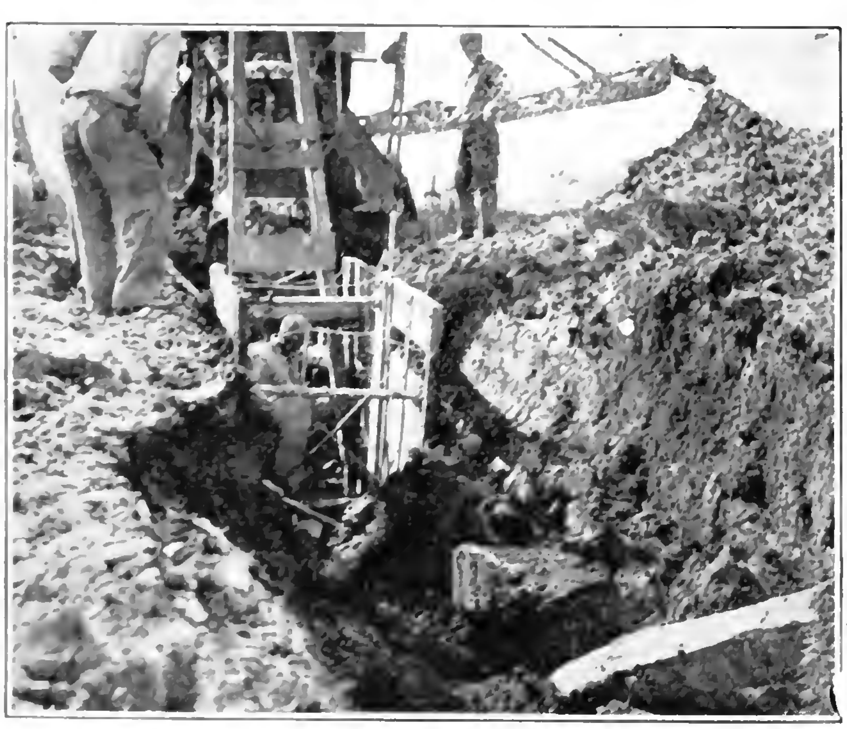
Trailer Shield Holds Sides of Caving Ditches in Pipe Laying

BY MEANS of a cage or shield pulled by the trench excavator and protecting the pipe-laying operations, drain pipe for a large system of tile drains was successfully laid without sheeting the badly caving ditches. Ordinary methods of handling caving ditches permitted a daily progress of only 50 ft. With the shield, a progress of 425 ft. per day was made under the worst conditions of spring work, and later in the season, when water was less troublesome, the daily progress was from 700 ft. to 1500 ft. of pipe laid. Two men working inside the shield laid the tile.

Other Articles in This Issue of Interest to Contractors:

The work was located near Garden Prairie, Ill., where soil conditions were very difficult. The top soil was a black gumbo about 3 ft. deep. Below the gumbo were 4 ft. of joint clay, very rotten and crumbly in texture, and below the joint clay there was from 1 to 4 ft. of fine sand and water. The sand was so fine that it was carried by the water from under the trench sides, causing them to cave in, until the trench was often 40 ft. wide at the top.

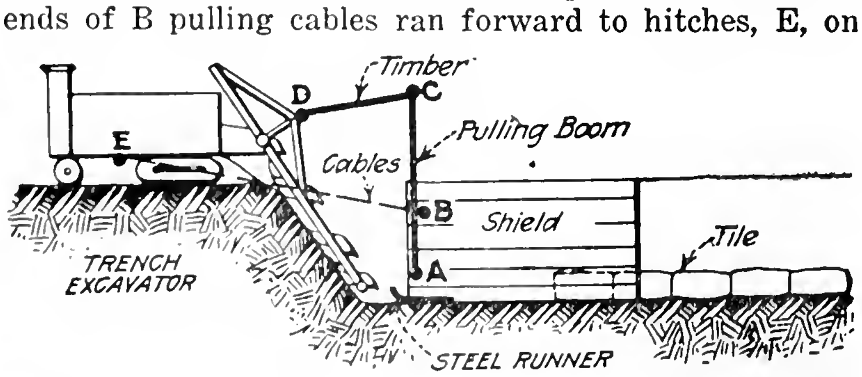
Tight sheeting was first used by the contractor and it was fairly successful in holding the banks, but its cost was prohibitive at the price for which the contract was taken. Sand boxes and various other methods commonly employed for controlling sand and water were tried, without success. Finally the contractor adopted the method of spading the sides of the ditch down into the excavator buckets until no more dirt would fall in. This method was very slow, the average daily progress being 50 ft. per day. The contractor was unable financially to continue the work and it was recontracted.



SHIELD PROTECTS PIPE LAYING OPERATIONS IN CAVING DITCH

Construction was resumed in the spring with an outfit consisting of a trench excavator, a power backfiller, a large power-driven diaphragm pump and a trench shield devised by the new contractor. At the beginning of the work the soil conditions could hardly have been worse; the spring rains had soaked the earth and the water level was the top of the ground. The shield met these conditions successfully. The accompanying view shows it in operation.

The success of the shield in operation was due wholly to the pulling method employed. Structurally the shield consisted of two side panels held apart by screw braces and held together against the braces by horizontal and diagonal turnbuckle ties. Between the sides, at the front end, stood a vertical mast or pulling boom. From the pin, C, at the boom top two timbers extended forward to the boom, D, of the trench excavator. The bottom of the pulling boom was set on a pulling bar, A, whose ends set into the side panels and which extended across the shield. The bar, A, could be raised or lowered, but ordinarily such a change was not necessary. At B another pulling bar extended across the shield, and its ends passed through the side panels. From the ends of B pulling cables ran forward to hitches, E, on the trench excavator. The bar, B, could be quickly shifted up and down with respect to the height of the shield and, being behind the boom, AC, it pulled against the boom. This method of hitching the shield to the excavator involves a care in adjustment which is not indicated in the diagram and upon attention to which, the contractor states, much of the success of operation depends. The shield weighed about 1500 pounds.



METHOD OF HITCHING SHIELD TO TRENCH EXCAVATOR

In the operation of the shield, two men worked between the sides of the shield with short-handled shovels, one man working in the front end cleaning up the bottom of the trench and aiding the second man, or the pipe layer, in making a perfect grade. This combination gave excellent results, and only very seldom was the machine stopped to wait for the pipe men, who were able to lay two tiles within the sides of the shield at one time.

The most serious obstacle encountered by the contractor was water. Heavy rains fell every few days, and the water at all times was so high in the pipe that had been laid that the pump was constantly used to keep the trench dry; nevertheless, the work went forward with a daily average of 425 lin.ft. Later in the year, after the rainy season was over and the pump was no longer needed, daily runs of 700 to 1500 ft. of pipe laid were frequently made.

The adaptability of the shield to any width or depth of trench was one of the main features. To change the width of the shield the screw jacks were run in or out, and the width of the shield was changed accordingly. At the time when the length of the screw jacks was altered, it was necessary to alter the turnbuckles. To alter the height of the shield to fit a trench of greater depth, it was necessary to add horizontal members. There were limits, however, to the practical depths and widths at which this device could be operated. The shallower the ditch, the easier it was to operate the shield. However, it could be operated with success down to depths of 10 ft. and out to widths necessary to fit a 60-in. trench.

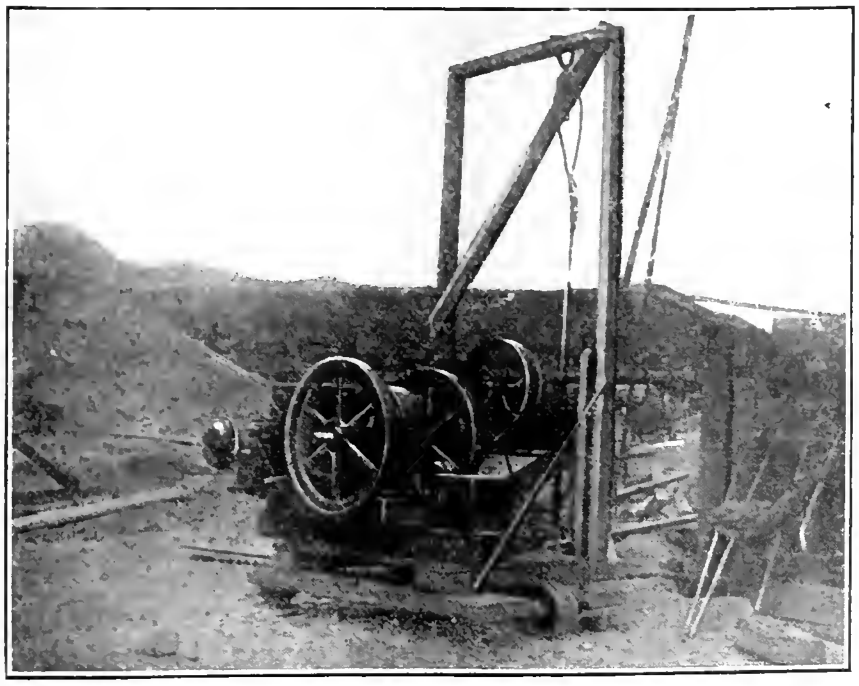
The contractor for the work was Monroe Farrer, of 4045 W. Van Buren St., Chicago, Ill., who designed the shield and perfected its operation.

Portable Home-Made Gasoline Drill

By C. M. Young

Engineering Experiment Station, University of Illinois, Urbana, Ill.

The accompanying illustration shows a portable outfit consisting of an auger drill, driven by a gasoline engine, which has been successfully used in boring vertical holes through soft surface ground and soft shale. It was developed by a subcontractor for boring holes in blasting the excavation for a building. The shale to be drilled is 3½ ft. thick, not hard but somewhat gritty. While the apparatus was intended for vertical holes, there is no reason why the drill should not be turned in any direction.



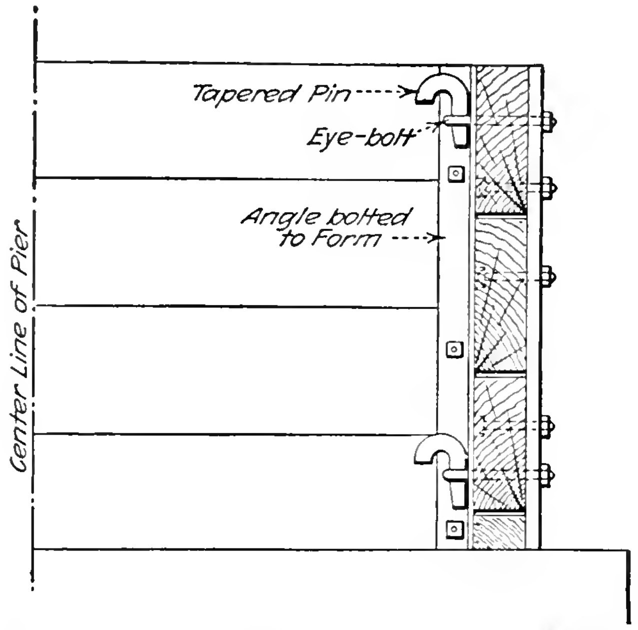
AUGER DRILL DRIVEN BY GASOLINE ENGINE BORING VERTICAL HOLES THROUGH SOFT SHALE

The outfit consists of the ordinary bit and chuck used in coal mining, a gasoline engine, and suitable belting and reducing gears. The engine is of 4 hp. and is belted to a shaft which carries the beveled gear for driving the drill. The speed of the drill is about 150 revolutions per minute.

The drill is fed downward by a rope fastened at one end, passing over a sheave wheel at the top of the drill rod and down to a hand winch. It is raised by a rope hooked to the end of the rod and passing over a pulley at the top of the frame. A 2-in. bit is used, and the machine is drilling 100 holes per day through the 3½ ft. of shale. The average time for drilling one hole, including one change of bit but not the moving of the machine, is 3¼ min. In surface soil of average hardness the drill has been put down 2½ ft. in 5 sec. The whole outfit is mounted on a frame carried on three rollers and is pulled from hole to hole by hand. Only one man is needed to run it and move it. The gasoline consumption is one gallon for eight hours of steady work.

Device Simplifies Footing Form Removal

The arrangement shown in the accompanying picture is in successful use by William G. Cooper, contractor, on his footings for the Gravesend Ave. elevated line in Brooklyn. These forms are used many times over, and the simplicity with which they may be assembled and stripped adds greatly to their life. To each end of the two cross-forms is bolted an angle which has been punched to allow an eye-bolt to pass through it at two or more places. These eye-bolts are a part of the longitudinal forms, and are spaced to match the holes in the angles. The two forms are held together by tapered pins with hooks at the top. Hammering on the top of the bend drives them snugly into place during assembly, while a few taps on the lower end of the hook loosens them as easily. Edward Murphy is superintendent and Charles Mannel is engineer for the contractor.



SIMPLE HOOKED PINS FOR PIER FORMS MAKE FOR RAPID REMOVAL

NEWS OF THE WEEK

New York, April 10, 1919

Railroad Wage Board Gives Engineers Hearing

Three Days Devoted to Pleas That Technical Engineers on Railroads Be Given Uniform and Higher Pay

Much sooner than expected, the Railroad Board of Wages and Working Conditions, on Mar. 31, Apr. 1 and 2 gave the technical engineers a hearing and a chance to present the schedule adopted at the National Conference of Railroad Engineers held Mar. 17 in Chicago, under the auspices of the American Association of Engineers.

Marshall O. Leighton, chairman of the National Service Committee of the Engineering Council, arranged for the meeting and the board sent an invitation to the American Association of Engineers to appear at the same time, an arrangement which suited both organizations. After Mr. Leighton opened the meeting Francis Lee Stuart, consulting engineer, New York, representing the Engineering Council, pointed out the need and justice of increasing salaries. While in sympathy, he was not in touch with the details, and turned the question for proofs over to the American Association of Engineers. C. E. Drayer, secretary of the latter organization, presented documentary evidence of the representative character of the railroad conference in Chicago, which he held represented the 40,000 engineers in subordinate positions, and submitted the following memorandum:

"We urge the classification and standardization of conditions and salaries for railroad professional engineers in the classes under consideration. Two illustrations are mentioned for the purpose of making plain the need. From questionnaires recently sent out, the American Association of Engineers finds that three roads are paying instrumentmen $105 a month, while several other instrumentmen on the Pennsylvania R.R. are doing resident engineers' work, consisting of the construction of an engine terminal, and are receiving instrumentmen's pay.

"The benefits to be derived from classification and standardization are: (1) Elimination of the discrimination that exists between engineers in railroad service; (2) it will permit readjustment of salaries and working conditions on a definite and sound basis.

"It is admitted by all that there should be certain definite relations in pay among men who are doing the same kind of work; that there should be certain standards whereby a man who is qualified to perform a certain kind of work, and does it, should receive a certain pay. We find on the different roads, from 1200 questionnaires sent out and received last week from some 60 different roads, that men doing precisely the same kind of work are being paid salaries differing by large percentages.

"The following principles should govern in classification and standardization of positions and salaries: (1) Standard and distinctive details of all positions having similar conditions and working requirements; (2) definitions of duties and responsibilities of each position; (3) definitions of classifications and requirements of each position; (4) placing of positions into classification according to the character of duties and according to responsibility and division of work; (5) positions of the same kind, made distinctive according to duties and responsibilities, should carry the same rate of pay."

(*Concluded on page* 745)

Employment

For the convenience of engineers returning from military life, and others, there are listed below agencies which may be helpful to those who are seeking employment:

Engineering Societies Employment Bureau; secretary, 29 West 39th St., New York City.

American Association of Engineers, 29 So. La Salle St., Chicago. Service to members only, but Army or Navy engineers in uniform who are eligible to certified membership may join without payment of entrance fees or dues while in uniform and for six months after discharge.

Engineers' Service Bureau, maintained by the Joint Council of Engineering Societies of San Francisco, Engineers' Club, 57 Post St., San Francisco. Only applications by mail or wire will be considered.

The Federal director of the United States Employment Service in New York State announces the receipt of a letter from J. P. Morgan & Co., in which $100,000 is offered for the purpose of continuing the work of the service up to July 1 of this year. The Professional and Special Section in New York will therefore be continued, but will be located at the main office, 469 Fifth Ave., New York City.

St. Louis $23,000,000 Bond Issue

A commission appointed by the mayor of St. Louis has listed the items which it considers should be covered by the proposed bond issue of $23,384,000, this being the amount the city can issue without exceeding its bonding limit. The tentative list is as follows: River des Pères channel, $10,495,000; sewers, $3,420,000; parks and playgrounds, $2,850,000; grade crossings and viaducts (city's share), $1,034,000; extension of municipal dock, $1,000,000; municipal belt railway, $1,000,000; connection between the municipal railway and tracks on the municipal bridge over the Mississippi, $1,000,000; municipal auditorium, $1,000,000; street openings and widenings (city's share), $750,000; municipal farm, $400,000; fire houses and equipment, $200,000; industrial farm, $150,000; jail extension, $85,000.

New Jersey Passes Tunnel and Bridge Bills

Bills authorizing the construction of a vehicle tunnel under the Hudson River at New York, and a street bridge over the Delaware River at Philadelphia, have been passed by the New Jersey legislature and are before Governor Edge for approval. Preparations have already been made to provide an appropriation of $1,000,000 as New Jersey's initial contribution to the Hudson River tunnel. Until 1922 money for this work will have to come from the state's surplus fund, but in 1922 a direct tax can be levied, under a new constitutional provision.

Free Service to Soldiers

A number of employment agents in Chicago, handling principally railroad labor, have addressed a letter to the Federal managers of the railroads having termini in Chicago, offering their services without charge in finding employment for returned soldiers.

Detroit and Duluth Vote Against Buying Street Railways

Municipal purchase of street railways was voted down at both Detroit and Duluth Apr. 7, the popular vote being 63,382 against and 59,479 for at Detroit and 8886 against and 4902 for at Duluth. The proposed purchase price of the United Railway lines at Detroit was $31,500,000.

Votes for Municipal Ownership

Municipal purchase of the water, gas, electric-light and power plants of Superior, Wis., was indorsed by a large majority popular vote Apr. 7.

War Department Has Locomotives and Cranes For Sale

Announcement has just been made that $45,000,000 worth of locomotives and cranes is for sale by the Director and cranes are for sale by the Director General of Military Railways, whose office is at 6th and B Sts., N. W., Washington, D. C.

The equipment to be sold is material which was built for shipment overseas, and for the most part is in crates at Atlantic seaboard ports of this country. It includes 22 locomotive cranes of capacities from 10 to 50 tons, 34 raised pier locomotive cranes of capacities of 10 and 15 tons, 20 railway track piledrivers, 6 two-boom cast gantry cranes, 212 standard-gage Baldwin locomotives, and three 36-in. gage dinkey locomotives, a great number of cars of the box, gondola and dump-car types, hoisting engines, railway rails, generator sets, steel searchlight equipment and automobile trailers.

The cranes, as stated, are all packed for export and are available for immediate shipment. The cabs of the cranes are built with French clearances for bridges and tunnels, considerably lower than those in this country. The cranes, however, are standard in their engine and working parts.

New York Port Treaty Postponed

After a number of hearings on the desirability of the immediate adoption of the interstate treaty governing the joint control of the port of New York, it has been decided that the proposed treaty will not be submitted to the two legislatures at the current session. This decision was reached by the interstate commission after it became evident that the city government of New York is opposed to the port treaty as it now stands.

Both states have promised funds to continue the commission's studies, and it is reported that a definite, comprehensive plan for port development will be submitted next year. This is in accordance with the vote of the Board of Estimate of New York City to withhold approval of the treaty until after such a comprehensive plan had been prepared.

Large Hydraulic Turbines Ordered

Orders have been placed with the Westinghouse Co. for two 45,000-kva. vertical water-wheel generators of 12,000 volts, three-phase, 25 cycles, for the Queenston development of the Hydro-Electric Power Commission of Canada. These will be the largest hydraulic turbines yet built.

Cleveland Clearwater Basin Case Hearings Concluded

Testimony before the master appointed by the court in the suit of the City of Cleveland against the Walsh Construction Co., on account of the reconstruction of the clearwater basin at the West Side filtration plant, has been concluded. The issues involved are a claim of the contractor against the city for unpaid balance, and a claim of the city against the contractor for damages on account of the necessity for reconstructing the basin by jacketing it with reinforced concrete. Robert Hoffmann, city engineer, was appointed master by the court to take testimony and report on the facts involved; it is likely that his report will be rendered soon.

Conflict Over Bids on Cost-Plus Contract for Viaduct

Bids received by Kansas City, Mo., for the construction of the 23rd St. viaduct on plans and specifications providing for a profit-sharing form of cost-plus bidding have led to a political conflict which is delaying the award of a contract. The Board of Public Works declared the A. S. Hecker Co. of Cleveland the lowest and best bidder, but the City Council refused to confirm the award of the contract. A local bidder was only a fraction of 1% higher. Ostensibly the opposition of the council majority is directed against the cost-plus form of bidding; it is claimed that the city is not adequately protected against excessive cost. Engineers familiar with the situation say, however, that the political organization opposes the award of the contract to an outside contractor.

Under the contract as drawn by Harrington, Howard & Ash, consulting engineers for the city on the viaduct, the bidders fixed an estimate of cost plus contractor's fee; if the cost exceeds the bid estimate the contractor will have to pay half the excess, but in all events he receives a minimum fee of $15,000, his bid fee, while if the cost is below his estimate the city and the contractor divide equally. The Hecker bid on this basis was $716,000, including a fee of $50,000.

Strong sentiment has developed in the city over the refusal of the council to approve the award of the contract. The Kansas City Engineers' Club on Mar. 31 held an open discussion on the subject of the viaduct contract in which a representative of the local bidder whose bid was next above that of the Hecker Co. received opportunity to present his side of the case. As a result of the hearing, the club passed resolutions affirming the imperative need of building the viaduct at the earliest possible moment, demanding that the city have open competition on all municipal construction work and accord outside bidders the same treatment as local bidders, and approving the profit-sharing cost-plus form of contract as used for the 23rd St. viaduct.

This is a radical departure from the principle which the club has followed in the past of not concerning itself with civic affairs, although in technical matters the club has been progressive and active. Local engineers have expressed great satisfaction with the club's action and believe that it will develop the organization into a more forceful one, and one of greater influence on public questions.

Allegheny Bridges Ordered Raised by Secretary Baker

In spite of strong opposition from the Pittsburgh council and from citizens of the city, Secretary of War Baker signed Mar. 31 an order requiring that the bridges over the Allegheny River at Pittsburgh be raised immediately. Work upon these raising operations was suspended during the war, and is now to be resumed upon the same terms as previously ordered. The county will have the same time limits as originally prescribed.

This action was taken as the result of a recommendation by the Rivers and Harbors Committee of the Pittsburgh Chamber of Commerce—although opposed by the Municipal Affairs Committee of the chamber—the final vote of the chamber as a whole resulting in favor of the adoption of the Rivers and Harbors Committee request. The original order was dated Mar. 23, 1917, at which time eight bridges were to be raised. Of these, one has burned down, the Pennsylvania R.R. bridge has been raised, and the owner of another is raising and rebuilding it voluntarily. The order, therefore, requires the county commissioners to proceed with the raising of five bridges immediately.

Pennsylvania Gets Early Start On Road Bond Issue Construction

In order to get an early start on construction under the new bond issue, the Pennsylvania State Highway Department, of which W. D. Uhler is chief engineer, has announced the appointment of the 15 engineers who will be in charge of the various districts into which the state is divided. A number of changes have been made in the personnel of the various districts. The engineer in charge, the district number, and headquarters are as follows:

District No. 1. D. C. Stackpole, Bellefonte.
" " 2. C. W. Hardt, Harrisburg.
" " 3. A. S. Clay, Bloomsburg.
" " 4. H. W. Claybaugh, Franklin.
" " 5. W. R. Wolfinger, Allentown.
" " 6. C. W. Erismah, York.
" " 7. W. F. Cressman, Philadelphia.
" " 8. W. O. Bennett, Du Bois.
" " 9. W. S. Hammacher, Chambersburg.
" " 10. J. S. Ritchey, Wellsboro.
" " 11. C. S. Lemon, Hollidaysburg.
" " 12. W. H. Bircher, Scranton.
" " 13. C. E. Myers, Pittsburgh.
" " 14. W. D. Myers, Washington.
" " 15. F. E. Winter, Warren.

Would Improve State Health Work in Texas

Recommendations for increasing the efficiency of state health work in Texas have been made to Governor Hobby by a special commission representing 11 state-wide organizations. It includes Charles Saville of the State Council of Defense. The commission advises that members of the State Board of Health serve for six-year terms, and that one member "be an experienced sanitary engineer"; that bureaus of sanitary engineering, communicable diseases, rural sanitation, child hygiene,

public health nursing, laboratories, and health instruction, each under "an experienced director," be created; that the state be divided into eight or more sanitary districts, each in charge of a full-time district officer; that fitness and not politics govern in filling positions; and that adequate health appropriations be made and reasonable salaries paid. Texas now spends only 5c. per capita for health protection, the special commission states.

Industrial Relations Discussed at Joint Meeting in Chicago

Safety engineering, scientific selection of workmen, and the inauguration of works councils of employers and workmen, have demonstrated excellent results at the works of the International Harvester Co., as told in an address before a joint meeting of the Western Society of Engineers and the Chicago Sections of the American Society of Mechanical Engineers, and the American Institute of Electrical Engineers by A. H. Young, manager of the industrial relations department of the company. He stated that by safety methods accidental deaths of employees had been reduced to 7 per year, from 47 to 56 per year.

The old haphazard methods of employing men had given way to the centralized employment office, where the applicant's qualifications are carefully appraised. It now takes 3 to 3½ days to hire a man, compared with 3 min. by the old practice. By the new method the employee is made to feel that he is a real part of the organization, hired to do the particular job for which he is best adapted. Moving pictures instruct him how his work is to be done. He is also instructed specifically by the foreman, and is warned of the various dangers connected with the work.

An interesting experiment is the new arrangement which the company now has by which all matters of mutual interest are passed on by a works council, of which 50% are employees and the other half are representatives of the employer, such as superintendents. This council determines the policy and the management carries it out. In this way the men are educated in the problems of management, they see and understand the difficulties, and have already shown signs of being fair and reasonable in the problems they have had a part in solving.

Yellow Fever Eradication Work to Be Continued

Resumption of the work of the Yellow Fever Commission, interrupted by the war, is announced in a Rockefeller Foundation circular (61 Broadway, New York City). The work will be continued under Dr. William C. Gorgas, who was recently retired as surgeon general, U. S. A. Dr. Gorgas will soon sail for Central and South America, from the countries of which it is expected that yellow fever can be eradicated.

Engineers Club Reports on Cement Prices

Committee of Duluth Society Recommends That Further Study Be Left to Labor Department

Some weeks ago the Duluth Engineers' Club appointed a committee, with Lyonel Ayres as chairman, to report on the reasonableness of the prices for portland cement. The committee's report, verbatim, is given below:

The following are the prices of portland cement net f.o.b. Duluth, from 1913 to 1919:

1913	$1.55
1914	1.50
1915	1.41
1916	1.56
1917	1.91
1918	2.01
1919	2.20

This range of prices shows an increase in 1919 of 56% over 1915 price.

From data obtained from the Universal Portland Cement Co., they contend that the cause of the increase in cost of production in 1918 over 1915 is approximately as follows:

Labor	127%
Fuel	115%
Mill overhead	110%
Packing and loading	167%
General expense	49%
Care of empty sacks	62%

Quoting further from their statement, the increase on certain classes of skilled labor ran as high as 146 per cent.

In comparison with other commodities used in construction work, we find that there have been the following increases:

Gravel	36.40%
Sand	56.25%
Crushed rock	50.00%
Brick	23.10%
Lumber	70.50%
Labor	100.00%
Teams	60.00%

These figures were obtained from records in the engineer's office of the City of Duluth.

In this regard we quote from bulletin of Mar. 4, 1919, issued by the United States Department of Labor Information and Educational Service, as follows:

"At the close of the war the index number of building materials, not including steel, had risen only 61% over the pre-war prices of 1913, while the index number for commodities, exclusive of building materials, have risen 113%. The average increase of wages in the construction industrial in 41 leading cities from 1914 to 1918 was only 28.5%, as against the rise of 94% in commodities."

From the foregoing data it would appear that the increased price of cement has not been proportionately greater than the average increase on other building materials.

Your committee with the time allotted has not attempted to go into a study or investigation of the cost of cement production. Furthermore, we do not believe that a production cost can be determined during the present chaotic industrial conditions without the full coöperation of the manufacturers. Likewise, we do not believe this society is in position to delve into the trade secrets of any business organization so long as there are other means for such investigation.

If the club decide to investigate further into the cost of production, we would respectfully recommend that they refer the matter for full investigation to the United States Department of Labor who are investigating the various conditions that would enter into a revival of the building activities.

Erie Mill Creek Work to Proceed

Active prosecution of the Mill Creek flood-protection work at Erie, Penn., where a concrete conduit is being built to carry the flow of the creek through the city, is about to be started. A report on the urgency of resuming construction was made last week by the superintendent of streets. The approval of the mayor and of civic bodies supported the proposal, and the City Council voted to carry the project through at once. A bond issue of $600,000 is needed to complete the work, which, with a balance of $400,000, should suffice to carry the project through. At present the conduit is completed to 19th St.; the work to be undertaken comprises two contract sections, one extending north from 19th St. to 9th St., and the other thence north to the Pittsburgh & Erie culvert.

New Secretary for Federal Trade Commission

Following the recent resignation of Leonidas L. Bracken, who has left the Federal Trade Commission to resume the practice of law, J. P. Yoder was appointed secretary. Mr. Yoder left the commission in February, 1918, being commissioned a captain in the Army Sanitary Corps. He has recently returned from service in France.

Prior to his former connection with the commission, Mr. Yoder was manager of the Washington bureau of one of the large press associations.

Research Council Gets Funds

The Rockefeller Foundation is to appropriate $500,000 to promote fundamental research in physics and chemistry, the money to be used to support research fellowships over a period of five years and to be administered by the National Research Council. It has announced that the board named by the council to control the work consists of H. A. Bumstead, Simon Flexner, G. E. Hale, E. P. Kohler, R. A. McMillikan, A. A. Noyes and W. D. Bancroft.

Platform Collapses at Ship Launching

At least four men were killed in an accident that marred the launching of the steel vessel "Waukau" at the yard of the Merchant Shipbuilding Corporation, Harriman, Penn., Mar. 31. Workmen crowded on a patrol walk passing behind the stern of the ship next to the "Waukau," and a few minutes before the launching the walk broke down, throwing a score or more of persons into the water.

Hearing on Engineers' Pay

(*Concluded from page* 742)

Willard Beahan, chairman of the conference, spoke on the increased cost of living, which he estimated to be fully 50%, while the engineer's salary in his opinion had not advanced more than 30%, but from a point long out of line with normal increases. Then for two days W. C. Bolin, chairman of the subcommittee which gathered the data for the original schedule, presented the concrete case for those positions which the board considered within its jurisdiction: Tapeman, rodman, instrumentman, tracer, junior draftsman, draftsman, leading draftsman or designer and engineer inspectors. Higher positions having supervisory duties are handled by the regional directors. As a matter of record, however, the board asked that the whole schedule be filed. Into the record was read part of the article on "Pay and Position of Engineers in Railway Service," by C. W. Baker, in *Engineering News-Record* of Jan. 30, 1919, p. 228, and also the calculation of the cost of an engineering education, with the deduction that an engineer should receive at least $75 per month more than a skilled mechanic in order to produce and educate for the world's service another engineer.

Normally, the board will require 60 days to investigate the question and get in reports from the regional directors, after which it will take 30 days in which to prepare a report. It may be said that the board seemed to listen to the pleas with friendly interest.

Oregon Reclamation Bills Go To Referendum Vote

Subject to referendum approval, the Oregon legislature has passed a number of bills providing for or facilitating irrigation and other reclamation work. Some $2,000,000 for reclamation and $500,000 for land settlement are included. It is hoped that the reclamation fund will be spent in coöperation with the Federal Government on a dollar-for-dollar basis. One of the measures submitted to popular approval is a constitutional amendment providing for a state guarantee of irrigation and district bonds for five years after the date of issue. Various amendments to the irrigation and drainage district laws are included in the program. The drainage district law is made to conform more closely than before to the irrigation-district law. P. A. Cupper, Salem, is state engineer of Oregon.

Bequests to Terre Haute and to Rose Polytechnic Institute

A trust fund of $100,000 to improve the sewerage system of Terre Haute, Ind., and a gift of $100,000 to buy land for a city park are among the bequests of the late William S. Rea, a wholesale grocer of Terre Haute. To Rose Polytechnic Institute, Terre Haute, $100,000 was given besides a trust fund of $50,000 to afford aid to worthy students.

One-Third Engineer Officers Discharged

On Mar. 20, 1919, 31% of the engineer officers in the United States Army had been discharged. The total number of engineer officers on Nov. 11, 1918, was 10,302. Of these 3,244 are now out of the service. The corresponding figures for other branches of the service are as follows:

Branch	On Duty Nov. 11	Discharged Nov. 11-Mar. 20	Percentage Discharged
Ordnance	5,925	2,811	47
Quartermaster	10,122	4,626	46
Infantry	85,373	39,126	46

Civil Service Examinations

For United States Civil Service examinations listed below, apply to United States Civil Service Commission, Washington, D. C., or to any local office of the commission, for form 1312.

United States.—Engineer-draftsman, Apr. 22, $1500 to $1800 per year. File Application before Apr. 22.

United States.—Transitman, $100 to $125 per month, and surveyor, $125 to $200 per month, Apr. 23-24. File applications in time to arrange for examination at place selected by applicant.

United States.—Expert patent investigator, $1800 to $2400 per year, and technical patent expert, $2400 to $3600 per year, May 20.

United States.—Assistant material engineer, Bureau of Construction and Repair, from $4.48 to $6.40 and upwards per diem. No date specified. Applications should be filed without delay.

United States.—Statistician, Department of Interior, $1800 per year, May 13. Apply for Form 2118.

United States.—Junior recreational engineer, Forest Service, Denver, Colo., $1800 to $2400 per year, May 6. Apply for Form 2118.

United States.—Chief of road survey party, $1800 to $2100 per year, transitman for road surveys, $1200 to $1800 per year, highway draftsman, $1200 to $1800 per year, Bureau of Public Roads and Rural Engineering, May 29. File applications before May 29.

United States.—Highway bridge engineer, $1800 to $2100 per year, junior highway bridge engineer, $1200 to $1600 per year, Bureau of Public Roads and Rural Engineering, May 21. File applications in time to arrange for examination at place selected by applicant.

Calendar

Annual Meetings

NATIONAL FIRE PROTECTION ASSOCIATION; 87 Milk St., Boston, Mass.; May 6-8, Ottawa, Can.

AMERICAN ASSOCIATION OF ENGINEERS, 29 S. LaSalle St., Chicago; May 13-14, Chicago.

AMERICAN WATER-WORKS ASSOCIATION; 47 State St., Troy, N. Y.; June 10-14, Buffalo, N. Y.

AMERICAN SOCIETY OF CIVIL ENGINEERS; 29 W. 39th St., New York; June 17-20, St. Paul-Minneapolis.

AMERICAN SOCIETY FOR TESTING MATERIALS; University of Pennsylvania, Philadelphia; June 24-27, Atlantic City, N. J.

AMERICAN CONCRETE INSTITUTE; 27 School St., Boston, Mass.; June 27-28, Atlantic City, N. J.

Engineering Societies

The Colorado Association of Members of the American Society of Civil Engineers and the Denver Section of the American Institute of Electrical Engineers held a joint meeting at the Denver Athletic Club, Apr. 9, in honor of Lieut.-Col. H. S. Crocker, supervisor of the work on the Army supply base at Brooklyn, N. Y. The work on the base was described by Colonel Crocker, who illustrated his address with lantern slides.

The Brooklyn Engineers' Club will hold a meeting Apr. 10 at which Maj. Robert Starr Allyn, U. S. A., will read a paper on "Artillery Preparation and Service with the 57th Regiment, C. A. C., near Verdun."

The Montreal Branch of The Engineering Institute of Canada will be addressed, at the meeting Apr. 17 by Phelps Johnson, G. H. Duggan and George F. Porter, who will speak on the Quebec Bridge.

The Engineers' Club of Philadelphia will be addressed by Morris L. Cooke on "The Participation of Engineers in Public Affairs," at the weekly luncheon Apr. 15.

The American Society of Civil Engineers, the American Society of Mechanical Engineers, the American Institute of Electrical Engineers, the American Chemical Society, the Pacific Northwest Society of Engineers, the American Institute of Mining Engineers, and the Associated Engineering Societies of Seattle were represented at a joint meeting held in Seattle Mar. 27 at which Calvin W. Rice discussed problems which engineers face in matters of society organization. After the talks by Mr. Rice and by representatives of each of the societies, there was a general discussion of the best plan for carrying out further organization of engineering societies in Seattle, to the end that centralization and closer coöperation might be secured.

The Engineers' Club of San Francisco at a dinner Apr. 3 had as a guest of honor Dr. W. F. Durand, who told of his personal experiences in France. Dr. Durand's headquarters were in Paris.

The New York Chapter of the American Association of Engineers will be

addressed at the meeting of Apr. 10 by Maj. C. R. Hulsart, Corps of Engineers, American Expeditionary Forces, who will speak on "The Engineers on the Hindenburg Line."

The Rochester (N. Y.) Society of Technical Draftsmen will be addressed Apr. 24 by Allan S. Crocker on "Power Plants," with particular reference to layouts, fuel saving, machine valuation and power-plant inventory assessment.

The Indiana Sanitary and Water Supply Association's annual meeting to be held in Indianapolis Apr. 9 and 10, as mentioned in these pages last week, will include the reading of papers on finance, rates, legislation, wells, water treatment, fire prevention, meters and war experiences. As a new law requires a regular analysis of waters offered for sale in Indiana, a model laboratory is to be exhibited. The United States Public Health Service has detailed one of its traveling laboratories to assist in creating interest in water purification and regularity of analysis.

The Western Society of Engineers held a meeting Mar. 31, devoted to a discussion of public affairs, to which members of all technical societies in Chicago were invited. First-hand information from the engineers' standpoint was presented on the state constitutional convention, deep waterways, better city administration, city planning, housing and zoning, proposed legislation on the Public Utilities Commission, licensing of engineers, and good roads. The discussion was led by James J. Barbour, state senator; B. H. Peck, electrical engineer, Public Utilities Commission of Illinois, and Douglas Southerland, secretary of the Civic Federation.

The Iowa Section of the American Water-Works Association will hold its fourth annual meeting at the State University of Iowa, Iowa City, Apr. 16-17. J. H. Dunlap, of the State University, is acting secretary-treasurer of the section.

The Washington Chapter of the American Association of Engineers has elected the following officers: President, Harry Stevens; vice-presidents, A. Y. Ross and Clegge Thomas; secretary, E. L. Howard, Bureau of Yards and Docks, Navy Department; treasurer, O. M. Sutherland.

The Kansas City Chapter of the American Association of Engineers has elected the following officers: Chairman, J. E. Jacoby; vice-chairman, W. B. Cost; secretary, C. N. Clarke, and treasurer, S. M. Bate.

The Detroit Engineering Society was addressed Apr. 4 by William B. Stout, chief engineer, United Aircraft Engineering Corporation, New York, who spoke on the "Commercialization of Aircraft," discussing various types of machines for different service, air routes of travel, wireless control, and the necessity for municipal air harbors. The annual meeting of the society will be held Apr. 19.

Personal Notes

COL. PETER JUNKERSFELD, who recently received his discharge from the Army, has resigned his position as assistant to the vice-president of the Commonwealth Edison Co., Chicago, to become engineering manager for Stone & Webster, with office in Boston, Mass. He has been with the former company and its predecessors for over 23 years, beginning as assistant to the mechanical engineer and rising to be electrical engineer and finally assistant to the vice-president, who is in charge of the operating, contract, construction and electrical departments. As a reserve major he was called into service in June, 1917, and in a few months was assigned to the Cantonment Division, which later became the Construction Division of the Army. He received his commission as colonel a few months later. A portrait and a brief biography of Colonel Junkersfeld were published in *Engineering News-Record* of Jan. 23, 1919, pp. 208 and 209.

MAJ. F. P. ADAMS, city engineer of Chatham, Ont., who went overseas with the 186th Battalion, has returned to Canada and resumed his duties.

W. W. HUFF, who recently left the Army service, has opened an office as consulting civil engineer at 605 Gumbel Building, Kansas City, Mo. Mr. Huff was constructing quartermaster in the Construction Division of the Army and was stationed at several points on the Atlantic coast. Before enlisting in the Army he was engaged in practice as consulting structural engineer.

GRUPE & WALTERS will open offices at 204 Bee Building, Omaha, Neb., as consulting engineers in paving, sewers, water-works, electric-light plants, municipal ice plants and heating layouts. Mr. Grupe has been engineer in charge of work at Florence Field, Omaha, Neb.

MAJ. JAMES MCGREGOR, of Halifax, N. S., resident engineer of the Halifax Ocean Terminals, has returned after two years' service in the 3rd Battalion of Canadian railway troops.

C. S. OGILVIE, formerly assistant engineer of the Grand Trunk Ry., at Belleville, Ont., who enlisted with the 13th Royal Highlanders and was a prisoner in Germany for over three years, has been appointed assistant engineer for the Ottawa division, Grand Trunk Ry, in succession to H. Mowat.

A. A. SCHENCK, engineer of maintenance, western lines of the Chicago & Northwestern R.R., with headquarters in Omaha, Neb., was recently appointed assistant to the chief engineer, with jurisdiction over the lines west of the Missouri River. His offices are in Omaha.

A. J. TURNER, consulting engineer, Seattle, has been appointed engineer of the Columbia Basin Commission, to take full charge of the preliminary survey which the commission is to make before the actual work of reclamation is undertaken.

RUDOLPH E. LEE, T. A. MACEWAN and A. R. TURNBULL have become associated under the firm name of Lee, MacEwan and Turnbull, architects and engineers, Charlotte, N. C.

I. F. STERN, who since February, 1918, served with the United States Shipping Board, Emergency Fleet Corporation, as consulting engineer in the Division of Wood Ship Construction, has resigned from the service and reopened his office in the Old Colony Building, Chicago, for private practice.

R. S. BONSIB, formerly in the service of the United States Shipping Board, Emergency Fleet Corporation, has been appointed chief of the Division of Safety Engineering of the Working Conditions Service, Department of Labor.

GUSTAV RASMUS, consulting engineer, Denver, has been appointed chief of the Industrial Bureau of that city, succeeding George A. Levy, resigned.

J. B. LIPPINCOTT has returned to Los Angeles and has opened offices in the Central Building for the practice of engineering, after having been in Government service in charge of the Housing Corporation's work at Neville Island, Pittsburgh. Associated with Mr. Lippincott will be Kenneth Q. Volk and E. A. Rowe, recently discharged from the Construction Division of the Army, where they held commissions as first lieutenants.

CAPT. S. J. GARGES, Construction Division, U. S. A., construction officer, Elizabethport Proving Grounds, has received his discharge from the service and has become associated with the Franklin Contracting Co., New York City.

R. M. HUBBARD has been appointed chairman of the Texas State Highway Commission, succeeding Curtis Hancock, resigned, as noted elsewhere.

THOMAS F. GIBSON, advisory engineer in charge of reinforced-concrete construction for the Construction Division, U. S. A., has received his discharge from the service and has returned to the employ of the Corrugated Bar Co., Buffalo, as district engineer, with headquarters in Kansas City, Mo.

CURTIS HANCOCK, chairman, Texas State Highway Commission, has resigned and will devote his entire time to private business.

JAMES POSEY, consulting engineer, Baltimore, who has been engaged in war work, has reopened offices in

the Fidelity Building, with branches in New York and Washington. Associated with him is George W. Gail, Jr.

C. V. HANSEN, chief engineer, St. John Levee and Drainage District of Missouri, has been appointed highway engineer of New Madrid County.

WILLIS E. AYRES and GARNER W. MILLER have become associated under the firm name of Ayres & Miller, consulting engineers, Memphis, Tenn., specializing in road, drainage and flood-protection work.

CAPT. CHARLES B. SPENCER, Ordnance Department, U. S. A., who recently arrived from France, has received his discharge from the service and has returned to his work with the Underpinning & Foundation Co., New York City.

ELMER O. FIPPIN, professor of soil technology, Cornell University, is to become director of the Agricultural Bureau of the Lime Association at the close of the present collegiate year.

DAVID A. SEALEY, assistant engineer with the Public Service Commission, New York City, and for the past six years engineering assistant to the engineer of subway construction, has resigned from the organization and has joined the staff of the Truscon Steel Co., Youngstown, Ohio.

N. A. GILMAN has resigned as city engineer of Yakima, Wash.

H. A. SEWELL, HANS STRAALSUND and C. W. STRAIGHT have formed the Interstate Engineering & Construction Co. at Newport, Wash., to specialize in timber and reinforced-concrete structures.

A. K. GAULT has been appointed division engineer of the eastern division of the western lines of the Chicago & Northwestern R.R. and the Missouri Valley & Blair Bridge, with headquarters in Omaha, Neb.

WALTER SHEPARD, consulting engineer of the Boston & Albany R.R., with headquarters in Boston, on Mar. 1 was retired under the pension rules of the company. He served 44 years in the engineering department of the railroad. Mr. Shepard was born Mar. 1, 1849, at Dorchester, Mass., and was graduated in 1870 from Harvard University and in 1872 from the Massachusetts Institute of Technology. In June, 1872, he began his railway work with the Boston & Albany R.R. as an engineer's assistant. For a few years he was out of railway work, until in March, 1875, he returned to the service of the road. In April, 1882, he became division engineer, and in December, 1886, was promoted to the position of assistant chief engineer. From November, 1891, until May, 1908, he served as chief engineer of the road, and since that time he has been consulting engineer.

ORLANDO H. FRICK recently became district engineer of the middle district of the Chicago, Milwaukee & St. Paul R.R., with headquarters in Milwaukee.

M. K. BARNUM, assistant to the general superintendent, maintenance of equipment, Baltimore & Ohio R.R., with office in Baltimore, has been appointed mechanical engineer for the corporation.

HAROLD R. MILES, assistant engineer on the Canadian Pacific Ry., with headquarters in Montreal, has been promoted to division engineer with headquarters at Winnipeg. Mr. Miles was born at Lethbridge, Alberta, in 1879, and entered railway service in March, 1899, with the Washington County Railway Co. in Maine. The following year he was employed by the Algoma Central on location work and in 1901 he entered the service of the Canadian Pacific as assistant engineer on maintenance, with headquarters at North Bay, Ont. Later he became resident engineer of maintenance on the Lake Superior division, remaining there until July 1, 1915, when he was transferred to Montreal as assistant engineer. More recently he has been division engineer, with headquarters at Lethbridge.

W. S. GEARHART has resigned as state highway engineer of Kansas. Captain Gearhart went to Kansas from the Illinois Highway Department and established a similar department at the Kansas Agricultural College. When the Kansas State Highway Commission was created, Mr. Gearhart became state highway engineer. Last year he received a leave of absence from the state service to enter the Army engineer corps.

W. T. MAIN has been appointed division engineer of the Black Hills division of the Chicago & Northwestern R.R. and the Wyoming & Northwestern R.R., with headquarters at Chadron, Neb.

H. K. YORSTON, until recently division engineer of the Canadian Pacific Ry. at Winnipeg, has been appointed locating engineer of the Canadian Pacific, Western Lines. He is succeeded at Winnipeg by Harold R. Miles, as noted elsewhere.

OBITUARY

ALLEN T. FRASER, of Winnipeg, chief engineer of the Canadian National Rys., was killed by a snowslide near Mount Robson in the Yellow Head Pass through the Rocky Mountains, Mar. 31. The train on which Mr. Fraser was proceeding west was stopped by the slide. Mr. Fraser and a section crew went to make an examination when another mass of snow and rock came down, burying the party. The section hands were dug out alive, but badly injured. Mr. Fraser was 46 years of age and had been in the service of the Canadian Northern Ry. for many years. He was formerly district engineer of that line, at Edmonton, but in January last was promoted to the position of chief engineer of the western division with headquarters at Winnipeg.

GEORGE H. GARDEN, formerly resident in Montreal, died recently at Rouses Point, N. Y., aged 70. He was born at Woodstock, N. B., and had been all his life engaged in engineering. At the age of 20 he was appointed assistant engineer on the location of the Intercolonial Ry. and was subsequently in charge of part of the location on the Crow's Nest Pass division of the Canadian Pacific Ry. Mr. Garden afterward became chief engineer of the Alberta Ry. & Coal Co. at Lethbridge, Alta., leaving that position in 1901 to practice his profession in the East. He retired in 1914, his last work being the location of a large section of the Canadian Pacific Ry. Montreal-Toronto (lake shore) line. Mr. Garden was a member of the Engineering Club of Montreal and the Engineering Institute of Canada.

A. C. WALKER, civil engineer of Blacksburg, Va., died in that city Mar. 21 at the age of 69. A large part of Mr. Walker's life was spent in railroad location work, among which was that of the Carlisle, Clinchfield & Ohio R.R. line across the Blue Ridge Mountains. He was educated at the United States Military Academy.

OWEN BRAINARD, consulting engineer and architect, New York, died in that city Apr. 2. He was 54 years old. After attending public and private schools, he engaged in machine-shop work for two years at Haddam, Conn., and Philadelphia, and in 1887 became associated with his father in the construction of buildings and general contracting in Middlesex County, Connecticut. Continuing in contracting and architectural work, he became general superintendent and manager of the firm of Carrere & Hastings, architects, New York City, of which he became a member in 1901. In 1907 Mr. Brainard opened his own offices as a consulting engineer and architect in New York City. During his association with Carrere & Hastings he had assisted in the design of the New York Public Library, the Senate and House office buildings in Washington, the extension of the United States Capitol, and the Yale memorial buildings. His later work has been the design of the New Theater, New York City, now the Century, and the industrial villages of the United States Steel Corporation.

J. E. JOHNSON, JR., mining and consulting engineer, New York City, died Apr. 4 as the result of an automobile accident. He was a director of the American Institute of Mining and Metallurgical Engineers.

National Foreign Trade Convention To Be Held in Chicago

Announcement has been made of the sixth National Foreign Trade Convention, which will be held in Chicago Apr. 24-26, inclusive. The session Apr. 24 will deal with America's need of foreign trade, while that on the 26th will be devoted to a discussion of the American merchant marine. A variety of subjects connected with the post-war problems of foreign trade will be presented Apr. 25. Among the subjects and speakers will be: "America's Financial Equipment for Foreign Trade," by Fred I. Kent, vice-president of the Bankers' Trust Co.; "The Interest of Labor in Foreign Trade," by Hugh Frayne of the War Industries Board; "The Element of Labor Costs in American Exports," by William Pigott, president of the Seattle Car & Foundry Co.; "The Effect of Increased Productive Capacity Upon Our Foreign Trade," by Edward Prizer, president of the Vacuum Oil Co., and "The Future of Our Foreign Trade," by Edward N. Hurley, chairman of the United States Shipping Board.

Other speakers will be William S. Culbertson, of the Tariff Commission; John M. Parker, president of the Mississippi Valley Association; J. W. Hook, president of the Allied Machinery Co., of New York; James A. Farrell, chairman of the National Foreign Trade Council, and Breckinridge Long, third assistant secretary of state.

Present Claims on Cancelled War Contracts by May 15

Benedict Crowell, assistant secretary of war, has given notice that contractors desiring to adjust cancelled war contracts through the machinery set up by the War Department must present their claims prior to May 15. He stated that nearly half the claims involved had not yet been formally presented. The inconvenience caused by this delay was stated by Mr. Crowell as follows:

"This failure on the part of contractors is occasioning the department embarrassment. The organization which is handling this matter is essentially civilian in character and composed of men who remain in this work only at a very great sacrifice and at the urgent request of the department. I do not feel that I can continue indefinitely to impose that hardship, and have determined that all contractors who desire to avail themselves of the existing organization for the settlement of their claims must present them prior to May 15, 1919."

Cement Price Is Lowered Throughout Country

There has been a general decline in the price of cement, amounting to from 5c. to 15c. net, 65c. to 75c. gross. The charge for sacks has been decreased 40c., or from $1 per bbl. to 60c. A statement of the situation is to be issued by the cement manufacturers Apr. 10.

Ditcher Arranged to Cut Close to Obstructions

A new mechanical ditcher, designed to cut trenches close to buildings, curbs, pole lines and other obstructions, has been designed by the Pawling & Harnischfeger Co. The machine, which is shown in the accompanying illustration, has corduroy grip tractions, and will cut a trench from 15 to 24 in. wide to a maximum depth of four feet.

Three changes of speed are made available by sliding gears without changing sprockets, so that quick changes can be made to suit the character of the material being excavated. By means of two sizes of chain sprockets a total of six speeds can be obtained, ranging in geometrical progression from about 1.5 to 5 ft. per minute.

DITCHER IN OPERATION NEAR WALL

Although the standard width of cut is 15 in., adjustable side clearance cutters enable the machine to dig 24 in. The corduroy grip tractions are of unequal width, a 19-in. width being used under the cutting side to take up the extra weight, while 15-in. width is used on the other side. Power is furnished by a 25-hp., four-cylinder vertical engine of the tractor type, arranged for burning kerosene, gasoline, or motor spirits. The various dimensions are: Width over all, 10 ft. 7 in.; length over all, 25 ft. 9 in.; height 9 ft. 7½ in.; total weight 19,500 pounds.

Business Notes

The Allied Machinery Co. of America announces the removal of its main offices in New York to 51 Chambers St., where it will occupy the entire eighth floor. This company is a subsidiary of the American International Corporation.

The Chicago Pneumatic Tool Co. announces the discontinuance of its office at Wichita, Kan., and the establishment of an office and warehouse at Eldorado, Kan. A new office has also been opened at Tulsa, Okla., at 313 Richards Building, with warehouses at 102 North Cheyenne St. It is thought that this arrangement will better serve the territories concerned.

The American International Steel Corporation announces that Lieut. Col. Merrill G. Baker has been appointed president of the company, effective Apr. 1, 1919. Colonel Baker was formerly assistant general manager of sales for the Cambria Steel Co., but has been in the Ordnance Department since shortly after America entered the war. He succeeds the late Edward M. Hager, who died over a year ago, since which time Morris Metcalf, vice-president, has been in charge of the business. Mr. Metcalf will remain in his old position. The American International Steel Corporation is a subsidiary of the American International Corporation and is engaged in the exportation of steel products and railway equipment.

The Bucyrus Co. has opened offices in Minneapolis, from which point it is intended to serve the Northwest district to and including Nebraska.

The Ideal Engine Co., of Lansing, Mich., manufacturer of power equipment, announces that it has added H. H. Lucas to its sales force. Before joining the United States Navy, Mr. Lucas was with the Lansing Co. Mr. Lucas will take up his duties early in April, after his discharge from service.

Trade Publications

"Checking Thermocouple Pyrometers" is the subject of bulletin No. 867-B, issued by the Leeds & Northrup Co., Philadelphia, Penn. This is an 8 x 10½-in. 23-p. pamphlet covering heat-measuring apparatus and is illustrated with half tones and line cuts.

The Quigley Furnace Specialties Co., 26 Cortlandt St., New York, N. Y., has issued bulletin No. 11, covering the preparation, distribution, and burning of powdered fuel, using the company's air transport system. The bulletin is 8½ x 11 in.; has 15 pages, and is profusely illustrated.

The Page Steel & Wire Co., of 30 Church St., New York City, has just issued a 4 x 6½-in., 60-pp. pamphlet, which deals with Armco iron rods and wire for oxyacetylene and electric welding.

"Absolute Permissive Block-System Circuits" is the title of a new bulletin issued by the General Railway Signal Co., of Rochester, N. Y. The booklet consists of 16 pp. 6 x 9 in. in size, and is illustrated with half tones of signaling apparatus. It contains an insert of seven pages of block-system circuits.

Volume 82 NEW YORK, THURSDAY, APRIL 17, 1919 Number 16

Modern Methods Applied To Group House Building

BUILDING a dwelling or a series of dwellings was raised during the war from a mechanic's job to an engineering operation. The designs for the numerous towns for the war workers involved little that was new. But the construction, turned over to contractors accustomed to handling large projects, was rushed through with methods and economies unknown in house building heretofore. Some of these methods are well illustrated in the article on another page describing the Cradock development. The effectiveness of machinery in place of men for such work cannot be questioned, although relative cost figures are not here available. Particularly to be noted for use where small amounts of concrete have to be placed over a large area is the system of central concrete mixing with distribution in tractor-drawn carts.

Governmental Buying of Construction Material

CLAUSES in contracts providing for the purchase and delivery to highway contractors of all materials, thus relieving them of the hazard of price changes, have had many advocates in the past, particularly during the war. Such a plan, operated in Outagamie County, Wisconsin, was described in *Engineering News-Record* of Feb. 6, 1919, p. 289. The advantages of this procedure to the contractor are obvious. Besides the relief from the risks already referred to, there is released for use that part of the contractors' capital usually tied up in delivered materials. Responsibility for quality also rests with those who let the contracts, and, where large amounts of work are under way, the authorities, by controlling shipments and changing routings on the indications of daily reports, can deliver the right amount of material at all times, thus eliminating delays and demurrage charges. The advantages to the state or county may not be so apparent, but the adoption of the custom would no doubt reduce the cost of the finished road. An added incentive at the present time lies in the fact that lower freight rates are offered by the Railroad Administration on materials bought by Federal, state, county, municipal and township governments. Considering these conditions, it would appear that now is a good time to try the system of Governmental buying.

Engineering Council and the Nonmember Societies

WHAT relations should the Engineering Council have with the national, state and local engineering societies which are not represented in it? It is announced that the delegates from engineering societies who have been invited by the council to meet in Chicago April 23-25 to confer on plans for a Federal Department of Public Works will, on the third day of the conference, have an opportunity to discuss the above question. At present the council has 25 members, representing the national societies of civil, mining, mechanical, electrical and testing engineers. The combined membership of these five societies is about 40,000, or an everage of 1600 members per representative. It will be necessary to take into consideration these facts, in discussing any plans for direct representation of the smaller societies on the council. What is needed is confidence on the part of engineers that the council is endeavoring to act for the interest of the engineering profession as a whole and not merely for the more successful and conservative portion of the profession which is active in the national societies. Unless the council is sympathetic with all classes of the profession and all sections of the country, its mission is bound to be relatively narrow. Such recent acts of the council as the broad invitation to all engineering societies to join in the movement for a public-works department, and this frank request for practical suggestions as to how the council may coöperate with all engineering organizations, will in themselves help to increase the needed confidence.

Navigation Improvement Under the Ohio Conservancy Law

A NEW application of the Ohio conservancy law, proposed by the city and county authorities of Cleveland, is under court test. Straightening of the Cuyahoga River where it winds along the bottom of its valley through the city is urgently necessary for the general commercial benefit of the city; it will improve navigation and thereby make dock property more accessible, will give far better utilization of the bottom lands for commercial purposes, will simplify railroad and freight distribution problems, will facilitate bridge and viaduct construction across river and valley, and, incidentally, will do something in the way of reducing the liability of floods in the bottoms. This is a new field of service for the conservancy law, which was drafted in the interests of flood protection as needed on the Miami and Scioto Rivers. However, the wording of the law specifically makes it applicable to broader purposes, and unless unforeseen objections are encountered the court may well find in its favor and decree the organization of a district. The fact is that river straightening at Cleveland is beset by many difficulties from the administrative viewpoint, and assessment of the costs upon the property directly benefited seems the only logical way to deal with the work on a justifiable basis of expenditure. There are unquestionably, many and sound objections to the creation of local improvement districts of this

character. Administered under the Ohio law, they are controlled without proportionate representation of the population assessed for the improvement. Objections of this character are sure to receive proper consideration in the court hearing, and the decision, by showing whether they prevail over the advantages obtainable in the Cleveland case, will represent a measurable advance in the processes of handling large public enterprises along rivers.

One Township Employs Effective Road Publicity

TOWNSHIP highway work is often not appreciated for lack of proper publicity. If the officials make reports they are pigeonholed and forgotten unless brought out only as a matter of political expediency. It is all the more refreshing, therefore, to receive the eight-page report of the highway commissioner, H. H. Sherer, of New Trier township, just north of Chicago. Everything is noted, from the formation of an advisory board (made up of two lawyers, two architects, a banker, an engineer and a drainage expert) to the daily cost sheet of road-drainage work. The report shows what the budget taught, what was the necessity of developing a nearby gravel pit for repair work in place of the ordinarily used but more expensive crushed stone, how the road drag at $7.50 per day replaced a grader at $15 and was found to be the tool really needed because of excessive crowning, how a patrol system was established, and how the prospective ditch work uncovered the fact that surveys and dedicatory plats for many of the traveled roads did not exist. A map showing all the roads and drainage work done is included in the report, which was printed and sent to every citizen. Only $18,348 was spent, but if every township would make as good an account of its expenditures, there would be less criticism because of the millions wasted by local authorities.

Narrow-Gage Railways Proposed in England

NARROW-GAGE railways in this country are relics of the past, but in England the exigencies of war and reconstruction are forcing them into engineering notice. Improved transportation is held there to be one of the immediate necessities. Strange as it may seem to an American, there are still many productive areas in England, isolated from the centers of consumption, which must be tied into the transportation net of the country if immediately increased production is to be realized. In France, and ready to go to France, when the war ended, was material for hundreds of miles of the light railways which had been developed so effectively in the zone of communications. These, it is urged, can now be put down in the remote districts of England by the experts who built similar ones in France, without the complicated legal and parliamentary procedure required to put through a standard-gage line and at much lower first cost and operating expense than either main-line railways or highways. The recrudescence of the almost forgotten narrow-gage will be watched with all the more interest now, on account of the growing claims of the highway and motor truck as a freight feeder. In this country the tendency has clearly been toward a larger and more effective use of highway transportation. Its recommendation is the very great flexibility of its vehicle—the motor car or the motor truck—and that advantage will be the great one against which the narrow-gage will have to contend if it is to receive attention.

Making Geological Survey Maps More Popular

STUDIES looking to the popularization of Geological Survey maps are being made by the cartographers of the survey in order that persons who are unable to read contour maps may find at least some of the future sheets issued by this bureau of service to them. It has been found that by shading contour maps the topography can be shown so clearly that even bright boys are able to read them readily. The studies now in progress are for the purpose of determining the best method of shading. The use of hachures involves so much time and requires so much highly skilled drafting and engraving to produce really satisfactory results that it is not available for such work. Attention is, therefore, being focused on tinting as a means of portraying the relief, and some very encouraging results have been obtained. The relative elevations of flat surfaces are indicated by flat tints, darkest for the lowest plains, while the hills and mountains are shaded in accordance with the shadows which would exist when the light comes from a direction somewhat north of west. The time spent in surveying a region like the Yellowstone or Yosemite Park and preparing the standard contour maps from the results of these surveys is considerable, and if a little more time spent in tinting the maps will make them useful to the general public, which demands large numbers of maps of our scenic districts, a useful public service will be rendered.

A Gasoline Tax On Motor Vehicles

HIGHWAY engineers are repeatedly raising the question as to the method by which motor trucks shall be made to pay a just share of the cost of building and maintaining highways. Comparison is often made with the economics of railway transportation, in which the shipper bears not merely the cost of operating the moving equipment but also a proper share of the cost of constructing and maintaining the track. In various states an attempt is made, by a graduation of motor fees, to charge back to the motor-truck user a proper proportion of the wear that the transportation of his goods causes to the pavement. Necessarily, these fees cannot be directly proportional to the use made of the road. Of two trucks of the same weight and capacity, paying the same yearly motor-vehicle tax, one may average only five miles a day and the other 30, the latter obviously causing six times as much wear on the highway as the less-used truck. To secure an equitable method of charging, it has been proposed to levy a tax on the gasoline consumed by motor vehicles. While there is some variation in fuel consumption between different makes of vehicles having the same carrying capacity, it is in general true that the fuel consumption is in direct proportion to the load and speed. At least, it is a closer measure of highway wear than anything we have found to date. Obviously, objections can be found to any form of tax. One of the apparent weaknesses of the gasoline tax is that a given capacity of vehicle carrying a certain load will produce more serious damage with hard-rubber tires than with pneumatic tires, and, again, still more serious damage if steel tires are

used. This difficulty for the present is a relatively negligible factor. In other words, practically all of the motor-truck traffic today is carried upon solid-rubber tires. If, in the future, the pneumatic tire becomes the standard for motor trucks of large capacity, some modification of the tax may be necessary, but, all things considered, the gasoline tax has much to commend it.

Danger Ahead for American Society for Testing Materials

IN THE establishment of a new organization to deal with shape and quality standards of constructional materials, discussed in these columns last week, the American Society for Testing Materials has an intensely personal interest. For other societies, as the Civil Engineers, the Engineering Standards Committee movement is only a minor incident. For the American Society for Testing Materials it is a life-and-death matter.

No development in technical society life during the past twenty years is more noteworthy than the rise and fruitful service of the American Society for Testing Materials. Steadily and in purposeful manner it has worked for efficiency, improved quality and economy in the production of engineering materials, through the study of tests and the drafting of standard acceptance specifications. Its future has seemed as bright as its past. The society's vitality was rooted in its serious purpose, its independence, and the authority which it acquired by virtue of the strong working spirit and conscientious coöperation of its members. When it becomes a secondary organization, subordinate in both initiative and achievement, as it must under the working plans of the Engineering Standards Committee, the wellsprings of this vitality would inevitably be dried. The society could no longer hope to be a center of such spontaneous energy and enthusiasm as its members have hitherto brought to its work.

To the members of the society as well as to that large circle of technical and industrial men outside the society who have been aided by its work, the situation now existing is, we believe, of immediate and most urgent concern. The profound loss which would be suffered through paralysis and decay of the society can hardly be made up or overbalanced by gains through the activities of the Engineering Standards Committee. Members of the society, and especially participants in its committee work, will never believe that the society's methods can successfully be duplicated by a far-away mechanism of nontechnical direction, such as is now to be set into action.

The governing body of the society has participated in the Engineering Standards Committee movement from the outset, and the society is at present represented upon that committee. Doubtless those who direct the society's policy have believed that its position of supremacy in the field of quality specifications would not be harmed by a coöperative agreement with other societies. But can supremacy and subordination be brought into harmony? Can the society's position of unquestioned authority in the field of materials, won through the most sincere and conscientious labors, be retained if that final authority is yielded up to another body? We believe that it can be neither retained nor transferred, but will be lost.

It is a noteworthy fact that the man who more than others had inspired the spirit and created the methods of the society, the late Prof. Edgar Marburg, was very apprehensive of the influence of the Engineering Standards Committee movement upon the society, and opposed the plan of participating. No man knew better than he the difficulties inherent in intersociety coöperation, commonly called joint-committee work; no one had been more successful in directing such work, and no one better knew that technical as well as personal disagreements are bound to enter, regardless of the source. He did not fear the success of the Engineering Standards Committee, we feel sure; what he feared was its failure. He was of generous nature, and perhaps he would not have opposed the formation of a body that could do the work of the society if it would do it better. But he was too clearseeing a man and too strong a leader to look with favor on a plan that might submerge his own society without assuring that its work would continue.

Now that the committee is in a period of reorganization, new opportunity is afforded to consider the broad questions at issue. We urge upon the council of the American Society for Testing Materials that it review its prior decision to participate in the Engineering Standards movement; and we repeat that the matter is one of vigor or paralysis, of life or death, to the society and to the cause which it represents.

Distributed Versus Centralized Passenger Terminals

WITH the growth of our cities the question of passenger terminals is one of repeated occurrence. The long drawn out discussions at Chicago and Cleveland are but the counterpart of what is being heard in dozens of cities in different parts of the country. The problems there may not be as acute, but as the number of cities of very large population increases there are sure to arise elsewhere situations just as difficult and provocative of as much discussion.

Usually, the discussion comes down to a dispute between the railroad and the representatives of the public. The railroad company faces large expense in the building of elaborate terminals in congested cities, while the public, seeking merely its own convenience, desires to dictate the location, and sometimes the character, of the terminal.

In all cases the argument revolves about the possibility of building another huge terminal, and the advantages and possibilities of the "distributed" type never come up for consideration. By "distributed" type is meant a shuttle service running into the congested sections from a terminal placed well outside of the city, such a shuttle road to have in town a number of stations similar to those of elevated and subway lines. It proposes, instead of a huge terminal putting on the railroads the terrific overhead of high property costs and an elaborate building, the substitution of a system relatively inexpensive and tending to give the people of the city a service far excelling the possibilities of the centralized terminal.

"Arrant nonsense," will be the immediate comment of many whose thoughts have never strayed beyond the huge terminal idea. But is it arrant nonsense?

Consider, for example, the Manhattan Transfer scheme of the Pennsylvania R.R. at New York. One can go from lower New York, from any Hudson and Manhattan tunnel station on Sixth Ave., from Hoboken, from Newark, from Harrison, from four points in Jersey

City, to Manhattan Transfer, and there wait for and board his train. The passenger need never see the Pennsylvania Terminal in New York City; he buys his ticket in any one of half a dozen places and checks his baggage at the same time. The passenger entering New York City, on the other hand, can terminate his journey at that one of the fifteen Hudson and Manhattan stations in the metropolitan district which best suits his convenience.

Moreover, the ferry systems of the various railroads terminating on the west bank of the Hudson River, opposite New York City, furnish another example of the distributed type of terminal. Land on the west bank of the Hudson is relatively expensive, yet not so expensive as that upon Manhattan Island itself. From each of these terminals radiates a number of ferry lines, dropping the passengers at points most convenient for them. Looking about, we can find other instances where the distributed terminal idea has been used to a minor extent. In Cleveland, Pittsburgh and Chicago there are stations in the outlying sections where goodly numbers of passengers board and leave through trains, while at Chicago the Elgin, Aurora & Chicago R.R., instead of having a downtown terminal, uses the Metropolitan Elevated Railroad Co.'s line and thus is able to distribute its passengers at any point on that extensive system.

Objections can be raised as the various difficulties involved in the distributed type are considered. What about waiting rooms, baggage, boarding trains which leave late at night, etc.? The answers to most of the objections can be found by a study of the Manhattan Transfer scheme of the Pennsylvania—although, manifestly, there, with a central terminal in addition to the distributed system, the full development of a distributed system has not been attained.

A distributed scheme may sound like "arrant nonsense" to those who blindly wrap themselves in tradition, but, from the standpoints of convenience and good business policy, it must give pause to those who defend as an alternative the $50,000,000 (and more) terminal, inconvenient because of its immensity, burdensome to the railroad as an investment, albeit monumental and creditable to a city which bears none of the cost, save to relieve later the inevitable street and transit congestion.

Some New Ideas in Concrete Proportioning

PROPORTIONING concrete by volume is so firmly established that to many the method of designing a concrete mixture proposed by Professor Abrams, as outlined in an article on another page, may seem unduly complicated. It is true that the machinery of the method requires some rather involved explaining, but the method itself is simple enough and the theory back of it rational. That theory is that concrete strength and wear depend on optimum plasticity, which may be brought about by varying the three ingredients—cement, aggregate and water. The studies on which the method is based emphasize, first, the importance of water, and, second, the effect of the grading of the aggregate on the amount of either water or cement. Since cement is the more expensive of the two, the design of a concrete mixture resolves itself into the determination for any given aggregate of the proper amount of water with the minimum amount of cement. This is good economy, because on any job the aggregate is the variable, to which the cement and water can most readily be adjusted for the best possible concrete.

In particularizing the water-content problem in concrete, Professor Abrams has done a service to all concrete users. The subject is not new. The dry concrete of the late '90s was based on sound enough theory, which was forgotten or discarded in the rapid growth in the use of reinforced concrete, with its impeding steel. Four or five years ago the wet pendulum began swinging too far, and students of concrete commenced to sound the dangers of the overwet mix. Professor Abrams more than any other investigator has pinned impressions down with facts. Very definitely he has shown the quantitative as well as the qualitative rôle of water in concrete.

In his theory of aggregate grading he, too, is treading on familiar ground, only he has gone further than previous investigators. In place of the Fuller grading curve, which was supposed to give an aggregate of maximum strength-making properties, he substitutes an area which any number of curves may satisfy, and—what is crucial—indicates that any such area of sieve-grading curves has its own water or cement content to produce a concrete of given strength. This has wide application, because aggregate rarely occurs according to any required analysis.

It is evident, however, that the insistence on a proper water content is the most important feature of Professor Abrams' work. One may disagree with his fineness modulus theory or ask for more confirmation thereof, and still accept the principle of the optimum water-cement ratio. There is plenty of evidence that too much water is dangerous, but the trouble is that the rank and file of concrete workers do not yet appreciate it. The subject has been hammered and hammered for the past two years and needs more hammering. The general rule, "Use the smallest amount of mixing water that will produce a workable concrete," should be cast in bright letters on every concrete mixer in the country, and the men who tend that mixer taught what the words mean in the very concrete they are placing.

Engineers must translate into better concrete such work as the Lewis Institute laboratory is doing. They must disabuse the concrete workmen and foremen of their present idea that such studies as this one are what Professor Talbot at a recent convention referred to as "artists' stuff." They must emphasize and advertise the fact that concrete is not a casual composition but a delicately balanced mixture responsive to every variation in its content or method of manufacture.

And these same engineers should not forget that, highly scientific as is the designing theory advanced by Professor Abrams, at bottom its operation depends on practical experience and visual expertness. Throughout the discussion the importance of "workability" is emphasized. Just what is an optimum workability? On nearly every concrete job expert opinion differs. The added pint of water which takes away exactly so many pounds of compressive strength may make the difference between success and failure in getting the concrete out of the mixer. The extra plasticity which perfect design forbids may be necessary to insure complete covering of close-knit reinforcement. This by no means detracts from the desirability of so exact a design of the mix, but it does indicate—what, of course, is true of all engineering—that the finished engineer is the one who can apply to the elegance of the laboratory and of the study the solid experience of years of practical observation.

Labor-Saving Machinery Used in Building Houses

Tractors Drag Plows and Also Haul Concrete Carts From Central Mixing Plant to All Parts of Extended Job—Lumber Pre-Sawed to Standard Sizes in Mill on Works

By Samuel H. Lea
Assistant Engineer, Cradock Housing Development, Portsmouth, Va.

CRAWLER TRACTORS HAUL MIXED CONCRETE AS FAR AS 1750 FEET ON UNITED STATES HOUSING DEVELOPMENT

LABOR was the element hardest to get in the construction of the United States housing project at Cradock, Va., which was started last summer, to provide homes for workers in the nearby Norfolk Navy Yard. For that reason a special effort was made to utilize all possible labor-saving devices and machinery, so that the men who could be obtained would be employed most effectively. This application of machinery extended from the unloading of material to the digging of the service trenches, but its most novel manifestation was the extensive use of the small tractor of the track-laying or "crawler" type to haul concrete from the central concreting plant and to do all manner of odd jobs of haulage around the works.

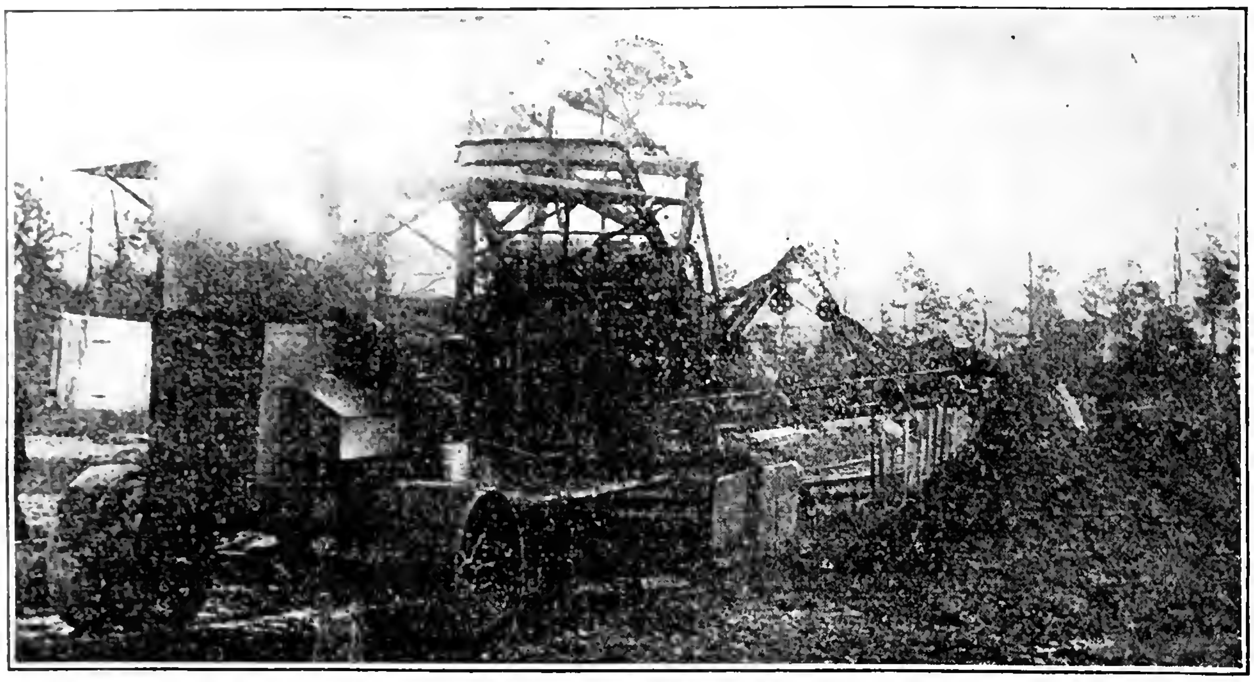
The original plans at Cradock contemplated sufficient houses for 5000 persons. After the armistice was signed it was decided to build 662 houses, including seven apartment buildings and 93 portable houses. All of these houses, together with the streets, roads, pavements and public-service appurtenances, had to be built on virgin ground on a site of about 400 acres adjacent to the Virginian R.R. and the Portsmouth-Gilmerton trolley line. In addition to the permanent housing buildings, there were many temporary buildings, such as bungalows and mess halls for the administrative force, barracks, kitchens, mess halls and canteens for the laborers, sawmills, storage buildings and hospitals.

THREE TRAILER LOADS OF LUMBER BEING HAULED BY A SMALL TRACTOR

Convenience of transportation in the site was facilitated by the location of the main-line railway. A loop track from the Virginian R.R. extends through the project for 2.6 miles, including sidings and spurs. Material brought in could be run around this loop and discharged at convenient places, from which it was delivered to the job by trucks, tractors and horse-drawn wagons. Temporary roads were built to take care of this traffic, and preliminary surfacing was also placed on the permanent roads. About 4000 cu.yd. of road metal, comprising slag and stream and pit-run gravel, was used for surfacing the main thoroughfares through the project. Most of the temporary roads, made at an early period upon the natural surface, were of gravel or slag, forming a solid bed during the rainy period. They were located outside of the regular roadway, to be out of the way of grading operations, sewers and water lines.

On streets where the utilities had been installed and where settlement of the trenches was anticipated, the roadways were graded to subgrade, and the permanent paving was delayed. Where concrete pavement is to be constructed the roadway was excavated to a depth of 6 in. below subgrade. A layer of furnace slag was placed in the excavation and rolled until the surface was even with the subgrade. This temporary pavement is used for traffic and serves as a sub-base for the later concrete pavement.

One of the first applications of labor-saving methods was in the unloading of the lumber. Freight cars loaded with lumber were switched on a spur track, and



TRENCHING MACHINE AT CRADOCK DEVELOPMENT AT WORK DIGGING SEWERS

collapsible platforms were erected, one against either side of the car door. These platforms were made of 2 x 4-in. lumber about the width of a lumber truck, with the floor a few inches higher than the truck floor. A truckload of lumber unloaded from the car to each platform projected about 3 ft. beyond the end of the platform. The lumber truck had flat floors with rollers of 3-in. iron pipe extending across the floor at intervals of about 3 ft. These rollers were embedded so as to leave their tops about 1 in. above the floor. In loading, the truck was backed under the projecting end of the pile of lumber which covered the nearest floor roller; the truck was moved back until the lumber was fully loaded; the platform collapsed during the operation and fell to the ground, to be rebuilt for the next load, leaving the lumber load on the track. The side of the car held the lumber in place while the truck was backing under. When the truck loaded with lumber reached its destination, it was stopped at the required place, and was then started suddenly and moved forward a few feet, which caused the load to shift backward a short distance. The operation was repeated a few times and the truck was out from under the load ready for another trip.

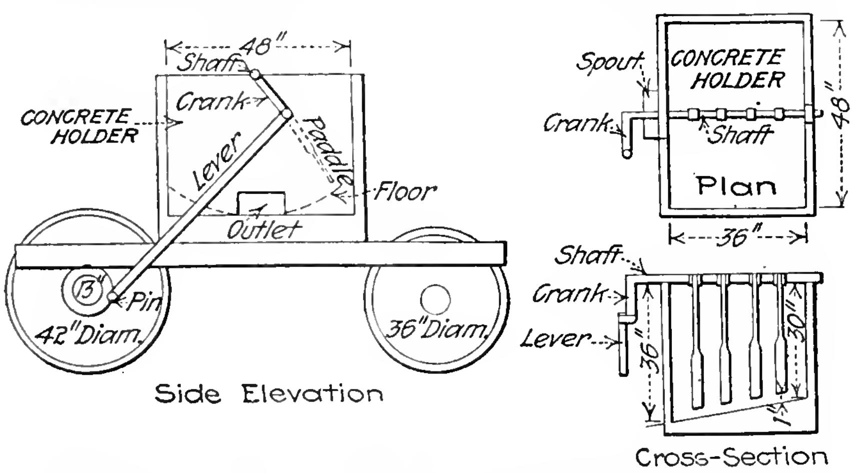
In getting the material around the job, the tractors which are seen in the views were useful. One view shows trucks with three loads of lumber. Such a train would make an average speed of six miles an hour along the temporary roads at the project. The same tractors were used for moving freight cars along the railroad track during the early part of the work before a locomotive was available. A log chain 10 or 12 ft. long was used for coupling the car to the tractor, which traveled close beside the track. One loaded freight car or two empties constituted a load. In one case a 10 x 12-ft. shack mounted on 6 x 8-in. skids was carried several hundred yards by three tractors traveling tandem.

The same tractors were used in clearing up the project before the construction started. They pulled down and removed small trees and stumps and, as shown in one of the views, were used to drag plows. Trees up to 3 in. in diameter were first cut around the roots, and a log chain was attached to the trunk several feet from the ground. The other end of the chain was hooked to a tractor which pulled down the tree and dragged it away. In plowing, the tractor was attached to the plow by a long chain.

Pre-sawed material was used in all the buildings, which were of frame throughout. The sawmill was equipped with swing saws which could be turned to any required angle for making square or mitered cuts of framing lumber and for the interior and exterior trim of the buildings.

From four to six pieces would be sawed at the same time. Pieces of lumber ready for use were passed from the saws through the mill door onto the truck or trailer. Each machine saw was driven by an independent electric motor. The mill supplied material for framing and for trim for from 10 to 15 houses per day.

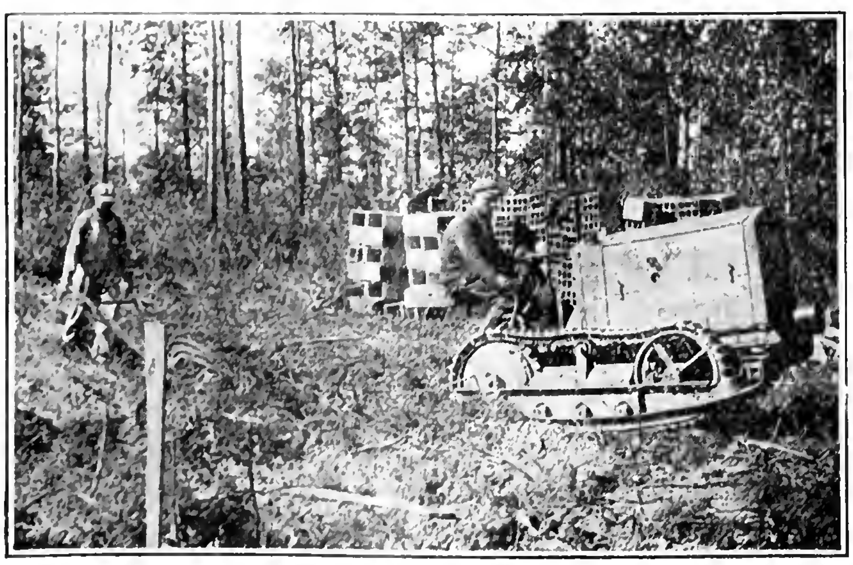
Concrete for the foundations of the buildings and for such other uses as were required was made at a central mixing plant and hauled to the place in special carts by



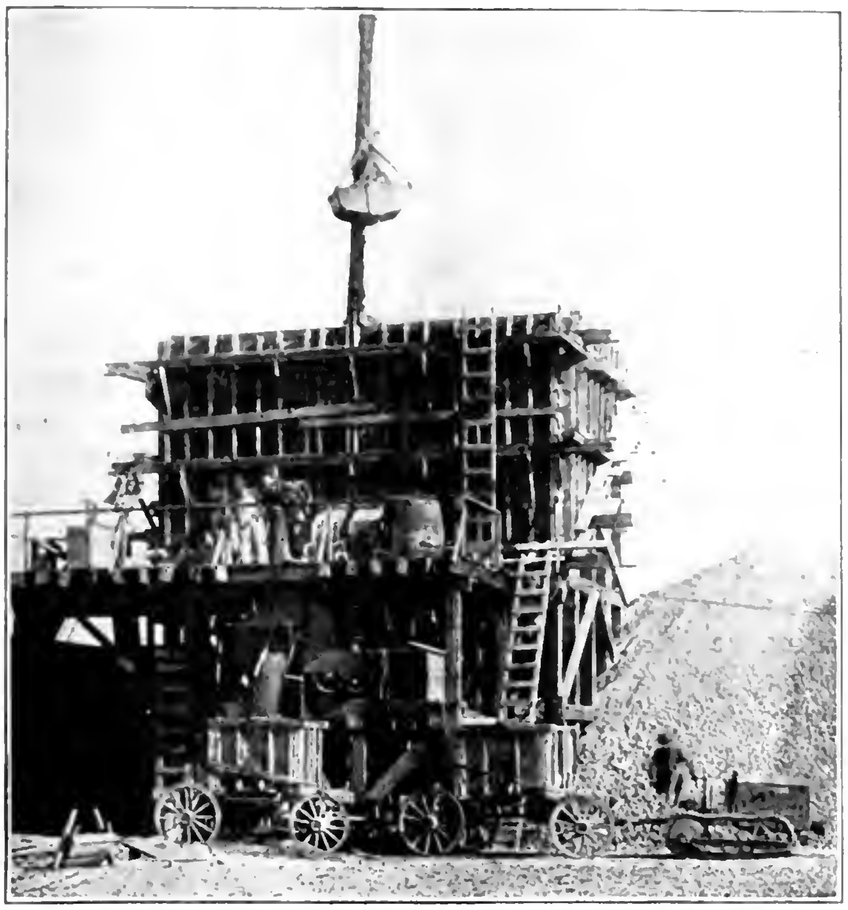
DETAILS OF CART IN WHICH CONCRETE IS CARRIED TO WORK

the same tractors. These carts, a drawing of which is seen above, have interior paddles which agitate the concrete during transportation and keep it in shape for use when delivered. The mixer, which is electrically driven, is upon an elevated platform, the concrete being discharged by gravity into the wagon.

The aggregates are taken from open-top freight cars

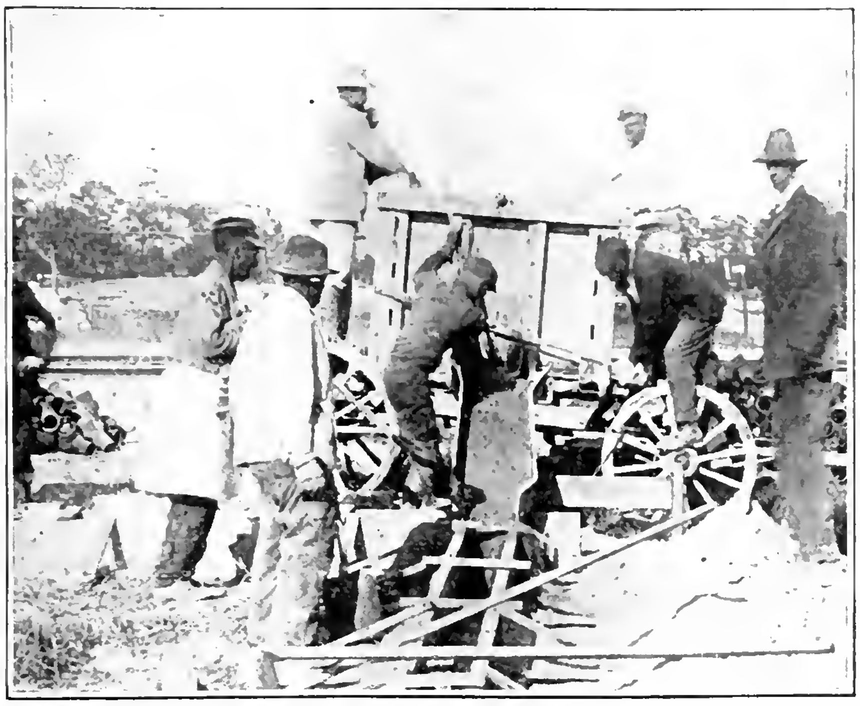


PLOWING FOR A HOUSING DEVELOPMENT WITH A TRACTOR FOR A MULE



TRACTOR-DRAWN CONCRETE CARTS BEING FILLED AT CENTRAL MIXING STATION

in a clamshell bucket operated by a steam derrick, and are deposited in bins above the mixer or in nearby stock-piles. Cement is carried from the adjacent storage room to the mixer platform by an electrically operated endless chain elevator. The loaded concrete wagons are hauled one or two at a time to place by the tractors, and the concrete is deposited through a small chute, shown in one of the views. The concrete is kept stirring during the trip by the agitator, which is operated by



DISCHARGING CONCRETE FROM A WAGON INTO HOUSE FOOTING THROUGH A CHUTE

a lever attached to one of the rear wheels of the wagon. A 1¼-in. round iron shaft across the wagon top is mounted on trunnions near the end. Four iron paddles, ⅜ x 2 in., are attached to the shaft and extend vertically to within about 1 in. of the sloping wagon bottom. The shaft is connected to a collar on the outer end of the hub. As the wagon moves the wheel revolves and operates the lever, which moves the four iron paddles back and forth through the concrete. On the long runs a distance of 1750 ft. was traveled, making a total of 3500 ft. for the round trip, which required 10 minutes. This included time taken for loading and placing the concrete after mixing.

Trenches for sewers and water mains were dug both by hand and machine. The deeper trenches were mostly excavated by hand, because the sides would cave so quickly behind the machine that the sheeting could not be placed and secured. This rapid caving was caused by the vibration of the heavy machine on the soft ground. At depths of from 4 to 7 ft., however, the machine was successfully operated, and a good-sized gang was kept busy laying pipe behind it.

Roadway grading was done with an elevating grader drawn by 16 horses. The excavated material is loaded into bottom dumping wagons and hauled to low places for filling. Only short runs can be made without turning, so conditions were not particularly favorable for this method of grading.

The average day's work is 225 cu.yd. of earth in cuts from 4 to 12 in. in depth, and the cost is about $1 per cubic yard of earth removed.

The Cradock development was in charge of the United States Housing Corporation. George B. Post & Sons, of New York, prepared the general architectural plans

ELEVATING GRADER PULLED BY SIXTEEN HORSES MAKING NEW STREETS

for the project. Hill & Ferguson, of New York, were the supervising engineers until Jan. 1, 1919, when G. C. & A. E. Wheeler, of New York, took over that end of the work. The Hegeman-Harris Co., Inc., of New York, is the general contractor; and William Wooley is works superintendent.

Water Treatment Saves Lives and Money

Reduction in the annual typhoid death rate of 54 per 100,000 at Columbus, Ohio, due to the introduction of a purified water-supply, means a financial saving of $1,188,000 for 2.2 years. This estimate was given by Prof. C. W. Fould, of Ohio State University, in a paper read before the Engineers' Club of Columbus, and was based on Mr. Whipple's estimate of $10,000 loss to a community for each death by typhoid. A total yearly saving per household (five persons) is made up of $3 saving on soap, $17 on plumbing and $15 in doctor's bills, funeral expenses and loss of time. Thus, for each household there is an average annual saving of $35 due to the purifying and softening of the city water.

Engineering Civic Federation

Proposed Organization of Engineering Societies Based Upon Our Political System of Representation

By W. L. Saunders
Past President, American Institute of Mining Engineers

THE engineers' symposium held in the auditorium of the Engineering Societies' Building in New York City, Mar. 26, 1919, brings prominently before us the question whether or not citizens of the United States, engaged in engineering and other scientific pursuits, are willing to organize for the purpose of using the influence of technical men in civic affairs. The speeches and the discussions showed clearly that there is something wrong with the present situation, that a great opportunity now exists for the engineer to render real service to the community.

Dr. Ricketts, in an address to the Engineering Association of the Princeton Club, said: "We vote, but we do not really serve our community, state and county. We have been so absorbed in advancing the industries with which we have been connected that we have failed to exercise our proper influence in behalf of the community. We have established splendid engineering schools where graduates are given superior technical training, but are not inspired by the true spirit of service to the commonwealth."

In order to crystallize this subject into a practical plan, it would seem that the first thing to do is to get together on fundamentals. There is much confusion and some difference of opinion as to whether this movement should be one of coöperation among engineering societies or whether it should take the line of an independent organization of engineers and scientific men, federating citizens of technical thought and training into a broad, nation-wide organization, planned in accordance with American ideals and to meet the conditions that exist in a democratic form of government.

Objects of Associations

Engineering associations, national and local, are usually organized and directed for the purpose of advancing engineering knowledge and for the maintenance of high professional standards. Such organizations are of the greatest value and importance to the profession, but their very nature tends toward concentration upon purely technical lines and to separation from civic and social duties. The highly trained civil engineer naturally considers that he is a better judge of things involving civil engineering than is any other type of engineer. He also considers his judgment superior to that of one of his juniors. If a question is before a legislative body, involving civil engineering, he would not look favorably upon a proposition to consider his vote as only equal to that of other men in the profession. He would naturally, and reasonably, favor submitting the question to a body of civil engineers.

The conclusion from this premise leads to permitting the engineering societies to take separate action in public questions. The unfortunate part of this, however, is that it is neither wise nor effective. It does not conform to the American system of government. Such a system is fundamentally one where the man in the street has an equal vote with the man in the counting house, even on a banking question, and experience has shown over and over again that legislative bodies are not influenced by banking associations when banking questions are before them. This may not be right, but it is a fact. It was shown recently in the case of the Federal Reserve act, which was opposed by the bankers and which is now generally approved.

Let me illustrate this point in another way: Let us suppose a project to be before a county board, a state legislature, or any governing body, involving the construction of either a bridge across or a tunnel under a stream. The civil engineer would perhaps be more interested in a bridge, the mining engineer in a tunnel. The question might appeal to the governing body on lines of general public interest; matters of finance may come in, so that a decision rendered on broad grounds should have its influences reach out to lines of general technical and commercial knowledge.

An association of technical men without special predominance in any branch of engineering is not only likely to do more effective work, but its influence would be broader. There may be but a few civil engineers in

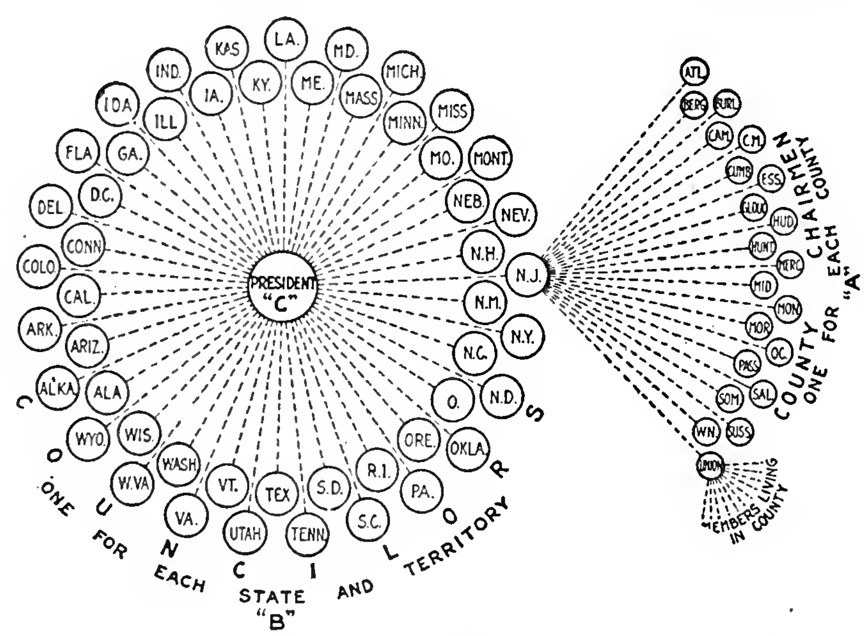


CHART OF PROPOSED SCHEME OF REPRESENTATION

A. *A County Chairman* for each county in each state and territory, elected by the majority vote of members who are legal voters in the county.

B. *A Councilor* for each state and territory, elected by the majority vote of the county chairmen in each state and territory.

C. *A President* elected for two years by the majority vote of the councilors.

A Governing Council to consist of the president and the councilors, who shall conduct all the affairs of the organization and who may vote by letter ballot.

Each county may express through a referendum in the county, the opinion of the county only on any question, but the opinion of the organization can only be expressed through a referendum vote of all the members of the Engineering Civic Federation.

that particular county or state, and this small group, acting in a community, would not be likely to have as much effect upon the governing body as the more widely distributed influence of a large number of engineers who might actually have been reasoned to their position by the superior intelligence of the small body of civil engineers. This would be specially so if the right and strength of the matter were on the side of this small group.

Engineering Societies Not Effective

The first reason why engineering societies are not likely to be effective as such in public matters is that, *their chief function being technical, they are now engaged and should continue to devote their time and energies, from the president down, to the advancement of scientific knowledge, and that if they attempt to divert those energies to public questions they are likely to do less in this fundamental line, which in itself is*

of the greatest importance. Furthermore, a departure from their true province to one which borders on politics will threaten to disrupt the organization.

It is proposed to organize an Engineering Civic Federation on practically the same basis as that on which the Chamber of Commerce of the United States has been established to represent business. Business men have their manufacturers' associations, their bankers' clubs, their trade associations, reaching into many lines of activity. They federate under the national chamber, an organization which is geographically widely distributed, the membership of which comprises all lines of business from the head of a large corporation down to the corner grocer. When this national chamber speaks it is with the voice of business, uninfluenced by personal considerations. It is the popular expression of the American business world. Why not have such an expression from the engineering world? If we make the attempt let us make it on a broad and not a narrow scale. Let us follow American systems.

The proposed Engineering Civic Federation is based in principle upon the national political organizations of the country. All members living in any county of any state elect a county chairman. The several county chairmen in each state by majority vote elect a councilor; the several councilors by majority vote elect a president. There is complete autonomy in each county, in each state and in the nation. Subjects relating to county interest only should be considered by the county members only, questions of state interest by state members only, and national questions by the entire organization. The opinion of the organization on public questions should be expressed only through a referendum.

It is proposed to elect Gen. George W. Goethals president. He is retired from the Army and is now in civic life. Here we have a man of international reputation, a great executive, through whom a membership at $1 or $2 each per annum of from 75,000 to 100,000 technical men might be enlisted for service. The possibilities of such an organization can scarcely be overestimated. Annual meetings might be held in Washington, D. C.; state meetings more frequently in each state, and county members might get together at any time. There should be no jealousy excited among the various engineering and scientific societies by such an organization as this. *It does not encroach upon their province. On the contrary, it draws a clear line of distinction between maintaining high professional standards and federating technical men for public service.*

The engineer has no one but himself to blame because his influence is so much less than that of the lawyer. He has been too modest. He looks upon engineering as too serious a thing, he hides his light beneath a bushel, he is too fond of avoiding the mire of politics, giving too little consideration to the fact that politics enters into every part of our life, and that if there is a mire there it is because the men who are best fitted to clean it up do not go in. We have a part to play—now let us play it. The problems of civilization are daily becoming more and more technical. The United States is the greatest industrial nation of the world. It is the engineer who has built up this industry. The men who have built it up are best fitted to conduct it, for engineering today is the art of organizing and directing men and of unfolding and utilizing the works of nature for the benefit of the human race.

Public Works Department Would Spend Over $125,000,000 Annually

The accompanying table shows the annual disbursements for four years of some of the principal bureaus of the Federal Government which it is proposed to bring together under control of a Federal Department of Public Works. (See *Engineering News-Record* of Apr. 10, 1919, p. 722.) The figures for the expenditures for 1918 are not yet available, but an increase of great importance is the appropriation for

ANNUAL DISBURSEMENTS BY FEDERAL GOVERNMENT BUREAUS CHIEFLY ENGAGED IN ENGINEERING WORK

	1914	1915	1916	1917
Treasury Department				
Public Health Service	$2,264,676	$2,767,820	$2,839,017	$3,045,598

Totals	125,450,534	125,843,825	99,167,701	90,935,00[illegible]

* Appropriations.

Federal aid to state road construction, expended under direction of the Bureau of Public Roads. The appropriation for the coming year for this purpose is $100,000,000.

If the above rate were to continue, the total expenditures of the proposed Department of Public Works would probably be in the neighborhood of $250,000,000—a greater amount than was disbursed by any department of the Government prior to the war.

Compression Tests Show Effect of Silt

Results of compression tests of portland cement mortars and concrete containing various percentages of silt, made by A. C. Alvarez and J. R. Shields, are published in a bulletin issued by the University of California, Berkeley, Cal.

In discussing the results of the recent tests, the authors offer explanations of the observed fact that in general the strength of all mortars decreased with increase in percentage of silt; but up to 10% of silt this decrease in strength averaged only about 4.5%; the decrease in strength jumped to an average of 15% for the addition of 14% of silt. The strength of 1 : 2 : 4 concrete increased when silt was added; the more so the greater the percentage of silt, 14% increasing the strength about 15%. The leaner the mixture, the greater is the percentage of silt which may be added with beneficial results.

It is concluded from the results of the tests that neither the injury to mortar nor the benefit to concrete due to the presence of 14% of silt is great. Such an amount of silt would be valuable to make mortar or concrete less permeable to water. The word silt refers to very fine, inert particles of durable minerals that have no chemical action on portland cement

How to Design Concrete Mixtures

Proper Proportions Can Be Determined for Different Kinds of Material—New Theories Regarding Aggregate Grading Advanced by D. A. Abrams as Result of Tests

PROPORTIONING concrete on an arbitrary volumetric ratio of the elements is a practice of long standing. Probably 90% of the concrete made today is specified to be a 1:2:4 mix, regardless of the material that makes the concrete. But for some years past a number of experimenters have been studying the make-up of concrete in the hope of discovering some more rational method of proportioning which will take into account the properties of the aggregate and the strength to be desired. Prominent among such investigators is Prof. Duff A. Abrams of the Structural Materials Research Laboratory of the Lewis Institute, Chicago. In the past three years this laboratory has made some 50,000 tests in the study of proper proportioning, as a result of which Professor Abrams has deduced a rational theory which permits the design of a concrete mixture from the particular aggregate available. His theories were advanced in a paper read before the Portland Cement Association in December, 1918, and have now been issued as Bulletin 1 of the Structural Materials Research Laboratory of the Lewis Institute. They are so important, however, that they are given in considerable detail in this article.

Experience has shown that the ordinary volumetric proportioning is far from satisfactory. The Chicago experiments further showed that other methods advanced are subject to serious limitations. They found, for instance, that the maximum strength of concrete does not depend on either an aggregate of maximum density or a concrete of maximum density, and that the methods which have been suggested for proportioning concrete by straight sieve analysis of aggregate are based on an erroneous theory. Furthermore, the tests emphasized what has been the growing impression in the past few years that proper attention has not been given to the water content of a concrete mixture. As noted in Professor Abrams' paper in *Engineering News-Record* of May 2, 1918, p. 873, the tests show that very small variations in water content produce more important variations in the strength and other properties of concrete ~~and~~ that similar changes in other ingredients.

Fundamentally, the main principles of Professor Abrams' theory are as follows: (1) With given concrete materials and conditions of test, the quantity of mixing water used determines the strength of concrete so long as the mix is of a workable plasticity; (2) a measurement of aggregate grading on a sieve, giving rise to a function known as the "fineness modulus" of the aggregate, is of the greatest importance in proportioning a mixture.

As corollaries to these main principles, it is stated that the aggregate grading which produces the strongest concrete is not that giving the maximum density—that is, the lowest voids. A grading coarser than that giving maximum density is necessary for highest concrete strength. The shape of the particle and the quality of the aggregate have less influence on concrete strength than has been hitherto reported. There is an intimate relation between the grading of the aggregate and the quantity of water required to produce a workable concrete.

The effect of water on the mix was shown in the article in *Engineering News-Record* of May 2, 1918. Tests represented by the diagram in Fig. 1 demonstrate that so long as the mix is workable, compressive strength of the concrete is a function of the ratio of the volume of water to the volume of cement in the batch—that is, the formula $S = A/B^x$ is generally applicable, where S is the compressive strength of the concrete, x is the ratio of the volume of water to the volume of cement, and A and B are constants whose values depend on the quality of the cement used, the age of the concrete, curing conditions, etc. For the tests in question this formula becomes $S = 14{,}000/7^x$.

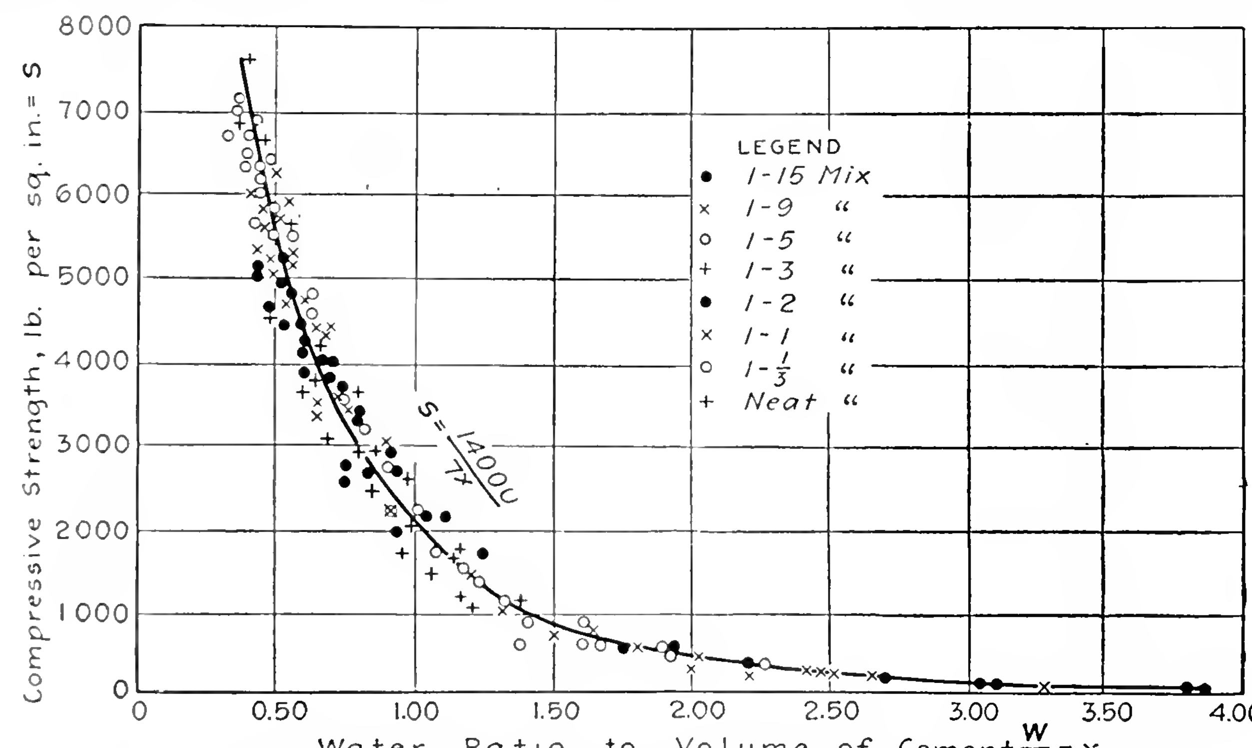

FIG. 1. RELATION BETWEEN CONCRETE STRENGTH AND WATER CONTENT
Twenty-eight-day compression tests on 6 x 12-inch cylinders.

The strength of the concrete responds to changes in water regardless of the reason for these changes. The water ratio may be changed, due to any of the following causes: (1) Change in mix (cement content); (2) change in size or grading of aggregate; (3) change in relative consistency; (4) any combination of 1 to 3. It should not be concluded that the tests indicate that lean mixtures can be substituted for richer ones without limit. The limitation is the necessity of using sufficient water to secure a workable mix. Therefore, according to Professor Abrams, the problem of designing concrete mixes resolves itself into the following: To produce a workable concrete which has a given water ratio, using a minimum quantity of cement, or the converse,

to produce a workable concrete with a minimum water ratio using a given quantity of cement. The method of securing the best grading of aggregate and the use of the driest concrete which is workable are thus seen to be only devices which enable the accomplishment of the above mentioned results.

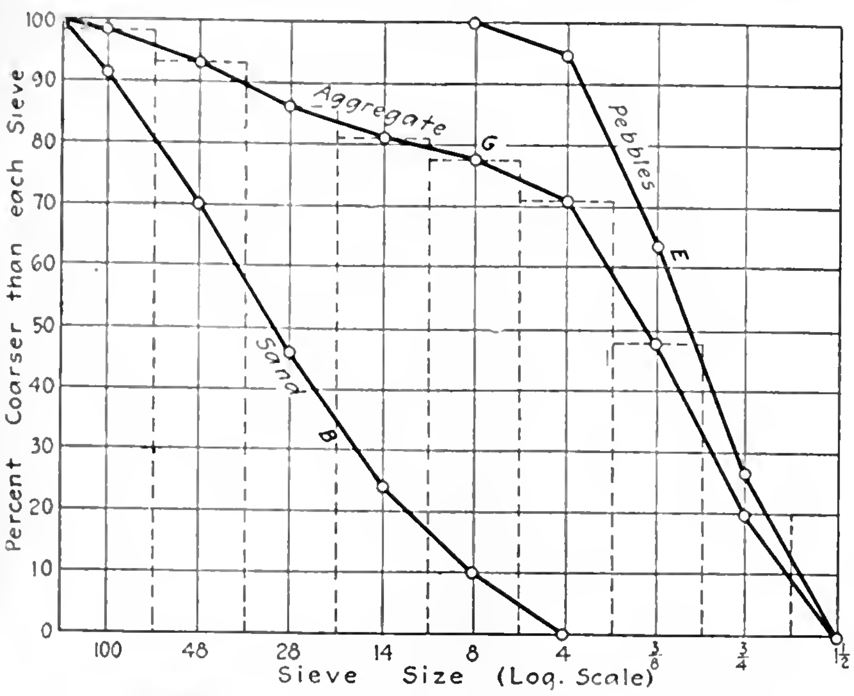

FIG. 2. METHOD OF PLOTTING SIEVE ANALYSIS OF AGGREGATES

Sieve analysis curves for aggregates B, E and G in Table 1.

TABLE I. METHOD OF CALCULATING FINENESS MODULUS OF AGGREGATES

Sieves commonly known as the Tyler standard sieves; each sieve has a clear opening just double that of the preceding one.

The sieve analysis may be expressed in terms of volume or weight.

The fineness modulus of an aggregate is the sum of the percentages given by the sieve analysis, divided by 100.

	Size of Square Opening		Sieve Analysis of Aggregates Per Cent. of Sample Coarser Than a Given Sieve						
			Sand			Pebbles			Concrete

1½-in.........	1.5	38.1	0	0	0	0	0	0	0
Fineness Modulus.........			1.54	2.41	3.10	6.46	6.86	7.36	5.74

* Concrete aggregate "G" is made up of 25% of sand "B" mixed with 75% of pebbles "E." Equivalent gradings would be secured by mixing 33% sand "B" with 67% coarse pebbles "F"; 28% "A" with 72% "F," etc. The proportion coarser than a given sieve is made up by the addition of these percentages of the corresponding size of the constituent materials.

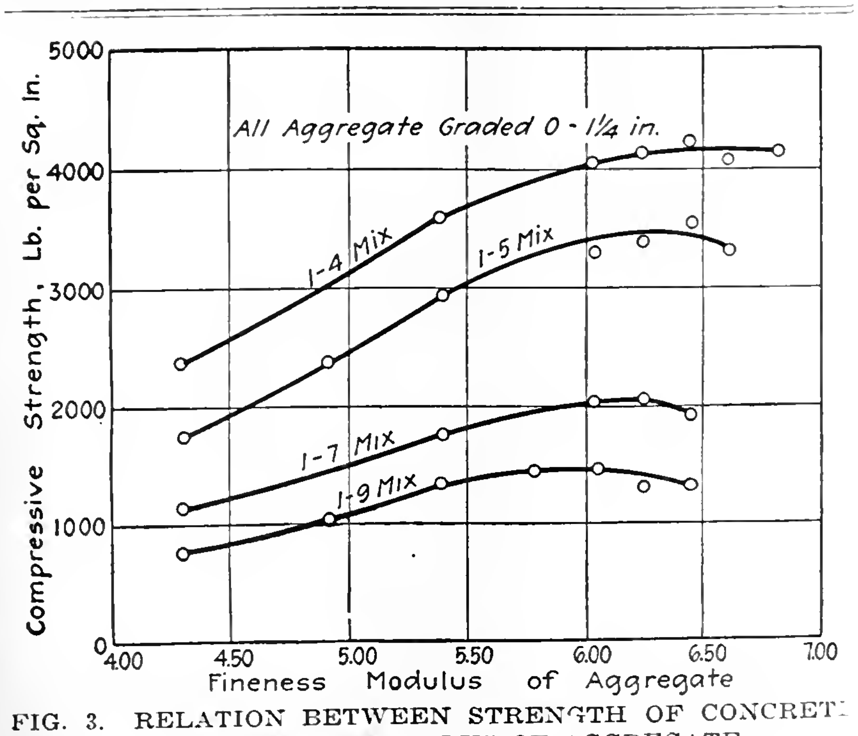

FIG. 3. RELATION BETWEEN STRENGTH OF CONCRETE AND FINENESS MODULUS OF AGGREGATE FOR DIFFERENT MIXES

In further investigation of the aggregate, the function called the "fineness modulus" was set up. In brief, this modulus is the sum of the percentages of the aggregate in a certain type of sieve analysis divided by 100. The sieve analysis is determined by using the following sieves from the Tyler standard series: 100, 48, 28, 14, 8, 4, ⅜-in., ¾-in., and 1½-in. These sieves are made of square-mesh wire cloth. Each sieve has a clear opening just double the width of the preceding one. The exact dimensions of the sieves and the method of determining the fineness modulus are found in Table I. It will be noted that the sieve analysis is expressed in terms of the percentages of the material by volume or weight *coarser* than each sieve. A well graded torpedo sand up to No. 4 sieve will give a fineness modulus of about 3; a coarse aggregate graded 4-1½ in. will give a fineness modulus of about 7; a mixture of the above materials in proper proportions for a 1: 4 mix will have a fineness modulus of about 5.80. A fine sand such as drift sand may have a fineness modulus as low as 1.50.

In explaining the use of the fineness modulus, Professor Abrams continues as follows:

There is an intimate relation between the sieve analysis curve for the aggregate and the fineness modulus; in fact, the fineness modulus permits the proper interpretation of the sieve analysis of an aggregate. If the sieve analysis of an aggregate is platted in the manner indicated in Fig. 2, that is, using the per cent coarser than a given sieve as ordinate, and the sieve size (platted to logarithmic scale) as abscissa, the fineness modulus of the aggregate is measured by the area below the sieve analysis curve. The dotted rectangles for aggregate "G" show how this result is secured. Each elemental rectangle is the fineness modulus of the material of that particular size. The fineness modulus of the graded aggregate is then the summation of these elemental areas. Any other sieve analysis curve which will give the same total area corresponds to the same fineness modulus and will require the same quantity of water to produce a mix of the same plasticity and gives concrete of the same strength, so long as it is not too coarse for the quantity of cement used.

Fineness Modulus Strength Relation for Concrete

Many separate series of tests have shown that for a given plastic condition of concrete and the same mix there is an intimate relation between the fineness modulus of the aggregate and the strength and other properties of the concrete. We have seen that the reason for this result is found in the fact that the fineness modulus simply reflects the changes in water-ratio necessary to produce a given plastic condition.

Figs. 3 and 4 give the results of certain compression tests which bring out the relation between the strength of the concrete and the fineness modulus of the aggregate. It

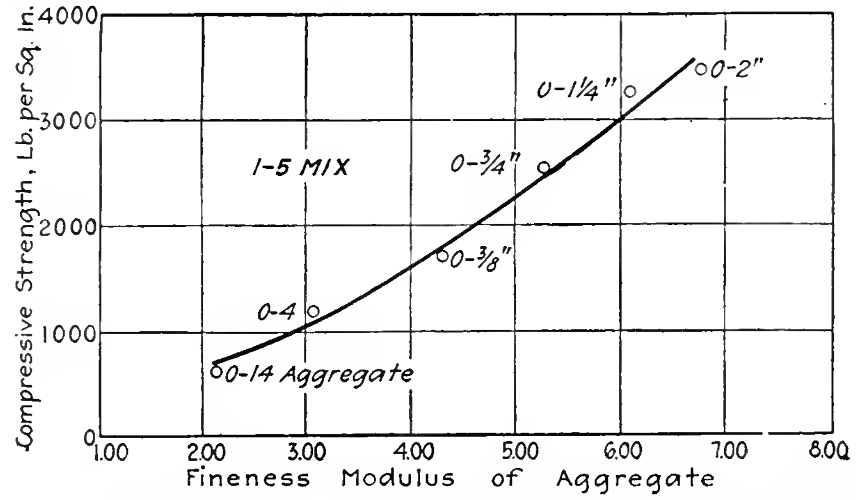

FIG. 4. RELATION BETWEEN STRENGTH OF CONCRETE AND FINENESS MODULUS FOR DIFFERENT SIZES

will be noted from Fig. 3 that a separate curve may be drawn for each mix. In each case there is a steady increase in the compressive strength of the concrete as the fineness modulus of the aggregate increases, until a certain value is reached which corresponds to a maximum point. It will be noted also that this maximum point corresponds to higher and higher values of fineness modulus as the quantity of cement in the mix is increased. In other words, the maximum strength comes at a fineness modulus of about 5.80 for the 1 : 9 mix and about 6.40 for the 1 : 4 mix. In these tests the different values of the fineness modulus were secured by using a preponderance of the coarser sizes, but in all cases maintaining the same limiting size, that is, 1¼ inches.

In Fig. 4 is found a similar relation between the strength and the fineness modulus, except that no maximum point is found. This condition arises from the fact that the maximum size of the aggregate is increasing without changing the type of the sieve analysis curve, consequently the fineness modulus strength curve continues to rise indefinitely. The height to which the curve rises is limited only by the maximum size of aggregate which may be used. It is important to note that there is no conflict between the indications of Figs. 3 and 4.

A given value for the fineness modulus of an aggregate can be secured with any combination of percentages in the sieve analysis which gives the same total; consequently, an infinite variety of gradings may be found which give aggregate of the same concrete strength. Table II gives the

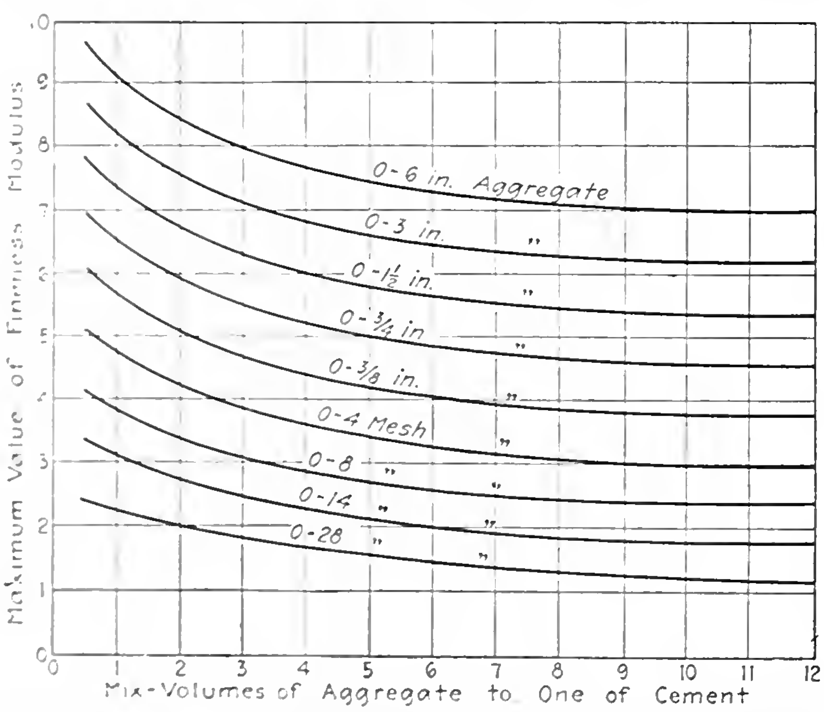

FIG. 5. MAXIMUM PERMISSIBLE VALUES OF FINENESS MODULUS OF AGGREGATE

Graphical representation of Table III. Based on sand and pebble aggregate.

TABLE II. EFFECT OF GRADING OF AGGREGATES ON THE STRENGTH OF CONCRETE

Compression tests of 6 by 12-in. concrete cylinders. Mix 1:5 by volume; age at test, 28 days; stored in damp sand; tested damp.
Aggregates—sand and pebbles from Elgin, Ill. Aggregates were screened to different sizes and recombined to conform to predetermined sieve analyses.
Same quantity of water was used in all specimens of a given consistency. The 110% consistency contains 10% more water than the 100%
Each value in the strength tests the average from 5 tests made on different days

results of groups of tests which bring out the wide variation which may be made in the grading of aggregate without producing any essential variation in the concrete strength. Twenty-seven different gradings of the same aggregate were made up. These gradings covered the widest possible range, but they had one property in common; that is, a fineness modulus of 6.04. All specimens were mixed with the same quantity of cement and water. Separate sets of specimens were made of two different consistencies.

Table II also furnishes some interesting data on the surface-area method of proportioning aggregates. It is seen that there is the widest variation in the surface area of the aggregate without any appreciable difference in the concrete strength. Our studies have shown that surface area is not a satisfactory basis for proportioning aggregates.

On the basis of the water ratio theory and of the

* Considered as "half-size" sieves, not used in computing fineness modulus.

For mixes other than those given in the table, use the values for the next leaner mix.

For maximum sizes of aggregate other than those given in the table, use the values for the next smaller size.

Fine aggregate includes all material finer than No. 4 sieve; coarse aggregate includes all material coarser than the No. 4 sieve. Mortar is a mixture of cement, water and fine aggregate.

This table is based on the requirements for sand-and-pebble or gravel aggregate composed of approximately spherical particles, in ordinary uses of concrete in reinforced-concrete structures. For other materials and in other classes of work the maximum permissible values of fineness modulus for an aggregate of a given size is subject to the following corrections:

(1) If crushed stone or slag is used as coarse aggregate, reduce values in table by 0.25. For crushed material consisting of unusually flat or elongated particles reduce values by 0.40.

(2) For pebbles consisting of flat particles, reduce values by 0.25.

(3) If stone screenings are used as fine aggregate, reduce values by 0.25.

(4) For the top course in concrete roads, reduce the values by 0.25. If finishing is done by mechanical means, this reduction need not be made.

(5) In work of massive proportions, such that the smallest dimension is larger than 10 times the maximum size of the coarse aggregate, additions may be made to the values in the table as follows: for ¾-in. aggregate 0.10; for 1½-in. 0.20; for 3-in. 0.30; for 6-in. 0.40.

Sand with fineness modulus lower than 1.50 is undesirable as a fine aggregate in ordinary concrete mixes. Natural sands of such fineness are seldom found.

Sand or screenings used for fine aggregate in concrete must not have a higher fineness modulus than that permitted for mortars of the same mix.

Crushed stone mixed with both fine sand and coarser pebbles requires no reduction in fineness modulus provided the quantity of crushed stone is less than 30% of the total volume of the aggregate.

TABLE IV. EXAMPLE OF INFLUENCE OF QUANTITY OF MIXING WATER ON THE STRENGTH OF CONCRETE

Water in a 1-Bag Batch: Gallons	Water in a 1-Bag Batch: Water-Ratio (x)	Relative Consistency Per Cent.	Compressive Strength of Concrete at 28 Days: Lb. per Sq In. (S)	Compressive Strength of Concrete at 28 Days: Relative Strength Per Cent.
5.75	0 77	100	2,770	100
6 0	0 80	104	2,600	94
6.25	0 84	109	2,400	87
6.5	0 87	113	2,250	81
7 0	0 94	122	1,950	70
7.5	1 01	131	1,670	60
8.0	1 07	139	1,470	53
9.0	1 21	157	1,100	40
10.0	1.34	174	830	30
12.0	1 60	208	480	17
15.0	2.00	260	200	7

Values calculated from equation

$$S = \frac{A}{B^x} = \frac{14{,}000}{8.2^x}$$

Where S = compressive strength of concrete (lb. per square inch); x = water ratio (an exponent)

A and B are constants whose values depend on quantity of cement and other conditions of the test. The values given for A and B are based on 28-day tests of 1:4 mix, pebble aggregate graded 0-1¼-in., fineness modulus 5.75.

The water-ratio is equivalent to the cubic feet of water to 1 sack (1 cu. ft) of cement.

The strength values are solely for comparative purposes in showing the influence of changing the water content.

fineness modulus, as noted above, Professor Abrams' method of proportioning is then outlined as follows:

1. Knowing the compressive strength required of the concrete, determine by reference to Fig. 1 the maximum water-ratio which may be used. In general, some allowance must be made for the high strengths in laboratory tests. In other words, a water-ratio somewhat lower than that given for the required strength in Fig. 1 should be used. For convenience in the subsequent steps we shall deal with concrete strength instead of water-ratio (as in Fig. 6), although it should be understood that it is the water-ratio which fixes the strength so long as we have a plastic mix.

2. Make sieve analysis of fine and coarse aggregate, using Tyler standard sieves. Express sieve analysis in terms of percentages of material by weight (or separate volumes) *coarser than* each of the standard sieves.

3. Compute fineness modulus of each aggregate by adding the percentages found in (2), and dividing by 100.

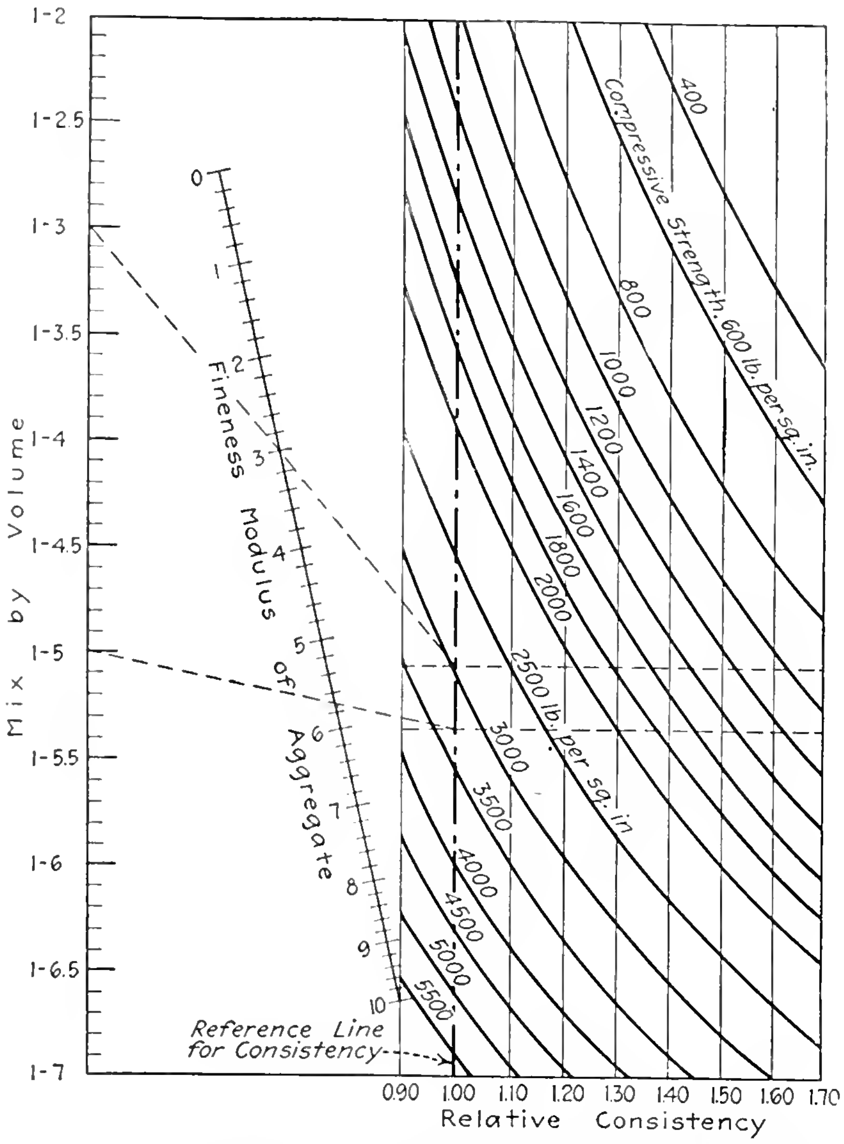

FIG. 6. DIAGRAM FOR DESIGN OF CONCRETE MIXTURES

Chart is based on compression tests of 6 x 12-inch cylinders at 28 days. Cement used gave strengths in 1:3 standard sand mortar, as follows:

Age	Lb. per Square Inch
7 days	1900
28 days	3200
3 mo.	4200
1 year	4300

TABLE V. QUANTITY OF MIXING WATER REQUIRED FOR CONCRETE

Mix Cem.-Agg. by Volume	Gallons of Water per Sack of Cement Using Aggregates of Different Fineness Moduli: 1.50	2.00	2.50	3.00	3.50	4.00	4.50	5.00	5.50	6.00	6.50	7.00

Calculated by Formula 4 in text.

In this table ($a - c$) is assumed as 0.02. This value may be used for ordinary limestones and pebbles. For crushed trap and granite it is somewhat high. It is too high in any case where the aggregate is saturated with water.

A relative consistency of 1.00 (normal consistency) requires the use of such a quantity of mixing water as will cause a slump of ½ to 1 in. in a freshly molded 6 by 12-in. cylinder of about 1:4 mix upon withdrawing the form by a steady, upward pull. This consistency is somewhat dry for most concrete work, but can be used where light tamping is practicable.

A relative consistency of 1.10 (10% more water than required for normal consistency) represents about the driest concrete which can be satisfactorily used in concrete road construction. Under the conditions mentioned above, this consistency will give a slump of about 5 to 6 inches.

A relative consistency of 1.25 represents about the wettest consistency which should be used in reinforced concrete building construction. Under the conditions mentioned above, this consistency will give a slump of about 8 to 9 inches.

For mixes and fineness moduli, other than those given in the table, approximate values may be determined by interpolation. For specific cases use the formula.

4. Determine the "maximum size" of aggregate by applying the following rules: If more than 20% of aggregate is coarser than any sieve the maximum size shall be taken as the next larger sieve in the standard set; if between 11 and 20% is coarser than any sieve, the maximum size shall be the next larger "half-sieve"; if less than 10% is coarser than certain sieves, the smallest of these sieve sizes shall be considered the maximum size.

5. From Table III determine the maximum value of fineness modulus which may be used for the mix, kind and size of aggregate, and the work under consideration. (The values in Table III are platted in Fig. 5.)

6. Compute the percentages of fine and coarse aggregates required to produce the fineness modulus desired for the final aggregate mixture by applying the formula:

$$p = 100\,\frac{A - C}{A - B} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

where p = percentage of fine aggregate in total mixture.
A = fineness modulus of coarse aggregate.
B = fineness modulus of final aggregate mixture.
C = fineness modulus of fine aggregate.

Fig. 7 may be used for solving Eq. (3), and for making comparisons of the effect of certain changes in proportions

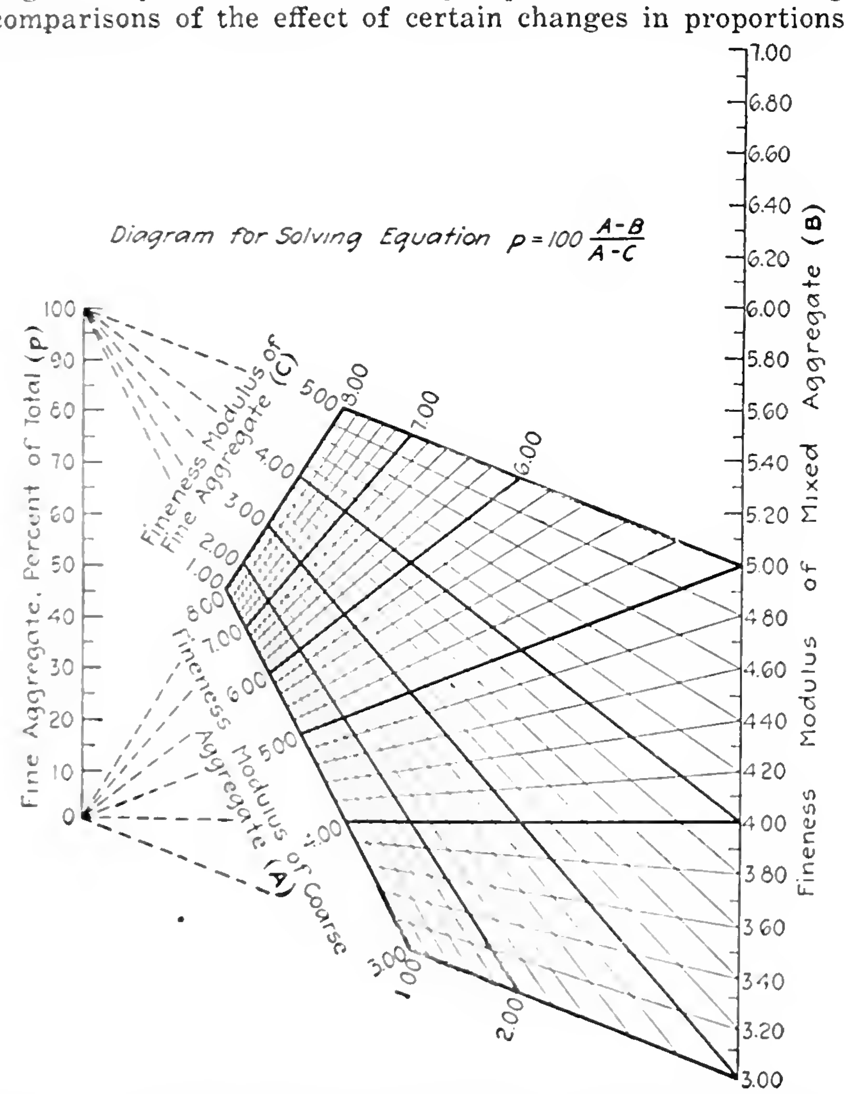

FIG. 7. DIAGRAM FOR DETERMINING QUANTITY OF SAND REQUIRED IN CONCRETE MIXES

of fine and coarse aggregates. The distinction between fine and coarse aggregate is solely for convenience in securing a uniform grading; the division may be made at any desired point.

7. With the estimated mix, fineness modulus and consistency enter Fig. 6 and determine the strength of concrete produced by the combination. If the strength shown by the diagram is not that required, the necessary readjustment may be made by changing the mix, consistency or size and grading of the aggregates.

The quantity of water required can be determined from Eq. (4) below, or approximately from Table V.

It must be understood that the values in Fig. 6 were determined from compression tests of 6 x 12-in. cylinders stored for 28 days in a damp place. The values obtained on the work will depend on such factors as the consistency of the concrete, quality of the cement, methods of mixing, handling, placing the concrete, etc., and on age and curing conditions. Strength values higher than given for relative consistency of 1.10 should seldom be considered in designing, since it is only in exceptional cases that a consistency drier than this can be satisfactorily placed. For wetter concrete much lower strengths must be considered.

Because of the important influence of the quantity of water in the concrete it is desirable to have a sound basis for proportioning the water. The quantity of water necessary for given proportions and conditions may be determined by the following formula:

$$x = R\left[\frac{3}{2}p + \left(\frac{.30}{1.26^{m}} + a - c\right)n\right] \ldots\ldots\ldots (4)$$

where

x = water required—ratio to volume of cement in batch (water-ratio).

R = Relative consistency of concrete, or "workability factor." Normal consistency (relative consistency = 1.00) requires the use of such a quantity of mixing water as will cause a slump of ½ to 1 in. in a freshly molded 6 x 12-in. cylinder of about 1:4 mix upon withdrawing the form by a steady, upward pull. A relative consistency of 1.10 requires the use of 10% more water and under the above conditions will give a slump of about 5 to 6 inches.

p = Normal consistency of cement, ratio by weight.

m = Fineness modulus of aggregate (an exponent).

n = Volumes of mixed aggregate to one of cement.

a = Absorption of aggregate, ratio of water absorbed to volume of aggregate. (Determined after immersion in water for three hours. Average values for crushed limestone and pebbles may be assumed as 0.02; porous sandstones may reach 0.08; very light and porous aggregate may reach 0.25.)

c = Moisture contained in aggregate, ratio of water contained to volume of aggregate. (Assume as zero for room-dry aggregate.)

This formula takes account of all the factors which affect the quantity of water required in a concrete mixture. These factors may be classified as follows:

1. "Workability" factor, or the relative consistency of the concrete. This is dictated by the kind of work being done; concrete must be more plastic (which generally means a wetter consistency) in reinforced-concrete building construction than is necessary in mass work. The term (R) in the equation takes care of this factor. (R) may vary from, say, 0.90 for a dry concrete to 2.00 or higher for very wet mixes.

2. Cement factor, which is made up of two parts: the *quality* of cement so far as normal consistency is concerned (p); the *quantity* of cement in the mix (n).

3. The aggregate factor. This includes the three terms within the parenthesis in Eq. (4). The first term, involving (m), takes account of the size and grading; the second (a) the absorption, and the third (c) the water contained in the aggregate.

While Eq. (4) represents the true water relation, it is somewhat complicated by the fact that the fineness modulus (m) appears as an exponent. The equation can be expressed in a simpler form as follows:

$$x = R\left[\frac{3}{2}p + \left(0.22 - \frac{m}{42} + a - c\right)n\right] \ldots\ldots (5)$$

This equation gives values for ordinary ranges of mix and grading of aggregate which are sensibly the same as given by Eq. (4).

Since a maximum practicable value of fineness modulus is found for each size of aggregate and mix, it is necessary to place certain limits on the value which may be used for proportioning materials for concrete mixes. Table III gives limits which will be found practicable. Subsequent experience may dictate certain modifications in the details.

The purpose of Table III is to avoid the attempt to secure an aggregate grading which is too coarse for its maximum size and for the amount of cement used. It is also useful in prohibiting attempts to use sands which are too coarse for best results in concrete mixtures. For instance, it would be found from this table that the use of a sand of

the nature of standard Ottawa sand is not permitted except in mixes 1:2 or richer.

The curves in Fig. 5 are platted directly from the values given for the standard sieves in Table III.

Fig. 6 is a nomographic chart for the design of concrete mixes. This chart takes account of the following four factors: (1) The mix (cement content); (2) the relative consistency; (3) the grading of aggregate (fineness modulus); (4) the compressive strength of concrete.

Given any three of these factors, the chart enables us to solve for the fourth. This chart is, of course, based on the results of certain tests. For practical application these values must generally be reduced by certain factors, which will depend on the judgment of the designer. In order to furnish some basis for comparison, compression tests of 1:3 standard sand mortars from the cement used in these tests are given.

Suppose we consider the case of concrete for road construction. This is generally specified as a 1:1½:3 or a 1:2:3 mix, with aggregate graded up to 1½ in. These mixes are about the same as what have been termed a 1:4 mix, the exact equivalent depending on the particular size and grading of the fine and coarse aggregate. Assume that gravel aggregate will be used, graded to 1½ in. Table III shows that we may use a fineness modulus as high as 6.00 — .25 = 5.75. Knowing the sieve analysis and fineness modulus of both sizes of aggregate, apply the formula or Fig. 7 to determine the proportions of each aggregate which must be mixed to secure this value. Assume that the concrete will be mixed to a relative consistency of 1.10, which is of such plasticity as will give a slump of 5 to 6 in. in the test described above. Place a straightedge in Fig. 6 on mix 1:4 and fineness modulus 5.75, and mark the point where it crosses the reference line for consistency; from this point project the line horizontally (as indicated in other examples) to relative consistency 1.10. It will be seen that this gives a compressive strength of 3,400 lb. per square inch at 28 days.

The effect of using other mixes, gradings or consistencies on the strength can be seen at once from the diagram. For instance, if the water were increased to a relative consistency of 1.25 (not nearly so wet as is frequently seen in road work) the strength will be reduced to 2,700 lb. per square inch—a reduction of over 20%. If the mix were changed to 1:4½ and other factors the same as in the first example, the strength would be 3200 lb. per square inch. We should have to change the mix to as lean as 1:5¼ in order to secure the same reduction in strength as was found above for a change from 1.10 to 1.25 consistency.

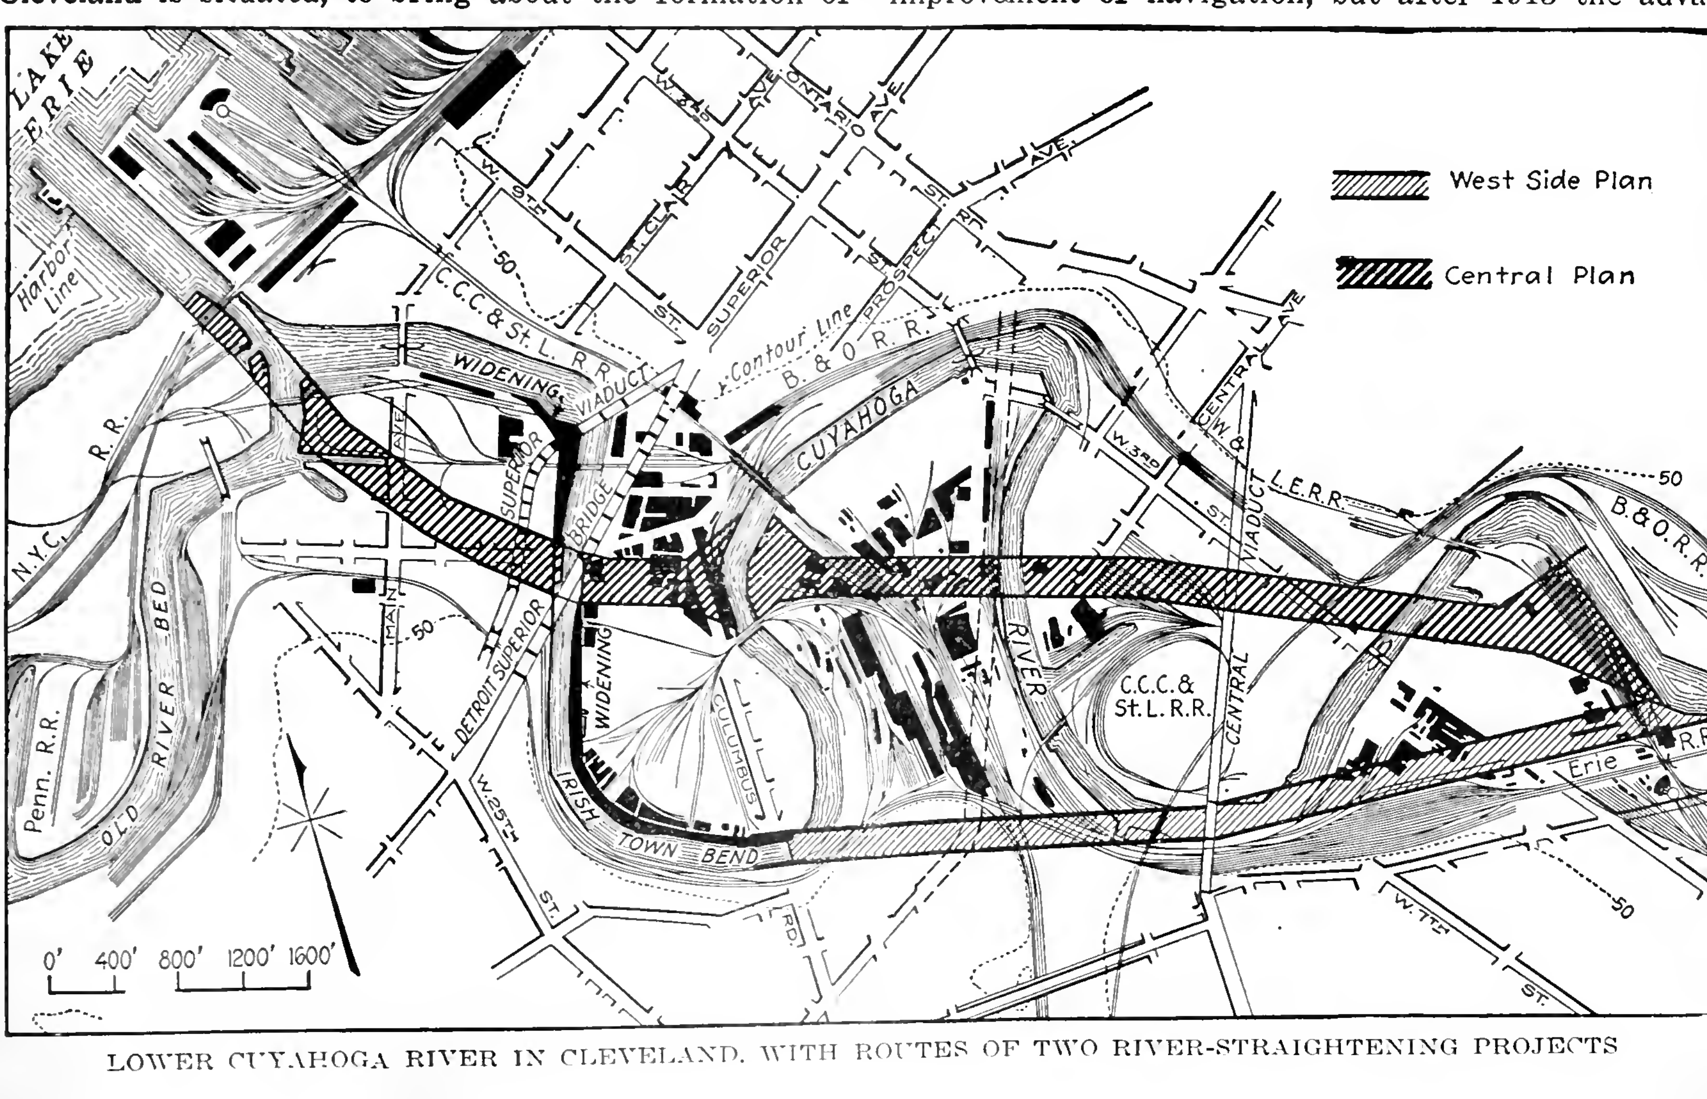
By using the wetter of the two consistencies we secure concrete of the same strength as if we had used one-third less cement and the drier mix. In other words, increasing the mixing water 13% causes the same reduction in strength as if we should omit 33% of the cement. This example shows the reason for emphasizing the importance of proper control of mixing water in concrete.

Eq. (4) and (5) show the elements which make up the water-requirements of a concrete mix. Table V gives the quantity of water required for certain mixes and values of fineness modulus. Quantities are given in terms of gallons per sack of cement. In this table the net absorption (that is, the quantity of water taken up by the aggregate in addition to that already contained) is assumed as 0.02 (2% by volume).

New River-Straightening Movement at Cleveland

Conservancy District Proposed — Choice Between Central and West Channels Affected by Union Station Scheme

STEPS have been taken by the county commissioners of Cuyahoga County, Ohio, in which the City of Cleveland is situated, to bring about the formation of a conservancy district under the Ohio conservancy law, in order to carry out the work of straightening the Cuyahoga River. A court hearing on the commissioners' petition that such a district be formed will be held Apr. 18. In 1913 the river flooded the valley bottom land sufficiently to do damage estimated variously up to $3,000,000. Numerous plans for straightening the river had been proposed before that time and others were developed subsequently, the object being improvement of navigation, but after 1913 the advan-



LOWER CUYAHOGA RIVER IN CLEVELAND, WITH ROUTES OF TWO RIVER-STRAIGHTENING PROJECTS

tage of straightening with a view to reduction of floods by increasing the channel capacity was also taken into account. As indicated on the sketch map herewith, the sharp bends of the river windings form a serious obstacle to navigation, their effect being made more serious by various low-level bridges, and at the same time they reduce the flow capacity.

A new factor was injected into the case two years ago by the vote of the people of the county appropriating money for a viaduct connecting Lorain Ave. on the west side with Huron Road on the east. As the referendum vote has been interpreted, a practically straight alignment of the viaduct between the ends of the two streets must be maintained, and this involves an unfavorable relation to the river. Doubt as to whether the construction of the bridge on this location is advisable while the river remains in its present condition led to delay in preparation of plans and initiation of work on the structure, and ultimately brought about the petition to the county court for the formation of a conservancy district.

Of the straightening projects now considered favorably, the two principal ones are those indicated on the map. The central one was worked out in 1916 and 1917 by a committee composed of E. B. Thomas, consulting engineer, W. A. Stinchcomb, county engineer, Robert Hoffmann, city engineer, and Maj. P. S. Bond, United States Engineer Officer. It is perhaps the most radical of the projects devised. Since it was prepared with the coöperation of a representative of the Engineer Corps, it has commonly been called the Federal plan.

A considerable amount of local sentiment, however, favors the west side plan, also shown on the map. This is composed of two sections, the northerly part being locally known as Plan No. 2, which is favored by the City Planning Commission, while the southerly extension is called the Mahoning Ave. cut. North of the Plan No. 2 channel a certain amount of river widening would be done to make the channel more easily navigable at the bends and to increase its flow capacity.

Believe One or Other of Plans Proposed Will Be Adopted

If a conservancy district is organized its studies would necessarily be general and not be limited to the two here shown. Cleveland engineers familiar with the river problem are, however, of the opinion that one or the other of the plans shown will almost necessarily be selected. The cost of the two projects was estimated something over two years ago at about $7,000,000 for the central channel and a trifle less than $5,000,000 for the west side channel as shown.

Until the formulation of the new union station project last autumn, which involves removal and relocation of many of the railway tracks and yards in the Cuyahoga valley, a serious obstacle to the realization of the west side channel scheme was the existence of important yards on or adjacent to the location of the channel. It is believed that with the removal of these yards through their replacement by yards in other parts of the city, in connection with the union station project (now planned to combine all roads in a passenger station on the public square and to rearrange freight facilities), the chief objections to the west side channel are removed, and its advantages in affecting a minimum of industrial property are held to be an important argument in its favor.

Operation Cost, Municipal Asphalt Plant of the District of Columbia

ITEMIZED costs for the operation of the District of Columbia municipal asphalt plant are contained in a report by the engineer department for the year which ended June 30, 1918. The plant output for the year was 185,952 cu.ft. of material, consisting of 151,152 cu.ft. of old-material mixture, 22,056 cu.ft. of asphaltic concrete mixture, and 12,744 cu.ft. of topping mixture. The plant was operated for 214 days with an average daily output of 869 cubic feet.

Hauling by motor truck was introduced during the year for hauling the hot mixture, and was found to be both economical and advantageous. About 90% of the hot haul is being done by trucks at the present time, replacing the horse-drawn carts and wagons.

MUNICIPAL ASPHALT PLANT COSTS AT WASHINGTON, D. C.

Based on 1 Cu.Ft. of Mixture

Old-Material Mixture		
Material cost:		
Old material, 0.6 cu.ft., at $1.05 per cubic yard		$0.0233
Sand, 0.34 cu.ft. at $1.43 per cubic yard		.0180
Limestone dust, 2.1 lb. at $3.63 per ton		.0038
Asphaltic cement, 4.12 lb. at $19.10 per ton		.0393
Total cost of material per cubic foot		$0.0844
Manufacturing and placing cost:		
Plant labor	$0.0593	
Hot haul	.0498	
Street laying	.1974	
Maintenance of plant and tools	.0188	
Supervision	.0432	
Total		$0.3685
Total cost per cubic foot		.4529
Asphaltic Concrete Mixture		
Material cost:		
Screenings, 0.5 cu.ft., at $1.30 per ton		.0331
Sand, 0.5 cu.ft., at $1.43 per cubic yard		.0265
Limestone dust, 4.2 lb., at $3.63 per ton		.0076
Asphaltic cement, 9.16 lb., at $19.10 per ton		.0875
Total cost of material		$0.1547
Manufacturing and placing cost		.3685
Total cost per cubic foot		$0.5232
Topping Mixture		
Material cost:		
Sand, 1.0 cu.ft., at $1.43 per cubic yard		$0.0530
Limestone dust, 4.2 lb., at $3.63 per ton		.0076
Asphaltic cement, 9.16 lb., at $19.10 per ton		.0875
Total cost of material		$0.1481
Manufacturing and placing cost		.3685
Total cost per cubic foot		$0.5166

A summary of the costs of material, operation, hauling, laying, maintenance and supervision is given in the table. The cost of minor repairs to sheet-asphalt pavements during the year averaged 1.7c. per square yard on a yardage of 3,064,706. The average costs for the past 10 years have been as follows: 1908, 3.8c.; 1909, 2.3c.; 1910, 2.6c.; 1911, 2.2c.; 1912, 2.4c.; 1913, 2c.; 1914, 1.9c.; 1915, 1.9c.; 1916, 1.8c.; 1917, 1.5c. The municipal asphalt plant began operations in 1912.

Heaviest Rapid Transit in New York City

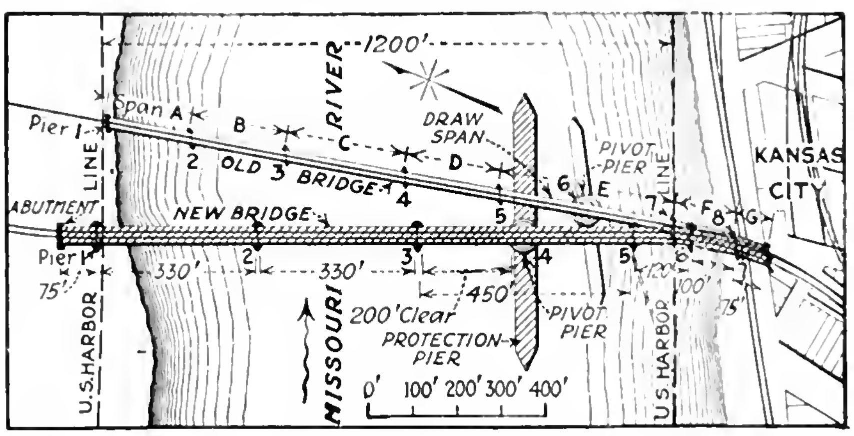
Record-breaking traffic on the New York rapid-transit lines occurred on Mar. 24 and 25, due to military reviews held in New York and Brooklyn. On Mar. 24, 1,824,735 passengers were carried on the subways of Manhattan Borough, and 1,332,607 passengers on the elevated lines of the same borough, making a total of 3,157,342. On Mar. 25 the corresponding figures were 1,753,772, 1,122,894 and 2,876,666. The latter figure is in excess of any previous record up to the day before. An unusually heavy traffic was also carried on the Brooklyn elevated lines, a few of these showing record-breaking figures.

Dismantle Bridge Spans Carefully for Use Elsewhere

Old Missouri Bridge of Burlington Railroad Is Removed—Drawspan Tied to Pivot Pier While End Panels Are Cut Off

REMOVAL of the old Missouri River bridge of the Chicago, Burlington & Quincy R. R., in 1916-17, was complicated by partial overlapping of the new bridge—which necessitated alterations under traffic—and by the requirement that the work should be done with such care as to permit re-erecting the spans at other sites. High water made it desirable to omit falsework at some points and compelled its omission at two spans. In dismantling the drawspan, cables anchored to the floor system held the span balanced on the pivot pier while corresponding members were removed simultaneously from opposite ends of the span.

This work followed the construction of a new bridge



LOCATION OF OLD AND NEW BRIDGES AT KANSAS CITY

partly alongside and partly on the same location, the old and new bridges forming a V, with the point on the south shore. At this point the approach is practically fixed, as it lies along a steep bluff with a high retaining wall protecting the tracks and through a cut on a heavy reverse curve. This made the center lines nearly identical for about 150 feet.

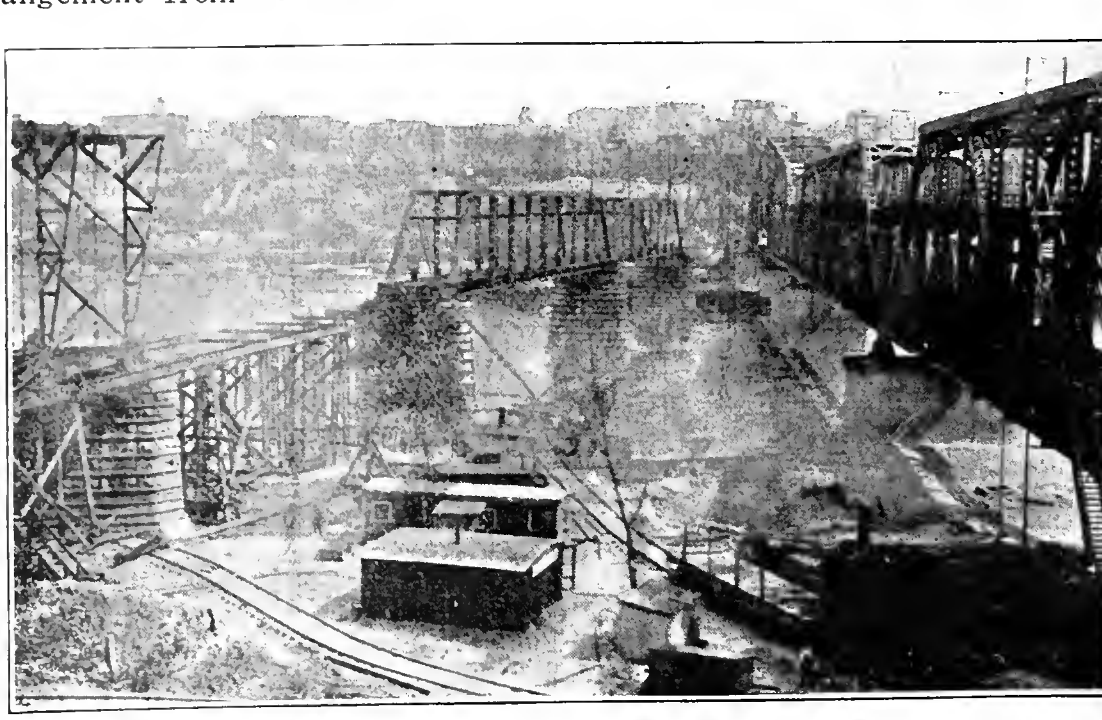
The old structure was known as the Hannibal bridge, having been built by the Hannibal & St. Joseph R.R. in 1867-69. Its original Howe trusses had been replaced at various times by steel spans. The arrangement from north and south was as follows: Four through truss spans of 177 ft., 200 ft., 250 ft. and 199 ft.; through truss swing span of 363 ft.; through truss span of 130 ft., through girder span of 69 ft. Dismantling the two south spans under traffic was necessary from the fact that they interfered with the new bridge. The other five spans were removed after traffic had been transferred to the new bridge. The relative positions of the old and the new bridges are shown by the plan. For the 69-ft. girder span, falsework was built downstream to permit rolling it out, which was done by a hoisting engine mounted on a flat-car on a track which passes under the bridge, the engine operating two sets of triple-blocks with $1\frac{1}{2}$-in. manila cables. The falsework was extended upstream to carry the new girder span, which was pulled into position in the same way.

The use of pile falsework was not advisable for the removal of the 130-ft. truss span, because of loose rock and shale dumped beneath the span, and of the danger from high water. Two heavy frame bents set on the concrete footing of the new pier No. 6 supported four 75-ft. deck girders, whose outer ends were carried on a timber grillage on a limestone ledge near pier No. 7. The bents were anchored to the shaft of the pier by dowels, and were high enough to allow for a 20-ft. rise in the river. Frame bents on the girders were placed under the panel points, and falsework stringers and blocking were placed on these.

As the old span extended about 40 ft. over new pier No. 6, a set of old 44-ft. girders was set between new pier No. 6 and old pier No. 7, to serve as falsework during the wrecking of the span and also to carry the traffic as long as the old bridge was in service. The old single track was connected at the south end of the draw with the outbound track on the new double-track through girder span which was then in place. This gave a dead-end spur on which the derrick car stood while taking down the old trusses and loading the members onto flat-cars placed behind it. From the crane boom was hung the ram with which the truss pins were driven out.

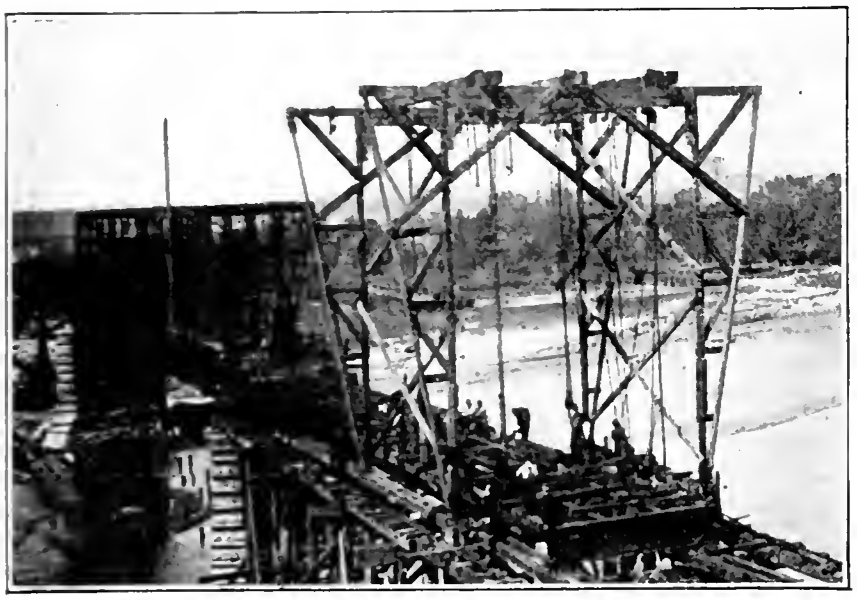
Removal of the old drawspan was the first proceeding as soon as the new structure had been opened to traffic, for until it was partly removed it was impossible to place the 120-ft. deck girders between the new piers Nos. 5 and 6, and to complete the double track. The use of falsework was dispensed with as a matter of economy and to avoid danger from high water. Four lines of $\frac{7}{8}$-in. cable were run at about 45° from the floor-beam of the second panel point on each side of the center panel and anchored to the pivot pier. In the dismantling, similar pieces were removed from each end at the same time, keeping the span balanced on the pier by means of the cables.

By blocking up on the downstream protection crib of the new pivot pier, and using this pier as falsework, the crane from the north end was run out on the second



MIDDLE SPANS WERE LEFT UNTIL THE LAST ON ACCOUNT OF HIGH WATER—AT THE RIGHT IS THE NEW BRIDGE

panel of the old draw. Five panels were removed by this crane and three by a crane on the south end. For this work 60-ton erecting cranes were used, fitted with 75-ft. booms. They loaded the steel on flat-cars placed behind them. The north crane stood on the old span D. The south crane worked from the outbound track, standing on the 44-ft. falsework girders between the old



TRAVELER IS USED FOR REMOVING TRUSS SPANS

pier No. 7 and the new pier No. 6. The remaining panels were removed by a 100-ft. steel boom rigged to a post of the new span and operated by a hoisting engine anchored on the outbound track, which had not been put in service at that time.

For removal of the fixed spans north of the draw, it had been intended to drive falsework and remove them in order, beginning at the draw, thus using the old track connection to handle the material. A rapid rise in the river, however, washed out several bents driven under span D, and the contractor decided to wait until all danger of spring high water was over. As this would have seriously delayed removal of the old piers, the railway company assumed part of the additional cost of removing spans C and D, and the contractors agreed to remove spans A and B at once.

A light overhead traveler was built on the job and erected on falsework placed under span B, this being outside the main current and in little danger from high water. While this span was being dismantled, frame bents were erected under span A, using five yellow-pine piles as posts in each bent. The same traveler removed this span and loaded the material on cars. This work had released piers 1 and 2 for wrecking, and as the river was still too high to permit driving piles in the channel, the removal of spans C and D was left until early in the fall of 1917.

Falsework piles were 70- to 80-ft. yellow-pine sticks. Those for span D were driven by a steam hammer in leads erected on a barge, while those for span C, where the water was only about 1 ft. deep, were driven by the same hammer in leads suspended from the top laterals. As the material was removed by the traveler it was run on a push-car to the north end of span C and loaded into cars by a stiffleg derrick set up on short piles and having an 80-ft. stick for a boom. The heaviest sections were end posts weighing about 3¾ tons.

Piles under span D were pulled by a triple block on a short boom rigged up on the barge. Those under span C, in an exposed sand bar, were pulled by a hoisting engine on the ground using a triple block hung from a gin-pole. This consisted of a 60-ft. pile with its lower end set on a short stringer and the top held by guys. The stringer was skidded from bent to bent.

Care in removing the spans was required by the contract, as the bridge department of the railroad intends to erect all the spans over other streams. It even specified the drilling out of rivets if necessary to prevent injury to the metal. Driving nuts were specified for removing pins, but most of these had been cut so badly by the eyebars, some to a depth of ¼ in., that new pins will be required in reërecting the spans. The parts were matchmarked by the contractors and were shipped to the railroad shops at West Burlington, Iowa. There they are being worked over, parts of the floor systems which were badly rusted being replaced. The drawspan will be converted into simple spans. Removal of the substructure will be described in a separate article. The superstructure was taken down by the American Bridge Co., under the direction of G. A. Haggander, bridge engineer of the Chicago, Burlington & Quincy R.R., with H. W. Smith as resident engineer.

Highway Bridge Piles Concreted to Avoid Replacing

Work Accomplished Without Interruption of Traffic When Piles Had Been Practically Destroyed by Teredos

By F. E. Semon
City Engineer, Port Angeles, Wash.

COMPLETE reconstruction of the pile foundation of a long wooden highway trestle which had been honeycombed by teredos, and the consequent interruption of highway traffic, were avoided by casing the affected portions in concrete. The bridge was a 2000-ft. connection across the bay at Port Angeles, Wash., and, being the only route, it was necessary to keep it open for traffic. Inspection showed that the piles were nearly eaten away at the ground line, there being only about 4 in. of riddled wood at the center. Instead of trying to renew them, it was decided to place the con-

FIG. 1. FORMS BOLTED TOGETHER AROUND PILES READY FOR CONCRETNG AT LOW TIDE

crete, thus protecting them from further ravages by the borer. Untreated piles last here only about three years.

In the placing of the casings, all work was carried on from the bridge floor. Sand and gravel were obtained from the beach near by, mixed in proper proportions, loaded in dump wagons and conveniently distributed on the floor. Cement was stored in small knockdown sheds, and water was provided by a 6-in. water main resting on brackets under the bridge, the pipe being tapped at suitable intervals.

The forms, which are shown in an accompanying illustration, were designed so as to be knocked down easily, and were constructed of 1-in. boards dressed on one side and nailed to 2 x 4-in. pieces. Four ½-in. iron rods were passed through the 2 x 4-in. pieces and tightly drawn up by nuts at either end, to hold the frames together. The inside faces of the forms received a heavy coat of black oil. The forms were 2 ft. square, inside measurement, and a piece of 4 x 4-in. timber sawed diagonally was nailed in the corner. It was found that forms not more than 6 ft. in length were the most convenient; if necessary they were extended after the first length had been filled with concrete.

Placing of the forms was accomplished at low tide, and the filling was done during the 8-hour period of lowest tide. It was afterward found that suitable wood

FIG. 2. PILES WERE HONEYCOMBED BY TEREDO AND COVERED WITH BARNACLES BEFORE REPAIR

yokes made from 2 x 3-in. material and of such size that they could be wedged around the outside of the forms, thus drawing them together, were much easier to erect, adjust and knock down than bolted forms. The forms were braced to the piles to keep them from floating at high tide.

Concreting was done with a small mixer, the proportions being one part of cement to five of aggregate. Each batch was turned for about 1 min., or until a very thorough mixture was obtained, and wheeled in barrows to the chute that led into the form around the pile.

The complete force consisted of nine men, one to handle the sand and gravel, one to put in the cement and water and run the mixer, two to wheel the mixed concrete to the chute, one to tamp the concrete in the forms, one carpenter and two helpers to erect the forms, and a foreman. All work was done by city force account.

The sand and gravel cost 60c. per cubic yard, delivered. The cement cost $2.45 net per barrel, and the rental of the concrete mixer, including the operator, gasoline and oil, was $5 per day. The laborers were paid $3 per 8-hour day and the foreman was paid $4. In all, 222 piles were concreted, with an average length of 7 ft.; the cost per pile was $7. The cost of concrete in place per cubic yard, including the cost of form setting, was $10.

Every effort was used to get dense concrete, not only to support the bridge, but also to overcome further destruction by teredos. Thus far results have been very satisfactory. The base of the jackets extended to 1 ft. below the ground and the top to a point slightly above ordinary high-water mark.

Baths', Pressure and Pipes' Influence Effect of Water Meters

THREE factors which may have an important bearing on the effect of metering upon the water consumption, but which are seldom taken into account, are noted by H. P. Matte, chief sanitary engineer of the Illinois State Department of Public Health, in a recent paper presented to the Western Society of Engineers. The three factors are as follows: Pressure upon the water system; extent of house connections with sanitary sewers, especially the use of bathtubs and water closets; effective size of mains and services.

The average pressure is rarely included in comparing per capita rates of consumption, says Mr. Matte, although in cities with higher pressure the leakage rate both through fixtures and underground piping will be greater than in those which maintain a lower average pressure. In Oak Park, Ill., the per capita consumption is varied between 1 and 2 gal. for each pound of change in pressure. That is, variation of 10 lb. either way will make a difference of 10 to 20 gal. per capita daily. Thus, the Oak Park rate of 65 gal. at 45-lb. pressure can be reduced to 45 gal. at 25 lb. In Niagara Falls, N. Y., where the rate was 300 gal., exclusive of the industrial use, Mr. Matte determined this rate to be from 3 to 5 gal. per pound change in pressure, or 30 to 50 gal. per capita for each 10-lb. change.

Consumers having faucets only are seldom classified separately from those having all the sanitary conveniences. In Oak Park it was determined that where no leaks or waste existed the average consumption per capita was 20 gal. for water closets and 15 gal. for bathtubs. A person who takes a cold bath every morning is likely to consume 40 gal. per day in this item. Low pressure and consequent increase in time required to fill the tubs often reduces the consumption for baths.

Limited services and sanitary facilities in foreign cities, cutting down the number of outlets for consumption and fixture leakage, are mainly responsible for their low per capita consumption, according to Mr. Matte. Figures obtained three or four years ago indicated that some European cities of over 2,000,000 population had about as many service connections as the average city of 300,000 in this country, while the number of services in foreign cities of about 350,000 equalled that of our cities of 40,000.

Loss of pressure by friction from the reduced area of corroded lime-coated service pipes and pipes filled with algæ, crenothrix and tubercles, indicates the importance of the effect of size of service pipes and mains on leakage and waste. Water bills on metered premises in which leakage and waste exist often double in size after the renewal of service pipes, both in the ground and in the interior of the house, especially when iron pipe has been replaced.

New Methods for the Solution of Backwater Problems

Use of Diagrams With Only One Major Variable Reduces Computations and Leads To More Accurate Results

BY H. R. LEACH
Saginaw, Mich.

COMPUTING the amount and determining the profile of water backed up behind an obstruction in a stream is one of the most difficult problems with which the hydraulic engineer is confronted. The complicated conditions which arise in actual practice,

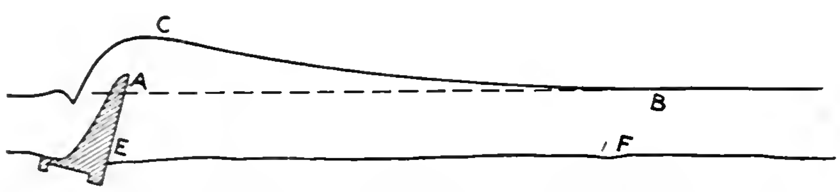


FIG. 1. OUTLINE OF A TYPICAL BACKWATER CURVE

coupled with the numerous variable factors which affect the results, often lead the engineer into a maze of calculations which render complete solution far from easy. It is the purpose of the present paper to explain some methods of treating this problem which the writer has found helpful in eliminating some of the more tedious parts of the computation, and which he believes will lead to more accurate and complete results.

A simple case of backwater is shown in Fig. 1. EF is the bed of a stream channel and AE represents a spillway or other obstruction placed across the channel at E. Under normal channel conditions, with no obstruction at E, the water-surface profile for a given discharge is shown by AB. With the obstruction in place the water-surface profile for this same discharge is shown by CB. The difference in elevation between these two profiles is the amount of backwater caused by the obstruction for the given flow. The usual method of determining the profile CB consists of dividing the channel upstream from the obstruction into reaches, computing the fall through each reach by means of slope calculations, and with this data plotting the backwater profile. The equation to be used in computing slopes through the reaches will be considered first.

The writer has adopted Manning's modification of Kutter's formula for the flow of water in an open channel, but this method is not confined to the use of this formula. Any discharge formula of the type $v = Cr^a s^b$ may be used provided C does not vary with s, so that it is adapted to either Bazin's or Manning's formula, or to some of the more recent exponential formulas. For a justification of the use of Manning's formula and a comparison with Kutter's formula, the reader is referred to the excellent discussion of this formula in King's "Handbook of Hydraulics." The coefficient of roughness in this formula is in most cases identical with that in the Kutter formula, and the engineer in adopting it can still think of channel roughness in terms of n.

By Manning's formula

$$v = \frac{1.486}{n} r^{\frac{2}{3}} s^{\frac{1}{2}}$$

in which n is identical with Kutter's n. For any short reach of a channel there is a definite relation between the depth of water in the channel, the discharge through the channel, and the slope of the water surface required to give this discharge, so that if any two of these quantities are known the third is also determined. The discharge of an open channel using Manning's formula equals

$$Q = CAr^{\frac{2}{3}}s^{\frac{1}{2}}$$

in which $C = 1.486/n$. For any given channel of uniform cross section $CAr^{\frac{2}{3}}$ is a definite quantity for a given depth, as it is dependent only on the size and shape of the cross-section of the channel, hence a curve can be drawn showing the values of this quantity corresponding to any assumed depth. This quantity $CAr^{\frac{2}{3}}$ has been called K_d to indicate a quantity varying only with the depth of water in the channel. Substituting in Manning's formula $Q = K_d s^{\frac{1}{2}}$, this equation is readily solved by a logarithmic diagram, Fig. 5, in which the Q lines are parallel, with a slope equal to $\frac{1}{2}$, and spaced on any s line in proportion to values of K_d. Only the Q lines corresponding to the discharges to be used in the problem need be drawn, though a complete diagram once drawn can be used in any problem.

The practical advantage in the use of the factor K_d is that this one quantity replaces three other variables, and thus eliminates the necessity for any further consideration of them, when it has once been computed. Besides this, it gives a direct index to the carrying capacity of the channel having the given cross-section and might well be called a "type curve" of the cross-section. Aside from the backwater problem, the writer believes that this curve may be adopted to advantage in many other fields of open-channel computation.

In solving the backwater problem, it is first necessary to divide the stream above the obstruction into reaches of suitable length. Each reach should be selected so that the channel conditions throughout its

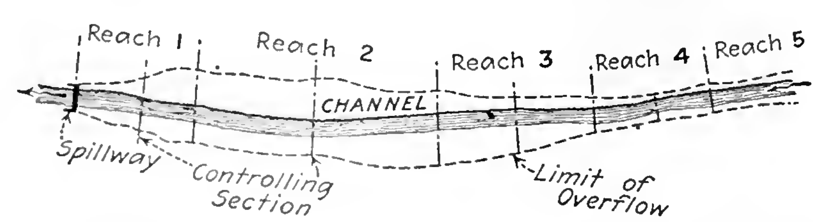

FIG. 2. METHOD OF DIVIDING A STREAM INTO REACHES

length are as uniform as possible and so that it may be fairly represented by one typical cross-section. The cross-section area of the stream determines the surface slope required for a given discharge, and hence any material change in this area, either through restriction of the channel or change in the depth of the water, will change the slope. With a slight slope, however, there may be considerable change in slope without material change in the total fall through the reach, so that in that portion of the stream near the obstruction where the slopes are comparatively flat, longer reaches may be used.

After the reaches have been chosen, the next step is the selection of a typical cross-section for each reach. For this it is desirable to use the average of several cross-sections of the stream in the reach, but where this is not possible care should be exercised to select a section representative of the entire length of reach. When the controlling sections have been selected, the K_d curve is drawn for each section, Fig. 4. This is done by determining the area and hydraulic radius for several depths covering the probable range in stage of water surface, and computing the value of K_d for each of these

depths from the equation $K_d = CAr^{\frac{2}{3}}$. Only enough values need be computed to determine the curve for each section.

In order to start the backwater calculations, the elevation of the water surface at the point of obstruction for the given or assumed discharge should be determined. If the obstruction is a weir or an overflow dam, the discharge curve for the dam is easily com-

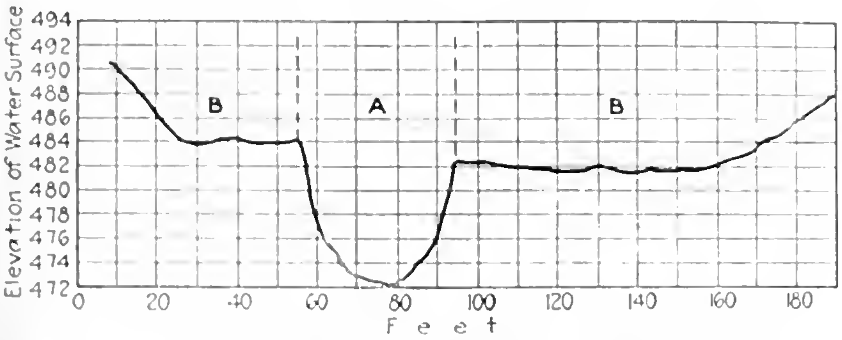

FIG. 3. TYPICAL CROSS-SECTION OF REACH (SEC. 1)

puted (see "Weir Experiments, Coefficients, and Formulas," by Robert E. Horton, Water Supply Paper No. 200, U. S. G. S. for data on discharge coefficients of weirs and dams), and this will give the elevation of the water surface above the dam for any discharge. The water-surface elevation above the dam which is found for the given discharge is the elevation of the water at the foot of the first reach. The elevation of water at the location of the controlling section of the first reach is then assumed, and the corresponding value of K_d taken from the K_d curve. With this K_d and the given discharge, s is taken directly from the logarithmic discharge diagram. Multiplying s by the distance from the foot of the reach to the controlling section gives the rise in water surface, and this added to the water-surface elevation at the foot of the reach gives the elevation at the section. If this elevation corresponds to the assumed elevation used in getting K_d, the assumption was correct, but if it does not, a second trial must be made, assuming a different elevation at the section and using the result of the first trial as a guide. When the computed elevation at the section coincides with the assumed elevation, the correct slope through the reach has been found. The fall through the reach is then computed, and this added to the elevation of water at the foot gives the elevation at the head of the reach. This is also the elevation of water surface at the foot of the reach above, and with it as a starting point the slope through Reach 2 is computed, using the same method as for Reach 1. In a similar manner, the computation is carried through the successive reaches as far as desired, or to the point where backwater becomes zero.

It may be stated in passing that the advantage of working through the slope calculations with only the

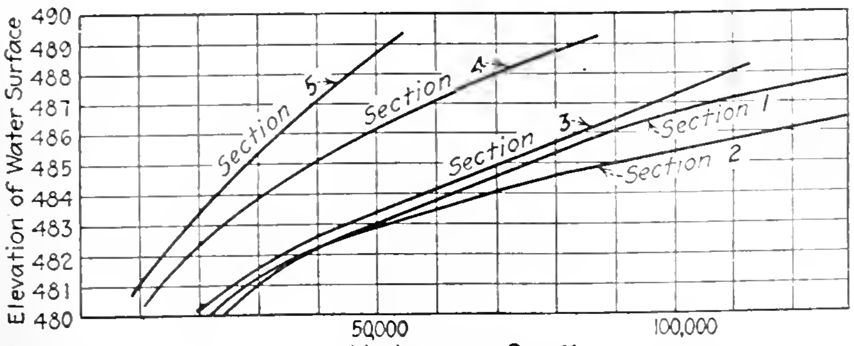

FIG. 4. CURVES SHOWING TYPICAL VALUES OF $K_d = CAr^{\frac{2}{3}}$

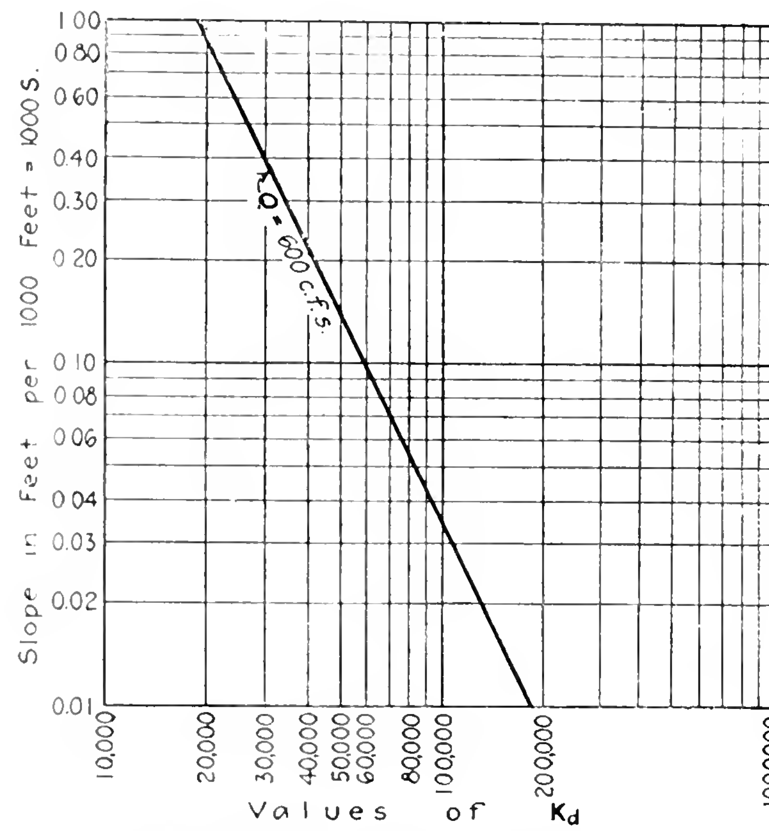

FIG. 5. DIAGRAM FOR THE SOLUTION OF $Q = K^p \sqrt{s}$

three quantities Q, K_d and s, instead of the six factors involved in the usual method, more than compensates the slight additional labor required in computing the K_d curves.

It will be noted that the coefficient of roughness has considerable effect on the results shown by the computations, and that it is therefore important that the value of this factor should be correctly determined. With a constant discharge, s will vary as n^2, and a small variation in the value of n will cause a relatively large variation in the required slope. If the slope is slight, a considerable change in its value may not produce any material change in the fall through the reach. As the slope increases, however, it becomes increasingly important that the roughness coefficient be correctly determined. Where it is possible, an actual profile of the water surface for a given discharge should be made,

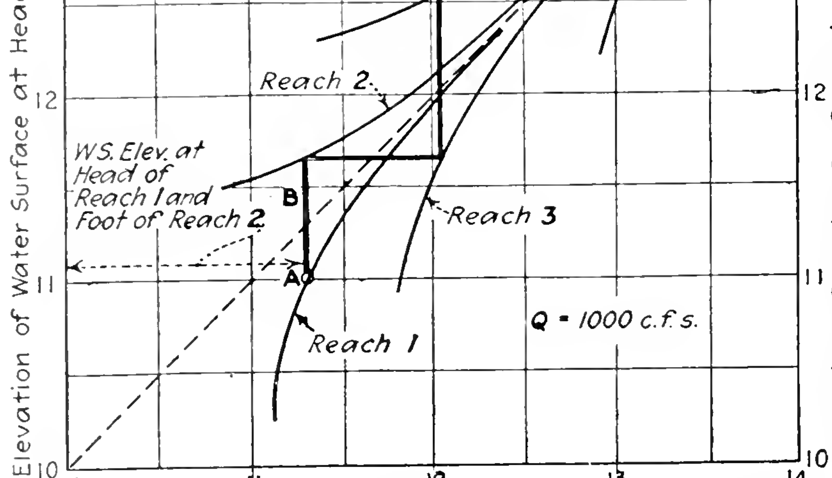

FIG. 6. CURVES FOR THE SOLUTION OF THE BACKWATER PROBLEM WHEN THE INITIAL WATER STAGE IS NOT DEFINITELY DETERMINED

TABLE I. METHOD USED IN TABULATING CROSS-SECTION DATA

Elevation of Water Surface	Channel Section: Area of Section A	Width of Water Surface w	Mean Depth d	Wetted Perimeter	Hydraulic Radius r	$r^{\frac{2}{3}}$	$K_d = \frac{1.49}{n} Ar^{\frac{2}{3}}$ $n = .030$	Overflow Section: Area of Section A	Width of Water Surface w	Hydraulic Radius r	$r^{\frac{2}{3}}$	K_d $n = .040$	Combined K_d
Section No. 1													
480	190	35	5.4	46	4.13	2.57	24,200	.	...	....	..	......	24,200
482	264	38	7.0	52	5.08	2.95	38,500	.	...	...	...	......	38,500
484	340	38	8.9	56	6.07	3.32	55,900	135	78	1.69	1.42	7,100	63,000
486	417	39	10.7	60	6.95	3.64	75,200	231	120	1.86	1.51	13,000	88,200
488	495	39	12.7	64	7.73	3.91	95,800	489	135	3.52	2.31	42,000	137,800

and this will give the data from which the roughness coefficient can be determined. Where this is not possible, it is advisable to investigate the effect of a change in the coefficient of roughness on the backwater profile. The assumption of too low a value for the roughness coefficient decreases the elevation of the water surface profile but increases the amount of back water, and vice versa. This is because the depth of water for a given discharge would be lower under normal channel conditions (no backwater) with the lower coefficient.

The case of the divided-flow problem offers the greatest opportunity for advantageous use of the K_d curve. This problem arises when the cross-section is so irregular that the flow in adjacent parts of the channel must be considered separately. This is best illustrated in the case of a channel in which the water is above the banks, so that for accuracy the flow over the adjoining overflow lands must be considered separately from that in the channel proper. The elevation of water surface throughout the reach must be the same for both the overflow land and the channel, so that, ordinarily, the given discharge must be apportioned by trial between the two until this condition is satisfied. The use of the K_d curve eliminates the necessity of proportioning by trial. The discharge capacity through the reach will depend directly on the total capacity of the two (or more) sections. Values of K_d are computed separately for the channel and for the overflow land, and these are combined to form one K_d curve for the entire cross-section which gives the total capacity of the entire cross-section at any depth. The slope calculation is then made in exactly the same manner as for a simple channel, using the K_d curve for the combined sections. A typical backwater problem is illustrated by the channel shown in Fig. 2. This shows the reaches selected and the location of the cross-section controlling each reach, which will usually be at the middle of the reach. Fig. 3 gives one of these cross-sections and shows the manner in which the flow through the section is divided in order to allow for the irregularity of the section. A is the normal stream channel and B the overflow land. Table I gives a tabulation of the data and the results used in determining K_d for this section, and Table II shows a convenient method of tabulating the slope calculations.

TABLE II. METHOD OF TABULATING BACKWATER COMPUTATIONS

Number of Reach	Length of Reach	Elevation of Water Surface at Controlling Section	K_d	S Ft. per 1000 Ft.	Fall Through Reach	Elevation of Water Surface Foot of Reach	Elevation of Water Surface Head of Reach
Discharge = 600 c.f.s.							
Elevation of water surface above spillway from discharge curve = 485.26							
1	400 ft	485.27	79,000	0.058	0.02		485.28
2	800 ft	485.30	101,000	0.036	0.03	485.28	485.31
3	500 ft.	485.32	75,000	0.064	0.03	485.31	485.34
4	400 ft	485.38	42,000	0.203	0.08	485.34	485.42
5	500 ft	485.52	31,000	0.375	0.19	485.42	485.61

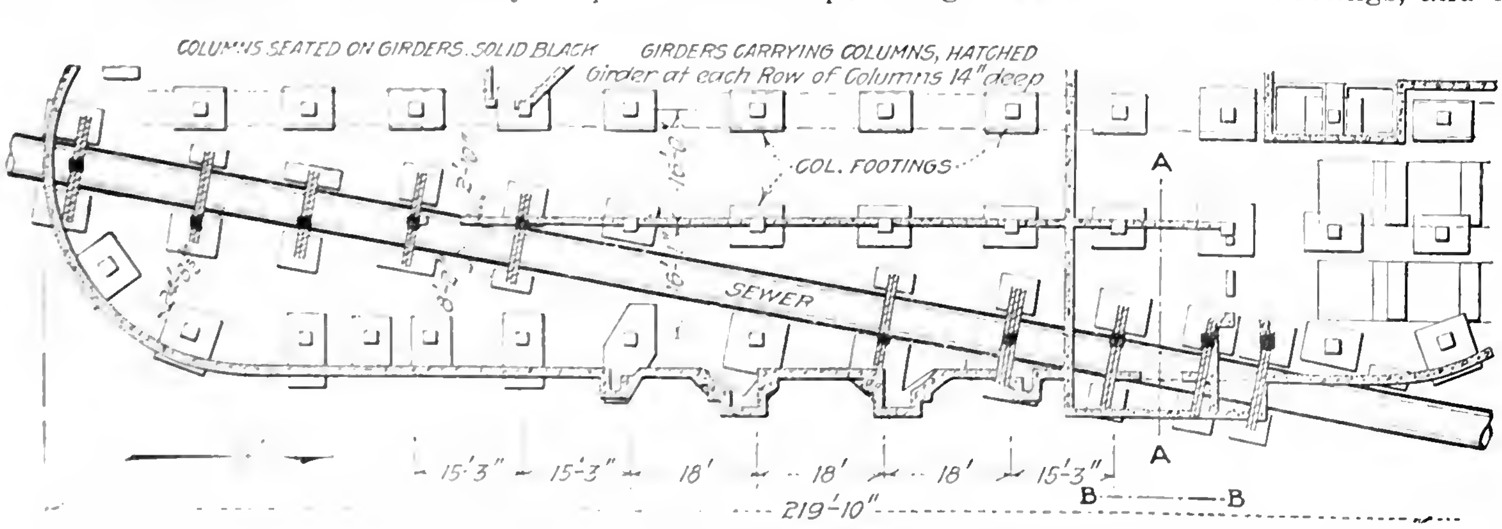
It may sometimes occur in backwater problems that the initial water-surface elevation at the lower end of the channel is unknown or not definitely established. Such a case might arise in the investigation of a proposed dam of undetermined height. It is obvious that for each assumed stage at this point, with a given discharge, there will be a different backwater profile. The writer has found the method shown in Table II very convenient in arriving at a complete solution of this problem.

Sewer Complicates Foundation Plans

Armory Building Has Concrete Columns Seated On Girders Spanning Sewer — Basement Floor Is Carried by Girders

UNSYMMETRICAL arrangement of the foundations of a Chicago armory was made necessary by the presence of a 4½-ft. brick sewer which crosses the site diagonally, as shown in the accompanying plan. The armory, built for the Second Illinois Cavalry, is a reinforced-concrete building, with pedestal footings on wood piles.

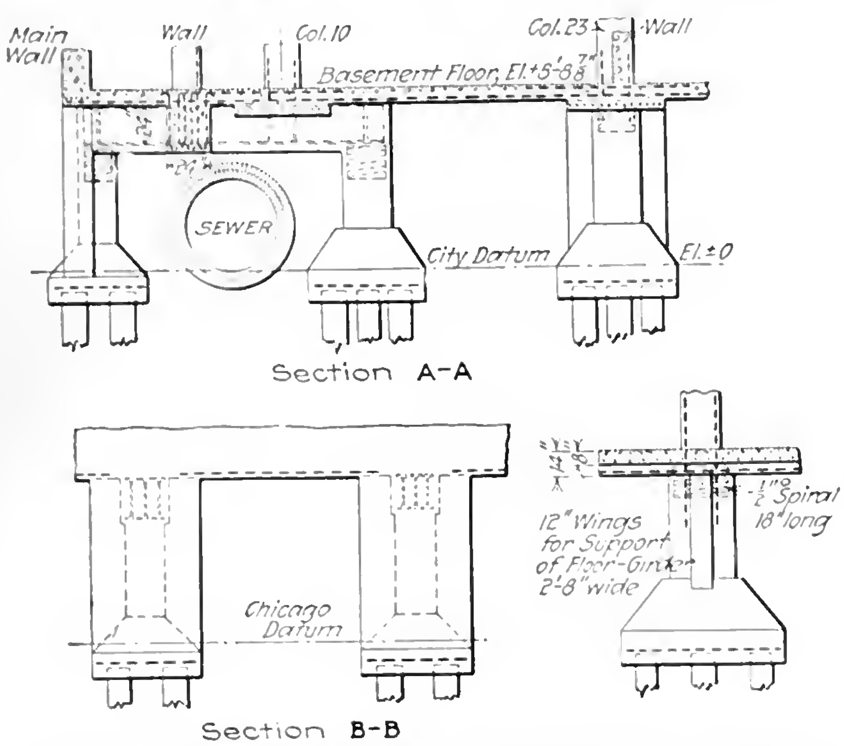
Where the sewer intersects column locations it is spanned by cross-girders which support the columns and are in turn carried by stub columns on footings on either side of the sewer. The girders are about 11 ft. long between centers of footings, and each is composed of three (in one case of four) I-beams of 18-in. to 24-in. size, the girder being cased in concrete as a protection against rust and corrosion. Where the sewer crosses the



SEWER UNDER ARMORY NECESSITATES UNSYMMETRICAL ARRANGEMENT OF FOOTINGS

line of the east side wall, this wall is carried on a continuous longitudinal girder extending between the cross-girders. The column loads on these cross-girders are from 130 to 165 tons. Typical construction is shown by the cross-sections.

Footings for the outer columns also support the 16-in. concrete wall of the basement, which is about 33 in. outside of the columns. This wall is irregular in plan, conforming to the circular or tower-shaped ends



SHORT COLUMNS CARRY CROSS-GIRDER FOR MAIN COLUMN AND LONGITUDINAL GIRDER FOR WALLS

of the building. Around the sewer and over the entire site the ground is filled to the level of the basement floor, but this fill does not carry the floor. An 8-in. slab covers the basement area, resting on the concrete footings and the cross-girders. Between the interior footings the thickness is increased to 14 in. for a width of about 4 ft., forming longitudinal girders which serve to brace the foundation and support the floor independently of the fill, as the armory is situated on ground reclaimed from the lake.

Column reinforcing consists of rods and spiral hooping, the rods being extended 4 ft. 3 in. into the footing or spliced to dowel rods 8½ ft. long, which are embedded in the footing. Spirals and dowels are omitted from the columns which rest on the I-beam girders. The floors above the basement are of slab-and-joist type, the joists being spaced 24 in. on centers and running longitudinally between the 12-in. transverse girders at the panel points. The depth of the joists is 10½ in., including the 2½-in. slab, upon which is a ¾-in. cement finish. Floor loads are 100 lb. for the basement and all floors.

This being a state building, the designs were made by J. B. Dibelka, state architect. Holabird & Roche, Chicago, as the consulting architects, prepared the plans. The general contract was let to the Hanson Brothers Co., for which C. T. McClelland was superintendent.

Electric Street-Cleaning Vans Efficient

Recent reports state that electrically propelled street-cleaning vans used in England have proved much more efficient than horse-and-cart methods for collecting street refuse. One van accomplishes the same amount of work as three carts. The operation cost per day of three carts is $19.58, while that of one van is $8.70.

Special Motor Equipment Used on Road Maintenance

North Carolina Highway Department Has Combination Truck and Tractor to Plow, Drag and Transport Materials and Men

By D. H. Winslow
State Maintenance Engineer, Raleigh, N. C.

MAINTENANCE is being succesfully handled in North Carolina by the use of specially constructed motor equipment. An interchangeable motor truck and tractor is employed and special maintenance autos are also being utilized by the district supervisor, who can thus cover a territory of from six to 14 counties. A new type of road drag is also being used.

With a view to keeping its large mileage of highways in good condition, the state has been divided into 10 districts, with a district maintenance supervisor placed in charge of each. A district consists of from six to 14 counties, and the supervisor has general supervision over all the patrolmen in his district, inspecting the roads and giving the patrolmen advice on maintenance methods. In order to cover this large territory, he is supplied with a specially constructed auto, as shown in an accompanying illustration. On account of the high prices for teams, labor and materials, the state has adopted new methods of maintenance. It was found that the patrolmen needed extra help under present conditions to cover their work, which consists of inspecting and dragging their roads after each rain, filling depressions with good material, removing débris from the right-of-way, repairing culverts, cutting weeds and brush at intersections to give a clear view, maintaining guard rails at culverts and bridges, and generally keeping the road in good condition. To give this extra help, the state has designed and had constructed special interchangeable motor trucks and tractors, which have been found of great assistance.

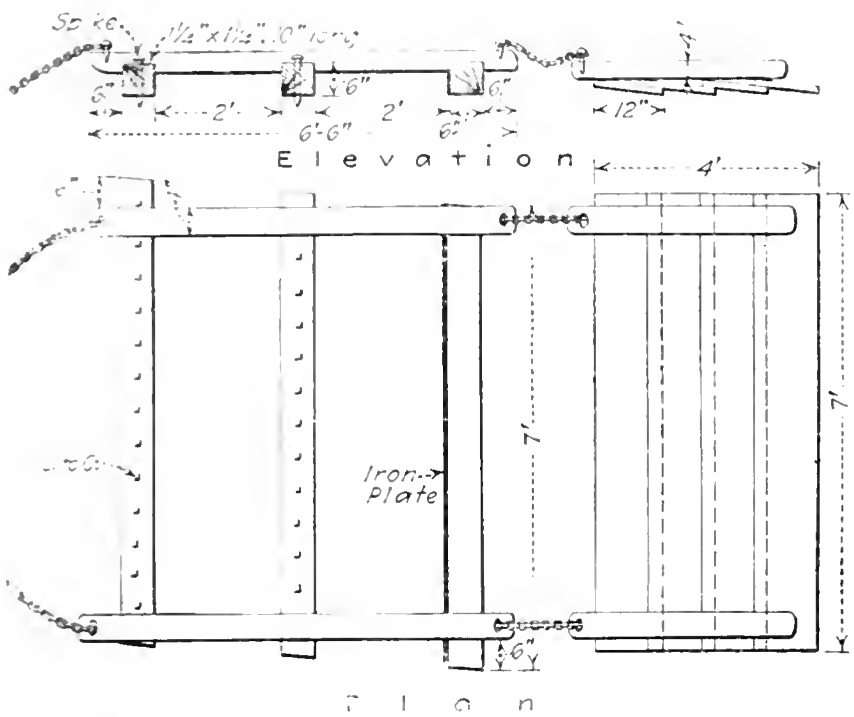
There are 100 counties in the state. Tractor trucks have been placed in 30 or more, and, on account of the satisfaction which they have given, are being placed in the others as fast as possible. A view of one of these

TRUCK WITH INTERCHANGEABLE WHEELS WORKS AS MAINTENANCE TRACTOR

trucks is shown in an illustration. Those in use at present have an ordinary small chassis with a truck body and a closed cab for the driver. The truck body is used to carry the special tractor wheels when moving from one section of road to another, and also to

carry such other equipment and men as are needed to do the work. Extra springs have been put over the rear wheels, so that a heavy load can be carried on the truck body. It is possible to change from a truck to a tractor in 15 minutes.

In some sections it had been necessary to move laborers 20 miles by mule teams, and then board the



RURAL ROAD PLANER HARROWS, DRAGS AND PACKS

men in addition to paying them. By the use of the trucks they can return home each night, which is an advantage to all concerned. As the truck is equipped with a closed cab for the operator, he is able to work in the heat of the sun and cover a greater mileage in all kinds of weather. Formerly the teams had to abandon work during very hot weather.

When the machine is used as a tractor for plowing and dragging and for hauling road machines, a special hitch is employed, so that the tractor can stay in the middle of the road while the grader operates in the ditch. It is estimated that in plowing and dragging the tractor saves the hire of from six to eight mules, and that two men can do the work previously done by four.

The highway commission is trying out a new road planer in connection with its tractor-trucks. The new planer, the details of which are shown, increases the mileage dragged in a day and does better work than the old-style drag. It is modeled somewhat after the hone and is a combination of a harrow, a drag and a packer. The forward part has case-hardened spikes and

SPECIAL INSPECTION AUTO USED BY DISTRICT MAINTENANCE SUPERVISOR

loosens the bumps on the road. The middle section cuts and spreads this loosened material. The rear portion packs the material. Unlike a road grader, it cuts the high places and spans the low sections.

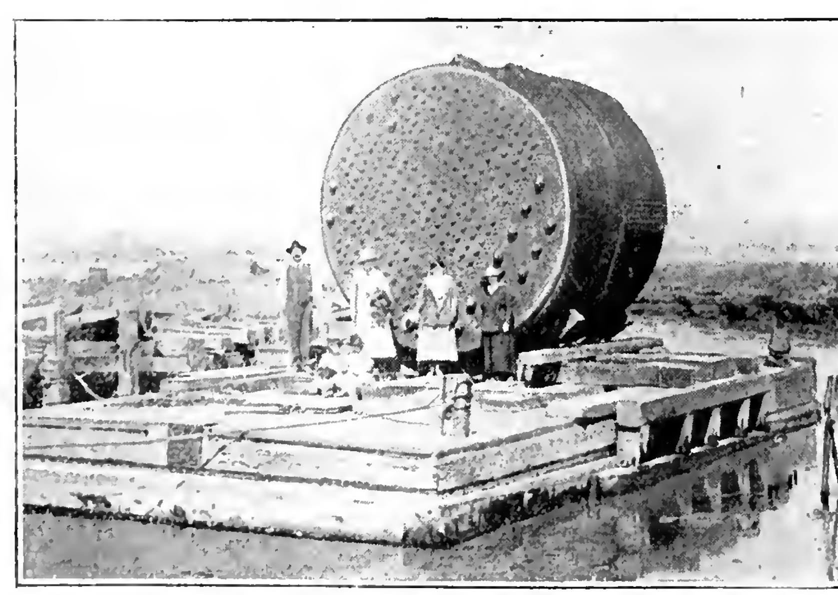
It has worked with marked success on earth, sand-clay, topsoil, gravel and on slightly worn macadam. The tractors have no difficulty in pulling it up almost any grade. By being made very light, it can be pulled with teams, but is designed for tractors or trucks.

Maintenance in North Carolina is carried on under the State Highway Commission; W. F. Fallis is state highway engineer, and the writer is in charge of the maintenance department.

How 45-Ton Boilers Were Rolled 21 Miles Along Coast

After Being Salvaged From Wreck, Donkey Engine Rolled Them, Between Tides and Storms, Along Improvised Roadway

MACHINERY and other equipment salvaged from the wrecked passenger steamer "Bear" was recently removed from the vessel as it lay stranded in the surf on the northern California coast. Salvaging the boilers presented a special problem, because of the bulk and weight of each piece. After the boilers had been taken out and landed on the beach, efforts were



LOADING BOILER ON BARGE AT MOUTH OF EEL RIVER

made at frequent intervals, extending over almost a year, to salvage them by towing them to sea. This plan was then abandoned, and a contracting firm undertook to deliver them at a wharf in Eureka, Cal., for a fixed sum. The boilers were successfully moved by rolling along 21 miles of ocean beach and rocky coast, making two river crossings, and finally loading them on a barge on Humboldt Bay for the last lap of the journey.

A donkey engine and other necessary equipment were landed on the beach near the boilers after they had been brought ashore, and a rough roadway was built on which to roll them. For the most part the roadwork consisted of breaking up large rocks with dynamite, but there were also several deep cuts which had to be made in solid rock. Part of the way work could be carried on only during calm weather and at low tide, because at high tide the surf broke against the cliffs. Progress was frequently delayed because a rough sea would wash out the roadway prepared for the moving operations.

PASSING THROUGH ROCK CUT IN BASE OF CLIFF

The boilers weighed 45 tons each and measured 12 ft. in length by 13 ft. 8 in. in diameter. They were rolled along one at a time by means of a single $\frac{3}{4}$-in. line from the engine drum. The end of the line was attached to the front of the engine frame and was laid thence along the ground, the bight being passed around the boiler and back to the engine drum. This method gave a direct pull on the boilers, and if roadway conditions had been favorable they could have been moved ahead at a rapid rate.

One of the chief problems was to keep the boilers rolling straight. With a diameter greater than the length, there was a tendency to "head off," first in one direction and then in another. This was overcome by attaching a block to a line on the ground just ahead of the boiler and pulling over the bight of the line with a team of horses. The block was attached to the line far enough ahead of the boiler so that the pull could be made and the block loosened before the boiler reached it. Thus, the tendency to roll off to one side could usually be corrected without stopping the engine. After the line had been moved sufficiently the block would be loosened and allowed to slip along the line as the team walked ahead, until it was necessary to pull to one side again.

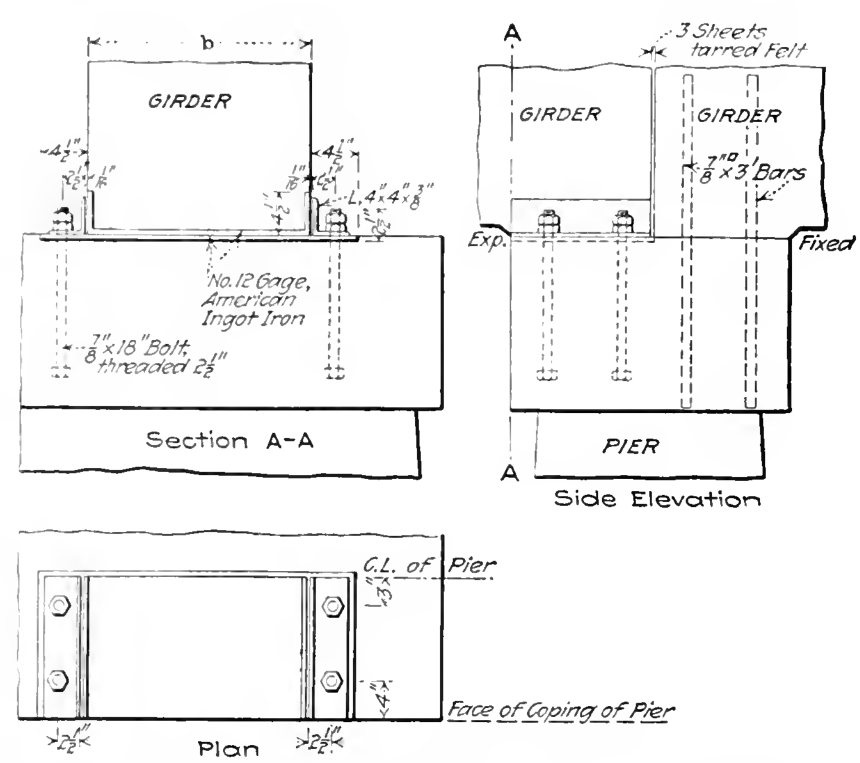
In this manner the boilers were sometimes moved an entire quarter of a mile without having to stop the engine. The donkey engine was usually set about a quarter of a mile ahead of the six boilers and they were rolled along one at a time until all had been brought up, whereupon the engine would be moved again.

In crossing the Bear River a ford was found where the boilers could be rolled across by the same method that was used along the beach. At the Eel River, however, this plan was not feasible, and there the boilers were loaded on a barge one at a time and towed for two miles to a favorable point for continuing the rolling process. On arriving at the shore of Humboldt Bay all six were loaded on a single large barge and towed to the wharf in Eureka. The contract was taken by the Mercer-Fraser Co., of Eureka, Calif., J. D. Fraser, president, and J. L. Brown, secretary.

New Type of Expansion Joint Devised for Concrete Girders

FOR a bridge just designed for the Highway Department of the State of Arizona, S. M. Cotten of the office of the state engineer has devised a new type of expansion joint, illustrated in the accompanying drawing. The joint has points of novelty and desirability for reinforced-concrete girder bridges. It consists, in effect, of a bent iron plate, in which the concrete girder is seated, which slides on a flat plate fastened to the pier, sidewise movement being avoided by guide angles also fastened to the bed plate.

The principal features of the design are ease of fabrication and low cost, according to the claims made. American Ingot Iron is specified for the plate because of the rust-resisting quality of this metal, this being a factor of most importance in the sliding expansion joint. The upper plate is not anchored to the girder in any manner. Mr. Cotten explains this feature as follows: The purpose of the expansion joint is to permit the movement of the structure with the minimum of friction. The coefficient of friction of concrete on steel



EXPANSION JOINT FOR CONCRETE GIRDER CONSISTS OF TROUGH-SHAPED STEEL PLATE SLIDING ON BEDPLATE

is much greater than that of steel on steel. Should these plates rust or for any reason develop a greater coefficient of friction between their contact surfaces then that of concrete on steel plus a certain amount of bond, the girder will move on the upper plate.

Motor Truck Used To Inspect Water-Supplies

Public water-supply field investigations made by the engineering division of the New York State Board of Health have been materially increased in number during the past season, largely by the increased facilities afforded by the use of a small motor truck. In every case they include a careful inspection of the watershed and of the conditions affecting the water-supply, and the collection of samples. The new method of transportation makes possible a much more extensive and complex sanitary control than existed heretofore.

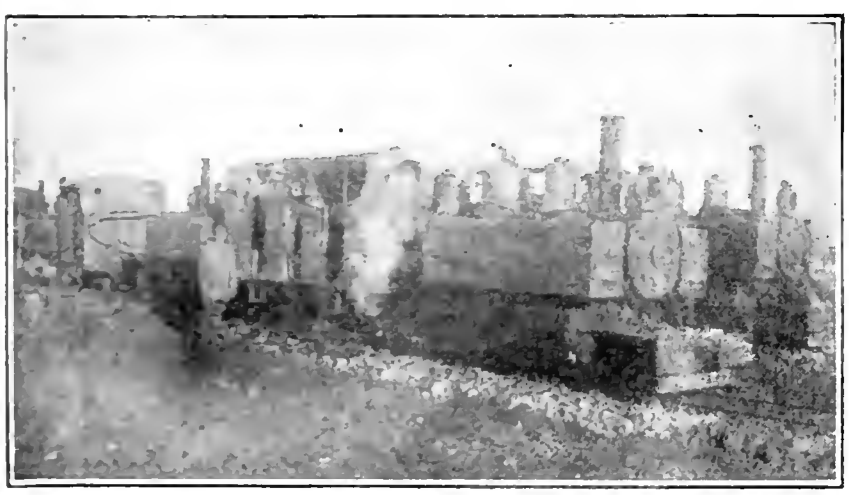
Dwarf Railways of the Front Line Trenches

The Soixante or 60-Centimeter-Gage Tracks Used For Many Purposes—Connect With Broad-Gage Railroads In Battle Areas

By James E. Sellers

Private, 23rd Engineers, American Expeditionary Forces, France

MOST effective of the "combat railways" which served the front-line trenches in the great war was the French narrow-gage *Voie de Soixante*, generally called the Soixante railway, the gage being 60 cm., or 1 ft. $11\frac{5}{8}$ in. Various types of locomotives and cars were used, and their work in the battle areas of France was of exceptional variety. The Soixante railway was used chiefly for the transportation of troops, taking the wounded from the front to hospitals in the rear, carrying to the front rations, ammunition, guns, fuel, clothing supplies, forage, water, engineering supplies, etc. The materials were received on the



AMERICAN NARROW-GAGE LOCOMOTIVE IN YARD

broad-gage track at the "railhead" and transferred to the narrow-gage cars. Some of the materials were received by canal barges.

According to the nature of the work and the proximity to the trenches, the means of transportation varied from mules and horses to the American (Baldwin) locomotives, the French double-end steam locomotives, and gas engines. It was not an uncommon sight to see three of these little "dinkies" chugging and puffing with their load of 28 cars over a grade of three per cent. The steam locomotives were used up to within 5000 yd. of the front trenches. Gas engine, horse, or man-power was used from this point to the destination, because the enemy was able to detect all movements of steam locomotives. A steam locomotive within a distance of three miles from the front, without careful camouflaging of its surroundings, would be "shot up" in 10 minutes.

Locomotives and Power

Locomotives used on the Soixante differ in size and design. The American steam locomotive, 2-6-2, is a 50-hp. engine with a wheel-drive base of 5 ft. 10 in.; total wheelbase 15 ft. 7 in.; overall length 21 ft. 7 in.; width 6 ft. 5 in.; height above the rail, 9 ft. 3 in., and weight 34,500 lb. The A. E. F. gas engine is equipped with a four-cylinder, four-cycle, 35-hp. water-cooled motor, wheelbase 3 ft.; overall length 10 ft. 9 in.; width 4 ft. $7\frac{1}{2}$ in.; height 7 ft. 11 in., and weight 8000 lb. The French double-end steam locomotive (Model 1888) has a total wheelbase of $12\frac{1}{2}$ ft.; total length about 18 ft. 9 in.; width 5 ft. 2 in.; height 9 ft. 5 in., and weight about 31,000 pounds.

Four kinds of cars were used: Box cars with a capacity of 600 cu.ft., or 22,000 lb., weighing 10,900 lb., with a length of about 24 ft., width of 6 ft. and height of 8 ft. 4 in.; gondola cars with a capacity of 210 cu.ft., or 22,000 lb., weight 9000 lb., length 24 ft., width 5 ft. 7 in., height $4\frac{1}{2}$ ft.; flat-cars with a capacity of 22,000 lb., weight 8000 lb., length 24 ft., width 5 ft. 7 in., height to the floor 2 ft. 4 in.; dump cars with a capacity of 27 cu.ft., weight 1050 lb., length 5 ft. 8 in., width 4 ft. 8 in. Tank cars, used for carrying water to the front-line trenches, were about the same design as the box car, with the exception of the tank, and weighed 12,200 lb. The French used generally a gondola car with a capacity of about 10 tons.

All buildings were made from standard designs when possible, calling for wood and corrugated-iron construction, except within the front area, where all buildings are in dugouts. It is not unusual to see a cluster of these dugouts, emerging from a cut or hillside, resembling a huge culvert, partially filled with drifting sands. From above and in front they are carefully camouflaged to resemble natural earth, and it is hard to detect them from a distance of 2000 yd., or more.

The narrow-gage railways generally run at right angles to the broad-gage line at the railhead, their main lines being connected with laterals in loop formation to form a continuous one-way road. Double tracking is only used when short hauls call for it. In this case, ample protection must be afforded to the operation of the line.

The single continuous track construction allows the handling of more traffic in a shorter time, and also tends to serve more area and allows for the diversion of traffic over any lateral when necessity demands. The average train run is about 10 miles.

Construction of the Railway

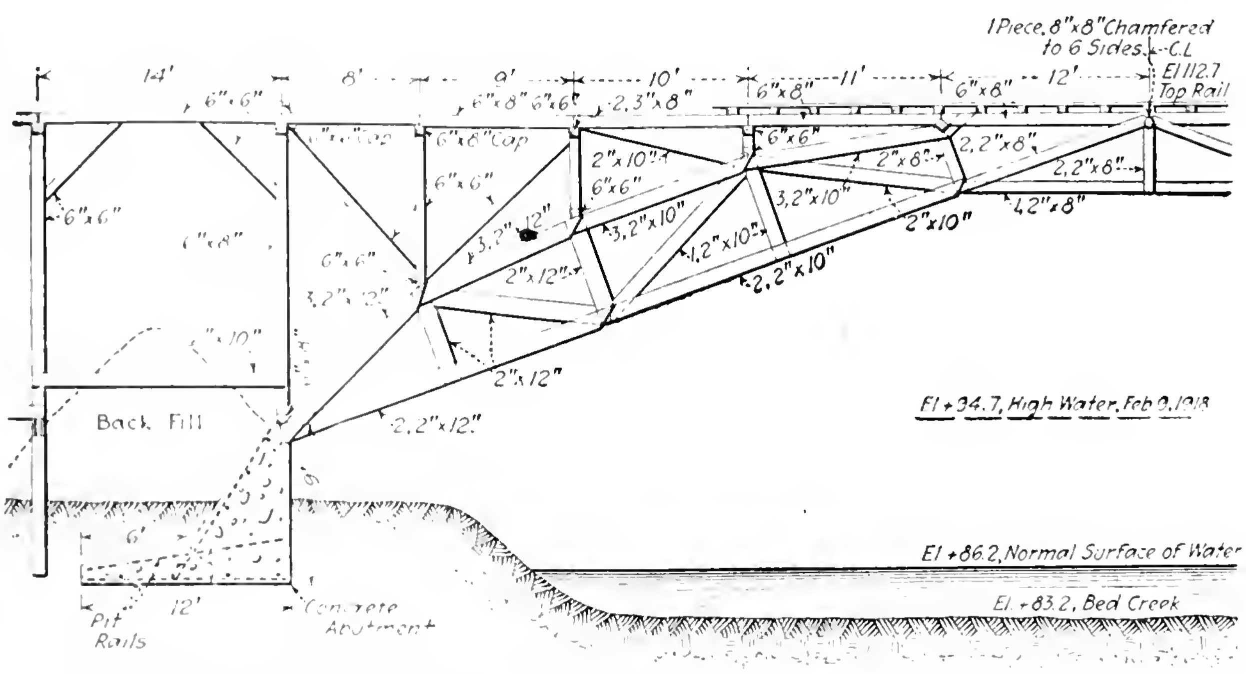
In the construction of the Soixante system it is very important that no grades should exceed three per cent., and curves should not be sharper than 50 m. (164.04 ft.) in radius. In the St. Mihiel salient the writer has traveled lines having 5% grade and 30-meter (98.42-ft.) curves, but this was unusual and would not have occurred if the topography had not made it necessary in order to traverse the territory without detection by the enemy. Compensation for curvature on grades is made at the rate of 0.02% per degree.

It is very difficult to determine accurately the cost of constructing this railway, as the data are kept by the Government. The British assume that one mile of track completely laid requires 7000 man-power hours; the French are capable of grading, tracklaying and ballasting about 0.75 m. (2.46 ft.) of roadway per man per day.

The track sections are composed of two 25-lb. rails, 5 m. (16 ft. 5 in.) in length, bolted to eight steel ties, and weighing about 25 lb. per yard. These sections are very easily handled and placed by four men. The British and French sections are similar in design, but,

instead of bolting the rail to the ties the French rivet them; the British use wooden ties in most cases in connection with steel ties, and this is also done on American lines when soft ground or muddy places are encountered. To illustrate the accomplishment of these narrow-gage railways—it is not uncommon to unload an entire trainload of supplies in 30 min. and place them in piles ready for distribution. For example, 308 tons of material have been received at 9 a.m., some five miles from the front, and in less than three hours' time placed in the hands of the cooks at the front ready to be made into "chow."

The Soixante was responsible in a great measure for the wonderful progress made by the Americans during the trying days of September, when they pushed the Huns out of the St. Mihiel sector. The many uses found for the narrow-gage railway during the past four years prove conclusively its value in military tactics.



DESIGNED IN ACCORDANCE WITH LUTEN FORMULA FOR CONCRETE ARCH

Timber Arch Bridge One Hundred Feet in Length

Forces of Fulton Coal Company Design and Build Structure—Luten Formula for a Concrete Arch Ring Used

BY D. R. WALKINSHAW
Greensburg, Penn.

A TIMBER arch span 100 ft. long was built recently over the Big Sewickley Creek at Hunker, Westmoreland County, Penn., for the purpose of getting out coal during the shortage. The bridge was designed by the writer for the Fulton Coal Co. and was erected by the forces of the company under the direction of the carpenter.

The increased demand for coal has caused the development of a large area of "Freeport" coal in the district around Hunker, which coal has hitherto been considered of little value. In a distance of five miles along the above-named creek some forty mines have been opened in the "Freeport" vein.

In order to provide the shipping facilities that were needed it has frequently been necessary to extend trestles or tipples across this creek so as to load the coal at the railroad sidings, and the accompanying sketch shows the design of one of these bridges with the various dimensions.

Big Sewickley Creek has considerable width at places, and the bridge shown was designed with a clear span of 100 ft. and a height of about 18 ft. The arched members were designed in accordance with the Luten formula for a concrete arch ring. The curve is therefore a mean between the semicircle and the ellipse. The bottom chords and trusses are merely used to stiffen the short panels. The bridge is symmetrical throughout and consists of two ribs spaced 4½ ft. c. to c. and completely X-braced. In order to prevent swaying at the center two ½-in. wire-rope guys were anchored to large trees along the bank. A photograph of the completed bridge, in which is seen the old suspension footbridge heretofore used for crossing the stream, is shown.

TIMBER ARCH CONNECTS COAL MINE WITH RAILROAD SIDING

The writer was the designing engineer and Joseph Kettering was the carpenter who had charge of the construction for the coal company.

Field Methods on Rapid Stadia Surveys at Columbus

All Lines Run by Stadia, Levels Taken With Transit—Special Rod Extension—Colored Cloths and Whistles for Signals

By H. K. Kistler

Instructor in Civil Engineering, Pennsylvania State College

COSTS and progress of the stadia surveys made for the Franklin County Conservancy District, Columbus, Ohio, were outlined by L. R. Howson in *Engineering News-Record* of Sept. 27, 1917, p. 606. A description of some of the details of the actual field work, as carried out by one of the parties, may be of interest. At the time the surveys were made the writer was assistant engineer for Alvord & Burdick and in charge of the field party making the survey of the Delaware reservoir area.

Primary transverse lines were run by stadia, the double-deflection method of measuring angles being used. Stadia distances were read in both directions on each line, the mean of the two readings being taken, or the checked-back reading in each case of apparent error in the forward reading. Levels were carried by transit. One tripod leg was graduated to indicate the height of the instrument above the hub when the point of the plumb bob was swung over to that leg. Level readings were taken in both directions on each line, and the difference of elevation was computed in both directions for each line, the mean of these differences of elevation being adopted. Where level readings could not be taken, the upper or lower cross-hair was read and the half interval applied. Vertical angles were seldom necessary on the primary line. Frequent level checks were had at United States Geological Survey bench marks. Primary traverses averaging 15 miles in length were easily kept within an error in minutes of angles of one-half the length of traverse in miles and within a linear closure of 1 in 1500, while levels always checked between Geological Survey bench marks as well as five-hundredths of the length of the levels in miles.

The transitman was provided with a referee's whistle, for signalling to the rodman. Each rodman carried a strip each of red, white and blue signal cloth. The red cloth tied in a single simple knot near the top of the rod indicated the bottom of a ditch, creek or ravine watercourse; the white cloth similarly placed meant a river bank or a road center line; the blue indicated a fence-line intersection; the hat held in the hand and waved or placed on top of the board meant the corner of a building. These signals were necessary, because one cannot call shots half a mile, and it is impossible to tell at that distance whether the rodman is at the corner of a building or 100 or 200 ft. nearer on line with it.

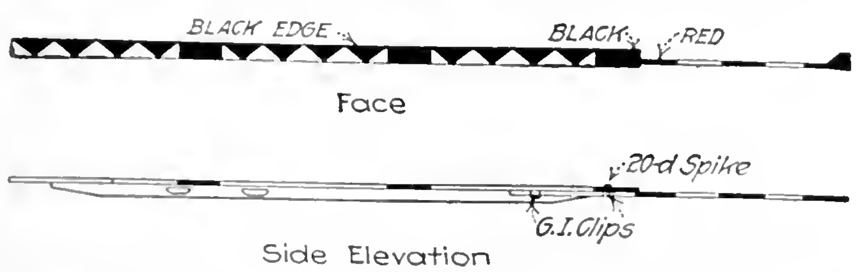
REPRODUCTION OF FACING PAGES TAKEN FROM NOTEBOOK—LOOSE-LEAF PAGES USED

In shots taken on the rod the following order was observed: Distance and level readings were taken and *remembered;* the rodman was signalled to move to a new point (one blast on whistle for Rodman No. 1 and two blasts for Rodman No. 2); the level reading and distance recorded and the azimuth read and recorded before the instrument was disturbed. If the level reading was taken the distance had been read on a



FIFTEEN-FOOT STADIA BOARD WITH EXTENSION

shot it would be taken first on the next shot, thus saving the time necessary to reset the bubble. Three blasts on the whistle indicated that Rodman No. 1 could not be seen and four blasts that Rodman No. 2 was not visible.

Inclement weather caused practically no loss of time. Each rodman was provided with a rainproof coat. A large wagon umbrella which had been treated with a coat of boiled linseed oil was used to protect the transit and the transitman during rain or snow. The umbrella was mounted on a sharpened oak post driven into the ground near the station and was carried between stations by the rodman giving backsight.

A system of rectangular coördinates was established for the area to be surveyed, and primary traverses were computed and adjusted before the plotting of topography was started. Secondary or topography lines were computed by slide rule. Having the coördinates of the primary stations previously established greatly simplified the work of adjusting and plotting the secondary lines.

A sketch, showing the station occupied, the back station and the forward station, was required for each topography point used; the top of the page being always oriented to the north. The form of notes kept is illustrated by the accompanying facing pages reproduced from the notebook.

Standard Bridge Abutments on Canal Projects

Two Types of Abutments, Reinforced-Concrete and Timber Pile, Are Used on Rio Grande Irrigation Development

By D. C. Willett
El Paso, Texas

ONE of the most serious problems in the Rio Grande project in New Mexico and Texas has been the construction of satisfactory foundation in the quicksand which underlies the surface soil throughout the region. On all main highways of the Reclamation Service, substantial timber bridges are being installed, usually with reinforced-concrete abutments of the type illustrated herewith, instead of the heavier gravity type of plain concrete walls. In this soil, piling is necessary, the piles being easily jetted into place.

The reinforced-concrete abutments, one of which (on the Borderland Road at Nemexas drain in the Mesilla valley) is illustrated here, are designed to have a base width of 70% of the height. The heel for a 6-ft. height is 2 ft. 4 in., and for each foot of height added or subtracted 4 in. are added or subtracted for the base. The wing wall is made at an angle of 45°, the length depending upon height and local conditions, the top generally having a slope of 2:1. Reinforcement is used as noted on the drawing, but for higher and lower walls the steel is spaced according to the United States Reclamation

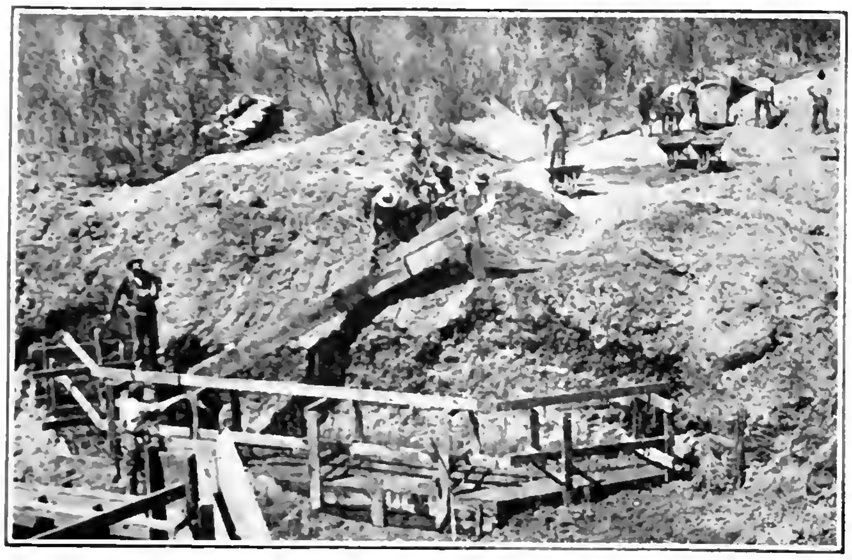
DETAILS OF THE TWO TYPES OF ABUTMENT USED FOR HIGHWAY BRIDGES



CONSTRUCTION OF REINFORCED-CONCRETE ABUTMENT

Service standards. The length of the pile below the concrete is varied to suit conditions, but the minimum is 5 feet.

The pile abutments are designed as shown; in the case of quicksand extra sheeting is carried down to several feet below the surface of the slope. The length of piles varies with soil conditions encountered, but the minimum is 12 feet.

The work shown in the photograph was done by the Government force, with L. R. Fiock as superintendent.

Algae Cause Taste in Fort Worth Water

By Robert H. Craig

Captain, Sanitary Corps, United States Army, Camp Sanitary Engineer, Camp Bowie, Texas

ALGÆ growths give the water-supply of Fort Worth so much vegetable taste in the summer and autumn months as to necessitate special treatment. Copper sulphate having proved to be inadequate an aëration basin is being built.

The water-supply is drawn from Lake Worth, an artificial reservoir formed by damming the west fork of the Trinity River. The lake has a capacity of 35,000,000,000 to 40,000,000,000 gal., an area of nine square miles and a drainage area of 1800 square miles.

Samples of water collected in November, from within a radius of a half mile of the water intake, showed the following microscopic organisms:

Diatomaceæ	*Navicula*
Chlorophyceæ	*Spirogyra*
	Pandorina
	Hyalotheca
	Closterium
Cyanophyceæ	*Gloeocopsa*
Protozoa	*Arcella*
	Paramaecium
Crustacea	*Diaptomus*
	Cyclops

Tumblerfuls of water collected from the top of the filters at times showed hundreds of crustacea.

The water from the lake flows six miles through a concrete pipe line six miles to the filtration plant. Iron and lime is used as a coagulent and liquid chlorine as a disinfectant.

After filtration the water often has a stronger taste than the raw water, giving rise to the belief that filtration breaks up the minute particles of the algæ and causes the vegetable oils to be diffused through the filtered water. The taste in the system is the same as the taste in the lake, showing that the application of chlorine does not make any alteration in the kind of taste.

It was the intention of the municipal authorities to clear the bed of the lake of trees and underbrush but not to strip the land, as the cost would have run into prohibitive expense. Some of the trees were removed, but difficulty was experienced with the contractors, and the lake was filled up without stripping and with little clearing.

Thousands of trees were covered with the water, and many are partly submerged and partly exposed. The theory was advanced by some that the taste was due to vegetable decay of the trees, forming such products as tannic acid, but as the taste disappears after the autumn "turnover" it would seem that the taste is entirely due to algæ. This belief is strengthened by the fact that handfuls of the algæ growths have an odor which corresponds to the taste noticeable in the water.

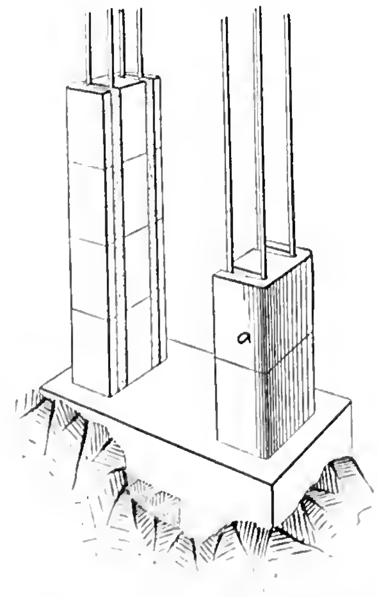
Attempts were made to rid the water of the taste by dragging bags filled with copper sulphate through the water from the rear of a motor boat, within a radius of three-quarters of a mile from the water intake. The "draw-off" level at the intake was also changed. These measures helped somewhat, but did not eliminate the taste.

An aëration basin is being constructed at the filter plant, designed by John Gregory, consulting engineer, Baltimore, Md. It is a shallow basin with 64 aëration nozzles spraying the water into it. The aëration will undoubtedly better the condition, and it is hoped will get rid of the taste entirely.

Reinforced-Concrete Columns of Precast Pieces

PRECAST concrete pieces of similar size and shape to the usual concrete block have been used in France recently to build up reinforced-concrete members, notably columns.

A typical detail of a column is illustrated herewith in the accompanying sketch. Each of the concrete pieces as shown is about 10 in. high and weighs about 20 lb., so it can be lifted into place by hand. In operation, a concrete base is poured in place and rods are left protruding from the base in such location as to form a reinforcement for the column. The E-shaped blocks with their two grooves to surround the reinforcement are then slipped into place, and the column is built up with mortar joints. After it has reached the proper height the grooves into which the rods slip are filled with poured concrete. A number of details have been devised for column connections and for various types of construction. The method is described in a recent issue of *Le Génie Civil.*



PRECAST CONCRETE COLUMNS

ENGINEERING LITERATURE

A REVIEW OF BOOKS AND A LISTING OF NEW PUBLICATIONS

"Engineering News" Book Index Completed

INDEX TO "ENGINEERING NEWS" FOR THE YEARS 1919 TO 1917 INCLUSIVE—Compiled by Nathan C. Rockwood, Assoc. Am. Soc. C. E., Formerly Associate Editor of *Engineering News*. New York: McGraw-Hill Co. Cloth; 6 x 9 in.; pp. 469. $3 net or $6 in combination with indexes for 1890-99, 1900-04 and 1905-09.

The publication of this volume completes the series of uniform consolidated indexes to *Engineering News* from 1890 to the close of March, 1917. The four volumes in the series are as many keys or guides to the history of civil engineering and construction for the 17 years preceding our entrance into the great war. The three earlier volumes, all fortunately still in print, covered the periods 1890-99, 1900-04 and 1905-09.

In the preface to the 1905-09 index it was stated: "This book is not 'an enterprise of profit' . . . it is published solely for 'the convenience of the users of *Engineering News*.'" The same is true of the present volume. It is designed to make easily and quickly accessible the contents of thousands of pages of *Engineering* News, from 1910 to its consolidation with *Engineering Record*.

Like the earlier volumes, the fourth is a carefully classified subject index, with liberal use of cross-references. The author had the advantage of intimate knowledge of the contents of *Engineering News* during the period covered, a knowledge acquired by service both on its editorial staff and as indexer of its half-yearly volumes. The general plan of the earlier indexes, made by a trained indexer under the guidance of the editors, has been followed by Mr. Rockwood, because long use has proved its value and also to make the whole series uniform in style, so all four may be used together with ease.

An idea of the wealth of material on leading topics made more quickly available by the 1900-17 index may be given by noting that Bridges, with its subclassifications, fills 22 pages; Buildings, nine; Canals, seven; Concrete, 15; Dams, nine; Engineers, eight; Railways, 26, not counting six pages on electric railways and electrification of steam railways; Roads, 19, besides three pages on Highways; Sewage Disposal and Treatment, nine; Surveying, nine; Tunnels, six, not counting three pages on Subways; Water Purification, seven; Water-Supply and Water-Works, 12.

The wide range of topics and a further idea of the large number of references included are indicated by the fact that aside from the 12 heads already mentioned as filling six to 26 pages each there are 35 or more that fill at least two pages. These heads are: Aqueducts, Arches, Cement, City Planning, Columns, Contracting, Drawing, Engineering and closely related matters, Engineering Schools, Flood Protection and Floods, Foundations, Garbage, Irrigation, Locomotives, Motor Trucks, Municipal, Patents, Piles, Pipe, Pumps, Rails, Reservoirs, Retaining Walls, Rivers, Sewerage, Ships, Steel, Subways, Tanks and Standpipes, Typhoid, Valuations, Viaducts, Water Power, Wharves and Docks.

Thoroughness is evidenced by not only the cross-references already mentioned but also by the inclusion of news notes of permanent value. To save the reader from being mislead, the notes are designated by the letter "n." As a further guide to be found under the separate entries the approximate number of words in each article of 500 or more words in length is given. Editorial discussion and letters to the editor are designated by abbreviations in parentheses.

Before concluding, it may be noted that an index to the first 17 years of *Engineering News*, 1874-90, was published in 1891 as a thin volume of 118 pages. It has long been out of print. Moreover, having been made before the days of trained indexers, this early volume is not satisfactory. Fortunately, the later and more important part of the period is covered by the valuable "Descriptive Index of Current Engineering Literature, 1884-1891," prepared under the direction of the late Prof. J. B. Johnson for the Association of Engineering Societies, and since continued as "The Engineering Index."

Finally, it is a pleasure to announce that it is the intention of *Engineering News-Record* to publish consolidated indexes to its contents at five-year intervals, thus carrying on without a break the work of making readily available the record of engineering practice and progress pursued for so many years by *Engineering News*. This, the editors feel confident, will encourage subscribers to preserve and bind their volumes, a practice which already prevails to a large extent but might well be extended with advantage.

Asphalts Broadly Treated

REVIEWED BY A. W. DOW

Consulting Paving Engineer, New York City

ASPHALTS AND ALLIED SUBSTANCES: Their Occurrence, Modes of Production, Uses in the Arts, and Methods of Testing—By Herbert Abraham, B.S. of Chemistry, Member A.C.S., S.C.I., A.S.T.M., I.A.T.M. New York: D. Van Nostrand Co. Cloth; 6 x 9 in.; pp. 606; illustrated. $5

There is hardly a subject with which the engineering profession has to deal that is more difficult to inform oneself on than the technology of asphalts and allied materials. What little has been written on this subject is scattered through numerous magazines, proceedings of societies and Government publications, many of which are out of print or inaccessible to the large majority. Mr. Abraham has gone far to remedy this difficulty by abstracting the literature on this subject and compiling it with considerable information from well known authorities and original data of his own.

The book is divided into five parts. In the first is a short history of the early discovery and uses of bituminous materials, and the classification, terminology, chemistry and geology of bituminous substances. The terminology and classification appear to be entirely original with the author, as is usually the case in all books published on this subject. Part II deals with semi-solid and solid native bituminous materials, their occurrence and methods of refining. Under this heading are classed such materials as ozokerite and other mineral waxes, pure native asphalts and those associated

with more or less mineral matter. gilsonite, grahamite and allied materials, elaterite, wurtzilite, albertite and bituminous shales. The third part takes up tars and pitches and their production from wood, peat lignite, bituminous shale, fatty acid and bone tar. It also deals with petroleum, its refining, and products made therefrom, such as all grades of burning oil, paraffine wax, wax tailings, residual oils, asphalt both straight run and blown, and pitches formed as byproducts in the manufacture of various petroleum products. The fourth part treats manufactured products from the various pitches and bitumens, and their application and uses in the arts, such as paving, waterproofing, roofing and paints. The fifth part deals exclusively with the methods of testing bituminous materials.

The book is comprehensively written, and the subjects are succinctly described and well illustrated by photograps and diagrams. As the work covers a very large field, many of the topics are of necessity greatly condensed, but the author has given preference to those topics concerning which little has been published, such as fatty-acid pitches; bituminized roofings, floorings and other fabrics; bituminous paints, cements, varnishes and japans.

As is to be expected in a book covering so large a field, there are a number of misstatements in various sections. These, in the majority of cases, are of minor importance and do not detract from the value of the work. There are, however, a few that should be commented on, as, for instance, in speaking of the steam distallation of oils for the production of asphalt, the maximum temperatures stated as those to which the stills are heated are entirely too low. Excellent California asphalts are often made at temperatures much over 700° F. It is also the custom in the production of high-grade asphalts from Mexican petroleum by steam distillation to carry the temperature considerably over the maximum stated by the author, and it is doubtful whether a practical run could be made at so low a temperature.

The description of the different grades of California asphalt under the designations A, B, C, D and E are very misleading. In the first place, the limits of the penetration of the different grades are not those usually in use, although there is considerable variation in this respect with different manufacturers. The description of how the different grades chew is very misleading. A material of 15 penetration will not grind between the teeth but will chew hard, while a material of 50 penetration will chew quite soft, and 75 penetration is about as soft as can be chewed without sticking to the teetn.

The statement relative to sheet-asphalt paving, where the author says, "Neither the dust nor bituminous cement should be present in excess, as these tend to make the mixture too smooth to form a proper bond with the foundation," is incorrect. In the first place, the normal mixture of a sheet-asphalt pavement does not adhere to the foundation and, contrary to the statement of the author, an excess of bitumen would tend to cause the mixture to adhere. The objection to the use of too much bitumen is that is produces an unstable, soft pavement.

The average penetration of the bituminous cement for sheet-asphalt paving is given as 35 to 77° F. This is very much too low, and is only used in pavements for the very heaviest traffic. Fifty-five penetration is about the average. The limitations of penetration at 32, 77 and 115° F. of the bituminous cement for bituminous macadam are so limiting that they exclude many of the better-grade asphalts. Several other tables giving the physical characteristics of asphalt are also open to this criticism.

The method described of laying wood block in a tar cushion, if followed, would be likely to result in having the pavement slide around on the foundation. The safest way, and the one that has been adopted as standard of late, is to coat the smoothly prepared foundation with as thin a layer of coal-tar pitch as possible and lay the blocks directly on this and not on a thick pitch cushion sprinkled with sand.

The book will be found of value to all who are interested in the subjects treated. Engineers, architects and contractors can inform themselves on the technology of bituminous paving, waterproofing, roofing, paints, insulation, etc., and on the origin and processes of manufacturing the various ingredients used in these arts. The manufacturer of products in which bituminous materials are used can enlarge his knowledge on how such substances are produced and of their chemical and physical properties, which knowledge may enable him to improve his own products. The technologist will find the book of value as a ready reference for methods of analysis and for the preparation of bituminous compounds. The many references throughout the text add greatly to the value of the book, and will be found most helpful to anyone wishing to make a more thorough study of the subject. Another excellent feature is the system used throughout the book of placing a number opposite all results of tests.

Water Disinfection by Chlorination

By Frank E. Hale

Director of the Mount Prospect Laboratory, Brooklyn, N. Y.

CHLORINATION OF WATER—By Joseph Race, F.I.C., City Bacteriologist and Chemist, Ottawa; Captain Canadian Army Hydrological Corps; Member of Committee Standard Methods of Analysis, American Water-Works Association. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd. Cloth; 6 x 9 in.; pp. 158; illustrated. $1.50.

The author has filled a niche which needed filling. Though this is a small book, every phase of chlorination seems to be covered. Many interesting and useful data have been gleaned from the numerous scattered publications containing information on the subject. Much original work is also included. At the end of each chapter is a short bibliography.

It is perhaps natural that the author should give credit to England for first employing chlorine in the disinfection of water, at Lincoln, in 1904-5, although it was in America, since 1908-9, that the importance of the method was first realized and low dosage utilized, so much so that London commenced only in 1916 to chlorinate its supply and Europe, as the book states, did not realize its importance until the war necessitated such action.

In the second chapter is brought together considerable interesting evidence on the old question as to whether oxygen or chlorine is the important active element in the hypochlorites. Such evidence as is contained in Table III appears to be inconclusive, as insufficient data are included. For example, permanganate in acid solution yields five oxygen atoms, in alkaline solution only three. No mention is made of the conditions of the experiment. The table shows the effect of relative stability, or rapidity of action, of two oxidizers rather than the amount of relative work done, since after

sufficient time the results are alike for practically the same oxygen content.

The chapter on dosage throws a considerable light on the effect of organic matter, temperature, admixture, time and light. Particular attention should be paid by operators to the statement on admixture, pp. 41 and 42.

Aftergrowths receive several pages in the chapter on "Bacteria Surviving Chlorination." The absence of sanitary significance is mentioned. The chapter on "Complaints" is particularly complete, referring not only to taste and odor and means of correction, but also to the effect of chlorination on fish life, plants, animals and corrosion. The chapters on "Bleach Treatment" and "Liquid Chlorine" contain information probably more generally familiar. So up to date is the book that reference is made to the mobile motor-truck filter and sterilization units employed by the United States Army late in the war. Possibly not so familiar is the chapter covering the electrolytic processes. The Montreal plant is described, with cost data.

The chapter on "Chloramine" (which employs ammonia with bleach) contains the results of this very recent method of chlorination developed by Race. Judgment upon this method must be withheld, since the most recent tests of its efficiency tend to show very little or no greater efficiency than that obtained by other forms of chlorine. Particularly important is the question of cost as well as the handling of two solutions instead of one. Its effect on aftergrowths may be due to greater stability. Under "Results Obtained" the author lays stress on reduction in cost of filtration by the use of chlorine and consequent increase in filter capacity by increase of load. The last two pages contain a very sane statement on the limits of use of chlorination.

The author deserves praise for producing so readable a book, covering so much ground in so few pages.

The Shipbuilding Art

PRACTICAL SHIP PRODUCTION—By A. W. Carmichael, Lieutenant Commander, Construction Corps, U. S. N., Member Society of Naval Architects and Marine Engineers. New York: McGraw-Hill Book Co., Inc. London: Hill Publishing Co., Ltd. Cloth; 6 x 9 in.; pp. 252; illustrated. $3.

To furnish the great army of new workers in the shipyards with a sound elementary introduction to the conceptions and methods underlying the construction of modern vessels, the Emergency Fleet Corporation last year issued a little pamphlet entitled "Shipbuilding for Beginners." Precisely the same motive thought, carried out very much more fully, is embodied in the present book. It is still a Shipbuilding for beginners, but it will carry them far into the art, and is capable of developing their ideas and stimulating their thoughts in highly effective manner to the point of a live understanding of shipyard requirements.

A rough notion of what the book contains may be gleaned from the chapter headings: Requirements of Ships, General Description of Ships, Structural Members, Design, Shipyards, Preliminary Steps in Ship Construction, and The Building of Ships. The first two chapters and the one on design, except for a short section describing the materials used in ship construction, are likely to be of less immediate value to the engineer than the other five. The last named, illustrated with many sketches of structural parts, of tools, of good and defective rivets, of bending-slab operations, and other vital matters in hull construction, should prove permanently valuable in tying together the structural engineer and the shipbuilder.

Condensed Handbook of Iron and Steel

IRON AND STEEL: (A Pocket Encyclopedia) including Allied Industries and Sciences. By Hugh P. Tiemann, B.S., A.M., with an Introduction by Henry Marion Howe. Second Edition, Enlarged and Revised. New York: McGraw-Hill Book Co. Flexible Cover, Pocket Size; 5 x 7 in.; pp. 514; illustrated. $4.

Having taken a commanding position in the ironworking industries in its first edition (see *Engineering News* of Dec. 15, 1910, p. 58 of the Engineering Literature Supplement) Tiemann's glossary and manual as now revised and rewritten makes an even stronger claim to this position. The author has evidently labored with care and devotion to bring the work up to date and to give proper recognition to the increased importance of the scientific aspect of iron, as represented in metallography. Incidentally, he has amplified the contents of the book considerably, by adding mill terms used in various special branches of the art as well as by expanding the monographs on separate scientific and practical phases of the subject—as Chemistry, Rolling, Heat Treatment, Special Steels. By a short introductory outline of iron metallurgy he has, furthermore, provided a valuable means of coördination. Altogether, the result of the revision is a book that is indispensable to everyone engaged in iron metallurgy.

In its present form the book is essentially a handbook, or highly condensed treatise, with an alphabetical arrangement of sections and with a directly incorporated index. The glossary, though important, is subordinate to the special discussions of the larger individual subjects, which, though arranged in their proper alphabetical position in the glossary, form a series of chapters on the several parts of the entire subject. Of the minor items, forming in number by far the larger part but in space occupying the smaller part of the total, a great number are merely cross-index entries, which refer to the appropriate point in one of the special discussions for the definition and explanation of the term in question.

Another Novel With an Engineer as Hero

THE GREAT HUNGER—By Johan Bojer. Translated from the Norwegian by W. J. Alexander Worster and C. Archer. New York: Moffat, Yard and Co. Cloth; 5 x 8 in.; pp. 327. $1.60.

Although the hero is a great engineer, this Norwegian story keeps engineering work in the background and depicts a lifelong soul hunger which not engineering achievements, wealth, wife or children appease. The reader is told something of the technical education of the hero, and gets glimpses of his work as a builder of a dam on the Nile and later as an engineer-contractor who ruined himself financially on what was perhaps a hydro-electric plant in Norway. Finally the "great hunger" is satisfied by a simple and secret act of self-sacrifice for a man who had done a great injury to the hero. The story is simply but strongly told.

Books on Ships and World Trade

The Free Public Library of Newark, N. J., has compiled for the United States Shipping Board lists of book on (1) "Ships, Commerce and the Merchant Marine; (2) "World Trade"; (3) "Foreign Countries." Each book is briefly outlined. Prices and publishers are given. The compilations were made by Miss M. L. Prevost, under the direction of John Cotton Dana, librarian. Requests for the pamphlets should be addressed to the library.

Publications Received

[So far as possible the name of each publisher of books or pamphlets listed in these columns is given in each entry. If the book or pamphlet is for sale and the price is known by the editor the price is stated in each entry. Where no price is given it does not necessarily follow that the book or pamphlet can be obtained without cost. Many, but not all, of the pamphlets, however, can be obtained without cost, at least by inclosing postage. Persons who are in doubt as to the means to be pursued to obtain copies of the publications listed in these columns should apply for information to the stated publisher, or, in case of books or papers privately printed, then to the author or other persons indicated.]

AMERICAN RAILWAY BRIDGE AND BUILDING ASSOCIATION: Proceedings of 28th Annual Convention, 1918—Chicago, Ill.: C. A. Lichty, Secretary. Cloth, 6 x 9 in.; pp. 196; illustrated.

THE AMERICAN YEAR-BOOK: A Record of Events and Progress for 1918—Edited by Francis G. Wickware, B.A., B.Sc. With Coöperation of a Supervisory Board Representing National Learned Societies. New York and London: D. Appleton and Co. Cloth: 5 x 8 in.; pp. 850. $3.50.

The ninth issue of this annual, like the earlier ones, has sections on engineering, Federal, state and local Government activities, public resources and public works, besides many other subjects.

BENGAL SMOKE-NUISANCES COMMISSION: Annual Report, 1917-18—Calcutta, India: The Commission. Paper; 9 x 12 in.; pp. 5. Price, 5 annas; or 6 pence.

THE COLLEGE OF ENGINEERING AND EXPERIMENT STATION, UNIVERSITY OF ILLINOIS: A Pictorial Description. Urbana, Ill.: The College. Paper; 6 x 9 in.; pp. 62; illustrated.

CONSERVATION COMMISSION, STATE OF NEW YORK: Annual Report, 1918. Albany, N. Y.: The Commission. Paper; 6 x 9 in.; pp. 205; illustrated.

DIRECTOR OF THE NATIONAL PARK SERVICE: Report to the Secretary of the Interior, June 30, 1918. Washington, D. C.: Department of the Interior. Paper; 6 x 9 in.; pp 284; illustrated.

DOMINION WATER POWER BRANCH: Annual Report, March 31, 1917. Ottawa, Canada: Department of the Interior. Paper; 7 x 10 in.; pp. 106; illustrated.

DRAINAGE IN MICHIGAN—By Dalton G. Miller and Perry T. Simons, Senior Drainage Engineers, U. S. Department of Agriculture; Prepared Under the Terms of an Agreement Between the Michigan Geological and Biological Survey, R. C. Allen, Director, and The United States Department of Agriculture, Bureau of Public Roads, [late] Logan Waller Page, Director. Prepared Under Direction of S. H. McCrory, Chief of Drainage Investigations. Lansing, Mich.: Michigan Geological and Biological Survey. Cloth; 6 x 9 in.; pp. 133; illustrated.

FIRST BIENNIAL REPORT OF THE CALIFORNIA HIGHWAY COMMISSION: A Subdivision of the Department of Engineering of the State of California; to Accompany the Sixth Biennial Report of that Department, Dec. 31, 1918. Sacramento, Calif.: The Commission. Paper; 6 x 9 in.; pp. 142; illustrated. Folding map in pocket showing state highway systems.

Reviews commission's work to date. Contains reports on the various phases of the work, tables of costs and tests of material.

GOVERNMENT OWNERSHIP OF PUBLIC UTILITIES IN THE UNITED STATES—By Leon Cammen, M. A., Associate Editor of the *Journal* of the American Society of Mechanical Engineers; Member New York Academy of Sciences, Etc. New York: McDevitt-Wilson's. Cloth; 6 x 9 in.; pp. 142. $1.50.

IRRIGATION ENGINEERING—By Arthur Powell Davis, D. Sc., M. Am. Soc. C. E.; Director and Chief Engineer U. S. Reclamation Service, Author of "Irrigation Works Constructed by the United States," etc., and Herbert M. Wilson, C.E., M. Am. Soc. C. E.; Former Chief Engineer and Irrigation Engineer, U. S. Geological Survey; Author of "Topographic Surveying," etc. Seventh Edition, Revised and Enlarged. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd. Cloth; 6 x 9 in.; pp. 640; illustrated. $4.50.

LABOR LOSS: Handbook on Employment Management in the Shipyard; Dealing with Modern Methods and Practices of Employment Management. Philadelphia, Penn.: U. S. Shipping Board, Emergency Fleet Corporation. Paper; 8 x 10 in.; pp. 30; illustrated.

THE LARGER UNDEVELOPED WATER POWERS OF TENNESSEE—By J. A. Switzer, Professor of Hydraulic Engineering, University of Tennessee, and Hydraulic Engineer of the Tennessee State Geological Survey. Nashville, Tenn.: Geological Survey. Paper; 6 x 9 in.; pp. 35; illustrated.

Reprint of a paper, which was prepared for presentation at the thirty-third general meeting of the American Electrochemical Society, held at Knoxville, Tenn., Apr. 30, 1918. The expense of the field and office work was met by the Knoxville Board of Commerce.

MAN TO MAN The Story of Industrial Democracy—By John Leitch. New York: B. C. Forbes Co. Cloth; 5 x 8 in.; pp. 249. $2.

MICHIGAN STATE BOARD OF HEALTH: Forty-Sixth Annual Report of the Secretary, June 30, 1918. Lansing, Mich.: The Secretary. Cloth; 6 x 9 in.; pp. 180; illustrated.

MOTOR TRANSPORTATION FOR RURAL DISTRICTS—By J. H. Collins, Investigator in Market Surveys. Washington, D. C.: U. S. Department of Agriculture. Paper; 5 x 9 in.; pp. 32; illustrated.

On motor-express routes. Some of the topics covered are selection of the route, advance estimates of operating costs, selection of equipment, determination of rates, bills of lading, and operation methods. Interesting to both those who are now operating and those who are intending to establish truck routes.

NEW YORK STATE ENGINEER AND SURVEYOR: Supplement to the Annual Report for 1917. Albany, N. Y.: State Engineer and Surveyor. Cloth; 6 x 9 in.; pp. 470.

NOTES ON TRANSPORTATION, WITH ESPECIAL REFERENCE TO TRANSPORTATION PROBLEMS ON CANE SUGAR PLANTATIONS—By Capt. Carl B. Andrews, Engineer Corps, U. S. A. Honolulu, T. H.: Hawaiian Engineering Association. Paper; 6 x 9 in.; pp. 63; illustrated.

Water transportation in flumes and such other means of transportation as steam, electric, and funicular railways, as well as cableways, are considered. The treatment is in part descriptive and in part it gives design data. But little is given on the specific problems of moving cane, and most of that seems to be under "Flumes," where there is also considerable on flume hydraulics in general.

PRACTICAL SHIP PRODUCTION—By A. W. Carmichael, Lieutenant Commander, Construction Corps, U. S. Navy, Member Society of Naval Architects and Marine Engineers. New York: McGraw-Hill Book Co., Inc. London: Hill Publishing Co., Ltd. Cloth; 6 x 9 in.; pp. 252; illustrated. $3.

PRINCIPLES OF COMBUSTION IN THE STEAM BOILER FURNACE—By Arthur D. Pratt. New York: The Babcock & Wilcox Co. Cloth; 6 x 9 in.; pp. 114. Free on request.

RECLAMATION BOARD OF CALIFORNIA: Fourth Biennial Report, 1918. Sacramento, Calif.: The Board. Paper; 6 x 9 in.; pp. 53; illustrated.

Deals with progress and status of flood control in the Sacramento and San Joaquin Drainage District.

SAVING STEAM IN INDUSTRIAL HEATING SYSTEMS.—Prepared by the U. S. Fuel Administration in Collaboration with the Bureau of Mines. Washington, D. C.: Bureau of Mines. Paper; 6 x 9 in.; pp. 14; illustrated. 5c. from Superintendent of Documents.

SEWAGE-DISPOSAL PROBLEM OF NEW HAVEN: Report, 1918—By C.-E. A. Winslow, D.P.H., Professor of Public Health, Yale School of Medicine, and F. W. Mohlman, Ph.D., Chemist, New Haven Experiment Station. New Haven, Conn.: The Authors. Paper; 6 x 9 in.; pp. 97; illustrated.

Describes experimental sewage-treatment plant, summarizes results and gives conclusions and recommendations. In briefer form, much of the same information appeared in *Engineering News-Record*, Jan. 2, 1919, p. 32.

SMALL SAWMILLS: Their Equipment, Construction and Operation—By Daniel F. Seerey, Logging Engineer. Washington, D. C.: U. S. Department of Agriculture, Bulletin No. 718. Paper; 6 x 9 in.; pp. 68.

STATE ENGINEER OF ARIZONA: Third Biennial Report, 1916-17 and 1917-18. Phoenix, Arizona: B. M. Atwood, State Engineer. Paper; 6 x 9 in.; pp. 243; illustrated.

A cost distribution system, instructions to highway engineers and the results obtained with convict labor—which are in general satisfactory—are included with the routine reports of work done.

STATISTICAL REPORT OF LAKE COMMERCE PASSING Through Canals at Sault Ste. Marie, Michigan and Ontario, During Season of 1918; With a Supplementary Report of Commerce Passing Through the Detroit River—Prepared Under Direction of L. C. Sabin, District Engineer, U. S. Engineer Office, Sault Ste. Marie, Mich. The Engineer. Paper; 6 x 9 in.; pp. 30; illustrated.

STATISTICS OF MANUFACTURES: Report for 1917—By Charles F. Gettemy, Director of the Bureau of Statistics. Boston, Mass.: The Bureau. Paper; 6 x 9 in.; pp. 129.

TABLE OF UNIT DISPLACEMENT OF COMMODITIES—Washington, D. C.: Bureau of Standards. Paper; 7 x 10 in.; pp. 67. Copies free upon request.

An alphabetical list of commercial commodities, giving the weight per cubic foot, cubic feet per long ton, cubic feet per short ton, and in many instances how the commodity is packed for shipment.

TARVIA ROAD BOOK: For Highway Engineers, Contractors and Road Builders. New York: The Barrett Co. Leather; 3 x 6 in.; pp. 70. Free upon request.

A handy pocket book primarily for the use of engineers who are applying tarvia to their roads, but containing some more general data. Among the tables are: Quantity of tarvia per mile; distance covered by various tank capacities; weight per cubic yard of various substances; spacing for covering material in half-ton piles; costs per mile at price per square yard. Also contains specifications for applying tarvia.

TESTS OF HOLLOW BUILDING TILES—By Bernard D. Hathcock, Laboratory Assistant, and Edward Skillman, Laboratory Assistant, Bureau of Standards. Paper; 7 x 10 in.; pp. 29; illustrated. Copies free upon request.

Records and discusses about 250 compression and absorption tests.

THE USE OF WOOD FOR FUEL: Compiled by the Office of Forest Investigations. Washington, D. C.: U. S. Department of Agriculture. Paper; 6 x 9 in.; pp. 40; illustrated. 10c. from Superintendent of Documents.

WATER STORAGE AND THE WATER CODE—By G. E. P. Smith, Irrigation Engineer. Tucson, Ariz.: University of Arizona. Paper; 6 x 9 in.; pp. 7; illustrated.

WATER SUPPLY PAPERS—Nathan C. Grover, Chief Hydraulic Engineer. Washington, D. C.: U. S. Geological Survey. Paper; 6 x 9 in.; illustrated.

No. 411: 1915. Part XI. Pacific Slope Basins in California. H. D. McGlashan and F. F. Henshaw, District Engineers. Prepared in coöperation with the State of California; pp. 345. No. 422: Ground Water in the Animas, Playas, Hachita, and San Luis Basins, New Mexico—By A. T. Schwennesen; with Analyses of Water and Soil by R. F. Hare. Prepared in coöperation with the New Mexico Agricultural Experiment Station; pp. 152. No. 427: Bibliography and Index of the Publications of the United States Geological Survey Relating to Ground Water—By Oscar E. Meinzer; pp. 169.

Society Service

A Section Dealing with the Results of Teamwork by Technical Men

Send Questionnaire on Legislation

To the membership of the Montreal branch of the Engineering Institute of Canada was sent a questionnaire, in anticipation of the meeting of the committee on legislation on Apr. 5, in order to provide information for the representatives on that committee. The following questions were used:

"1. Are you in favor of a closed corporation for engineers having responsible charge of engineering works?

"2. If so, do you favor legislation embracing all engineering works, or only public works?

"3. In the event of the majority of the members of the institute residing in Quebec declaring in favor of a closed corporation, what are your opinions on the following questions: (a) Do you consider that the only method of entrance into the engineering profession should be through the engineering colleges? (b) If not, do you think that candidates who do not follow college engineering courses should be obliged to pass an examination for admission to study somewhat along the lines of the matriculation examinations required for university entrance? (c) Do you think that candidates should be required to pass an examination for admission to practice, similar to the examinations required by the bar and medical associations? (d) Should candidates be obliged to serve a period of apprenticeship or employment under an engineer before being allowed to take the final examinations for admission to practice? (The word practice is understood to mean taking responsible charge of engineering works). (e) If in favor of examination, do you consider that these should be held by the Corporation only or by a joint board of the members of the Corporation and representatives of the McGill and Laval faculties of applied science? (f) Do you consider that graduates of engineering schools should be exempted from any or all the examinations? (g) If so, from what examinations should they be exempted? (h) Do you think that graduates of engineering schools should be required to prove that they have had experience under some engineer before being admitted to take charge of engineering work?"

Western Society Studies Legislation

A "public affairs" meeting to inform the members of the Western Society of Engineers concerning bills and projects now before the Illinois legislature is the latest development in the broadening activities of the society. That it sees the need of extending the field of thought of the engineer, who has been too much centered in his technical work, and that this applies especially to the young men, was the keynote of the opening remarks by the president, A. S. Baldwin, at the recent meeting. Brief notes of several bills relating to waterways, licensing, housing and other subjects were presented by the secretary. State Senator James J. Barbour, who attacked particularly the present housing bill and some labor bills, expressed the opinion that most legislation is so bad that the community would benefit if the legislature should meet only at 10-year intervals. The housing bill was criticized in form but not in principle by H. K. Holsman, secretary of the Chicago chapter of the American Institute of Architects.

Society Backs Railway Organization Plan

A comprehensive plan for railway organization was outlined by Dean William G. Raymond at the annual meeting of the Iowa Engineering Society, and the society, believing that it contains ideas and suggestions which may be of service in the solution of the present difficult railway problem, has had the plan printed and distributed (through its publicity committee) to newspapers and periodicals. The society has also brought the plan to the attention of members of Congress, as well as of Congressional committees dealing with the subject. In general, it provides for a Federal holding company in financial control, with separate management for each property under the direction of a board on which both the stockholders and the employees are represented.

Co-operation at Pittsburgh Proposed

Engineers in Pittsburgh who are working for progress in professional organization have taken active steps toward bringing about local and state coöperation. The Pittsburgh Association of Members of the American Society of Civil Engineers delegated a committee to confer with the Engineers' Society of Western Pennsylvania with a view to associating all local technical bodies in a federation for professional service and cooperation in city and state. The latter society has the matter under advisement.

Letters to the Editor

Comment on Matters of Interest to Engineers and Contractors Will Be Welcome

On The Strength of Concrete in Shear

Sir—The tests on reinforced-concrete beams described in your issue of Feb. 27, 1919, p. 430, by W. A. Slater, and your editorial of the same date, would seem to warrant the use of higher units on concrete in shear than those in common use. Before adopting higher unit stresses it would be well to look into these tests and examine the results to see just what they do disclose.

On the face of it the tests seem to show that the concrete of these beams carried shears amounting to more than 2000 lb. per square inch in some cases. It must be remembered, first, that the concrete webs had failed long before this shearing value was reached, and, second, that these shearing units are a conventional thing and not the actual shear on the concrete section.

The thing that was subject to shear was a system of very closely spaced web members, unlike the stirrups in an ordinary beam both because of the close spacing and the large section. If these web members had been spaced as they usually are in reinforced-concrete beams, there would have been a chance for the beam to break between two web members, and quite a

different story might have been told of the capacity of concrete to carry shear.

The only thing of interest in tests of this sort for ship work is what the unit shear on the actual area of concrete is at the first crack, for it is the first crack of the hull of a ship that would let in the ocean. It would not matter particularly whether there was a residual strength after the first crack from shear of 10 or 20 times this real ultimate. For it is the first crack that tells what the concrete will stand, and, as Professor Talbot showed some years ago in a series of tests, stirrups do not perform any office until the concrete web has failed.

The test results show that all of the beams had cracked when the shear on the nominal resisting section was 400 lb. per square inch. How much earlier in the test this failure had occurred is not stated.

The section assumed in shear by Mr. Slater is only the web of the beam. Now, there are large heads on these beams which have an area much larger than the web. Why should a broken and utterly failed web be considered as taking so much shear per square inch when the only thing that is approximately whole is the two heads of the beams with their steel connecting web members?

If there were no concrete web whatever in these beams, they would probably take nearly the same ultimate load. This supposed shearing strength of concrete could then be increased *ad libitum* (by using a thinner web) just as some laboratory tests made some years ago attributed all of the tensile resistance in a whole reinforced-concrete beam to the reinforcing steel, and as, even at this date, the tensile resistance of flat slabs is attributed to the reinforcing steel aided by the opinions of adroit mathematicians.

Pittsburgh, Penn. EDWARD GODFREY.

[This letter was submitted to Mr. Slater, who has replied as below. Note should be made of the typographical corrections of the original article appearing in *Engineering News-Record* of Mar. 20, 1919, p. 570. —EDITOR.]

Sir—On reading Mr. Godfrey's letter, I am convinced that he failed to see the significance of the data presented in this paper, or else he ignored the data entirely. In order to bring this out, I wish to call attention to the nature of many of his statements, in approximately the order in which he makes them.

1. "The thing that was subject to shear was a system of very closely spaced web members. . . . If these web members had been spaced as they usually are in reinforced-concrete beams . . . quite a different story might have been told, etc."

The data in the paper refer to a system with closely spaced web members, and no conclusion on any other kind of system was attempted. The article in question even calls attention to the importance of extending the investigation to determine "the effect of variation of spacing of stirrups."

2. "It is the first crack of the hull of a ship that would let in the ocean." Concrete ships are not free from cracks, and yet they do not sink.

3. "Stirrups do not perform any office until the concrete web has failed."

If by "failure" he means the formation of tension cracks the statement is practically correct. But this is quibbling, for it is common knowledge that a reinforced-concrete beam has not failed when the first tension crack occurs. The test data given should remove the last doubt on this point. The first tension crack occurred at shears generally ranging from 200 to 300 lb. per square inch, while the shear at maximum load for the same beams ranged from 950 to 2400 lb. per square inch.

4. "Now, there are large heads on these beams which have an area much larger than the web. Why should a broken and utterly failed web be considered as taking so much shear per square inch when the only thing that is approximately whole is the two heads of the beam with their steel connecting web members?"

Mr. Godfrey would have found by reading the article that I recognized that the shearing stress given "must be somewhat in error, etc." The only difference of opinion is as to how large this error is. I judge that Mr. Godfrey thinks the flanges carried most of the shear. Mr. Godfrey will perhaps recall that approximately the same relation between flange area and web area exists with a steel plate-girder as with the reinforced-concrete beams under discussion; yet I doubt if he would give much shearing value to the flanges of a steel plate girder.

Mr. Godfrey assumes that the two heads were "approximately whole" when the web was "utterly failed." As a matter of fact, they were not.

5. "If there were no concrete web whatever in these beams, they would probably take nearly the same ultimate load."

Had Mr. Godfrey read the article carefully, he would have noted that beam 4AD1, which was of exactly the type to which he refers, carried 174,000 lb. less load than similar beams (4X1 and 4X2) which had concrete also in the web. That is, he would have noted that the beams with steel alone in the web carried only half as much load as one with a web having the same amount of steel and the concrete in addition.

Not only is Mr. Godfrey's statement at variance with fact, but, further, it is at variance with his own conviction as stated in the *Journal* of the American Concrete Institute for December, 1914, p. 19, where he says: "The Joint Committee report does not state whether the stress in a shear member is shear, or compression, or tension. All three are equally absurd." On this as a basis it is difficult to see why the web reinforcement in these beams carried so much load and why Mr. Godfrey now even expects it to carry so much more load than it did. Perhaps he has torsion in mind.

Philadelphia, Penn. W. A. SLATER.

Cost-Plus Contracts and Proposals

Sir—E. T. Johnson in your issue of Apr. 3, 1919, p. 683, hits the nail squarely on the head in amusing fashion. I quote his opening paragraph:

"In your issue of Mar. 6, 1919, p. 485, is a communication from J. B. Chaffey, major, Quartermaster Corps, U. S. A., Fort Sill, Oklahoma. He descants upon the beauties of cost-plus contracts. What especially interests me he does not touch upon—that is, how to get one. I am a contractor and tried hard during the war to get a cost-plus contract, not only in construction, but also in spruce production. What I received was a polite bowing out. I could not find any way at all to break in."

Here we have light, not heat. Proposals form a method of selection.

The difficulty, in my experience, is not to find one

good contractor for a project, but to select among a number of good contractors. Proposals naming price and time, from a list of selected contractors, upon properly prepared drawings and specifications by engineer or architect, are the final examination to determine the contractor best qualified, at that particular time, for the particular project.

When this method is not followed your correspondent's query, "How Were Cost-Plus Contracts Obtained?" is always pertinent.

CHARLES H. HIGGINS,
New York. M. Am. Soc. C. E.

Would Use Surrendered German Warships to Form Training Walls for Channels

Sir—The problem of what to do with the surrendered German warships seems to be causing quite a difference of opinion, and I would suggest that they might be advantageously used as jetties or training walls for the improvement of channels to obtain a greater depth of water over sandy river bars, if sunk in line on each side, taking the place of jetties constructed of logs or stone.

In this position they would serve a double purpose, not only deepening the channel for navigation, but as a monument of the great war, for all ages, and they would become a great attraction for excursionists and sightseers. The submarines and other small captured craft could well be used to fill gaps between the larger ships that might unavoidably occur in sinking them. They would all be linked together with chain cables, and the seacocks opened.

Old vessel hulks have before this time been used in this way, by engineers, on several occasions.

It seems almost a crime to sink these costly ships in the deep sea, when there are so many good uses to which they could be put and at the same time preserve them for their moral and patriotic effect on coming generations. J. FRANCIS LEBARON.

Panama City, Fla.

Draftsmen Assert Further Unfair Play on Part of Navy Department

Sir—The attention of the International Federation of Draftsmen's Unions, chartered under the American Federation of Labor, has been invited to the article in the letter columns of your issue of Mar. 27, 1919, p. 634, entitled "Navy and Fleet Corporation Unfair to Their Own Draftsmen." I am directed to request the insertion in an early issue of the following statement, in which it is desired to point out and elaborate certain points in the article referred to, and also to bring your article up to date.

The letter by William F. Fox is correct as regards the action of the Navy Department in putting into effect, for the navy yards, bureaus and other offices and stations under that department, the award for draftsmen of the Shipbuilding Labor Adjustment Board, commonly known as the Macy Board.

Furthermore, the letter of Secretary Daniels is, on its face, correct except in one particular. This particular is the last paragraph, which involves two inaccuracies. These are not placed to the discredit of Mr. Daniels, as everyone familiar with department procedure may be certain that Mr. Daniels did not write the letter himself. It is incredible that anyone familiar with the facts "believes" that the Macy Board award has been effected for Government draftsmen. The award which was effected was that of the secondary board mentioned by Mr. Daniels, the so-called Henry Board, which was based, not upon the Macy Board award, but upon the recommendations submitted by the various chiefs of bureaus, industrial managers, commandants, etc. As these recommendations were themselves a cut as compared with the Macy award, and were further cut by the Henry Board, it is easily seen that the Macy award is not in effect in Navy Department offices.

Neither letter brings out the vexatious delay resorted to by the department to avoid putting even the Henry award into effect.

The Macy award went into effect in private yards immediately upon its announcement in October and was retroactive to Oct. 1. It was not approved by the Navy Department until Nov. 12, although the original award was signed by Dr. Marshall as official representative of the Shipping Board and the Navy Department. The instructions of the department were so vague that prompt action by the various yards was impossible. Numerous letters and telegrams between the yards and the department for interpretations of innumerable points were necessary. Owing to the incompetence of the instructions, a month elapsed before any of the yards submitted its recommendations. The total delay so far was about one and one-half months.

The papers were turned over to the Henry Board late in December, but all department activity ceases during the holidays. When this board finally got to work it realized its utter inability to reclassify over a thousand men of whom it had no personal knowledge and no way of knowing the local conditions governing the recommendations for each individual. The board therefore hit upon the expedient of fixing an arbitrary average increase of $1.60 per diem, with this exception, however—yards whose recommendations showed increases averaging over $1.60 were brought down to give about that figure, but those yards whose average increase was less than $1.60 were kept where they were and not brought to this average.

The papers were returned to the department Jan. 17, and two months after the department's approval of Nov. 12. Action was then delayed until Feb. 4, owing to the personal refusal of Mr. Daniels to approve the award of his own board, his opinion being that the award was too high, although it was far below that of the Macy Board, which the Government had forced the private yards to grant some four months previously. Even then Mr. Daniels signed practically under coercion, as the temper of the men had been stretched to the breaking point, and was scheduled to break Feb. 8.

On Feb. 4, however, Mr. Daniels signed a letter putting the Henry award into effect, but as certain revisions in the recommendations were required, it was several days, and in some cases weeks, before the men received the new pay. There was no retroactive feature to compensate them for the long and needless delay.

The draftsmen did not enjoy the fruits of this award in peace for very long, however. On Mar. 13 the department issued a circular letter reducing the force 10%. This was on the eve of Mr. Daniels' departure for Europe, and the answer to all protests has been that Mr. Daniels had issued emphatic orders which could not be changed in his absence.

The reason assigned in the letter was "economy." Let us examine that reason. Draftsmen are paid from an appropriation covering several classes of employees, yet of these only the draftsmen are affected. There are about a thousand draftsmen in the Government service, and as the reduction is 10%, the saving would be the pay of about 100 men. The real reason for the reduction is found in the last part of Paragraph 1 of the letter of Mar. 13, as follows:

"If it is desired to retain the services of any draftsman with a civil-service status, selected for separation in his particular grade, in a lower grade, he may be so reduced only upon his own application or consent, but he shall be considered among the total number of draftsmen in such lower grade in figuring the percentage reduction in that grade."

This is the kernel. The object is to reduce wages and to deprive the draftsmen of the benefits awarded them by an impartial board appointed by the President of the United States. They are offered the choice of having their pay reduced or of losing their jobs in these times of unrest and at the very time when the Government is appealing to private firms to furnish jobs for the unemployed.

Motor Truck Costs Much Higher Than Generally Assumed

Sir—I have read with interest the article in your issue of Feb. 27, 1919, p. 438, entitled "Motor Truck Costs Much Higher Than Generally Assumed." It calls to mind a letter by myself published in *Engineering Record* of Feb. 13, 1915, p. 211, criticising an article in that journal describing the hauling of 400 tons of stone per day with auto trucks for 8.28c. per ton-mile. There was a marked tendency at the time to underestimate greatly the cost of auto-truck haul—a tendency which today is being largely overcome.

Data collected by me on a truck operating for a general contractor from Sept. 1, 1913, to Oct. 1, 1915, harmonize quite closely with those now published by the Motor Truck Association of America in your recent article. This truck, the operation of which furnished the data collected by me, was a five-ton Locomobile truck, which was new when it went into service at the beginning of the period described. During this period, quarter-monthly reports were made by the driver; they gave all data as to loads hauled, daily expenses, mileage, ton-mileage, accounts or individuals for whom work had been performed, etc.

In order to make a comparison of cost with earnings, it was necessary to estimate and charge on this report certain regular rates per mile traveled to care for interest, insurance, depreciation and tires. The charges for the first three of these items were lumped at 10c. per mile. This figure was obtained by dividing the annual cost therefor by the estimated annual mileage. The charge of 6c. per mile for tires was obtained by dividing the cost of a full set of tires by the manufacturers' guaranteed mileage.

The charge for interest, insurance and depreciation proved too low for this particular case, because the truck was not kept steadily engaged. It traveled only 16,242 miles in the 25-month period, and thereby, at the 10c.-per-mile rate, earned only $1624.20 for interest, insurance and depreciation. The charge of 6c. per mile for tires proved higher than necessary, because it was found easy to exceed the manufacturer's guaranteed mileage on tires. Approximately 4¾c. would have been a sufficient charge to compensate for tire expense.

The truck was engaged in a miscellaneous lot of hauling, and was seldom long at any particular line of work. The roads were almost always poor and some were almost impassable. It was necessary to provide a helper for the driver during a considerable portion of the time. Gasoline was then 17c. per gallon, as compared with 21c. now, and lubricating oils and distillate, which was used to a large extent instead of gasoline, were correspondingly cheaper. The driver was paid $4 per day and his helper $2.50.

The truck was in actual operation only 450 days, during the 25-month period, and averaged approximately 36 miles per day of operation. The table herewith gives the segregated costs:

OPERATION COSTS PER MILE FOR FIVE-TON TRUCK

Driver	$0.111
Helper	.052
Gasoline, distillate and lubricants	.068
Repairs to engine and chassis	.086
Miscellaneous expenses	.013
Charges for interest, insurance and depreciation	.100
Charges for tires	.060
Total cost	$0.490

Waterford, Calif. EVERETT N. BRYAN.

Railway Bridge Impact Allowances

Sir—Referring to the editorial on p. 454 in your issue of Mar. 6, 1919, entitled "Railway Bridge Impact Allowances," I entirely agree with you concerning the fallacy of increasing materially the impact for short spans and decreasing materially that for long ones.

There seems to be a tendency these days to change bridge specifications in most illogical ways—for instance, stressing steel 20,000 lb. per square inch for tension members and less than 12,000 lb. per square inch for short compression members, without there being any legitimate foundation for such a radical modification. While I am not at all opposed to making changes in standard bridge specifications that are really improvements, I am decidedly against altering anything therein until after it has been shown that there is a valid *raison d'être* for the innovation—especially when the suggested modification militates against true economy.

Recognizing that both of the old standard impact formulas

$$I = \frac{30,000}{L + 300} \quad \text{and} \quad I = \frac{40,000}{L + 500}$$

for railway bridges with open floors give percentages of impact which are too low for very short spans and too high for long ones, according to the A. R. E. A. tests, a few years ago I established the formula

$$I = \frac{16,500}{nL + 150}$$

where n is the number of tracks and L is the span length in feet. For single-track spans of 15 ft., which is about as short as railroad spans are made, this formula gives percentages of impact equal to 100; and very few impact records have ever exceeded that amount. At the same time, for long spans the formula holds fairly well, the curve passing above all the records taken from single-track railroad bridges. By referring

to my diagram on p. 926 of your issue of Nov. 21, 1918, the correctness of these statements will be seen: and it will be there noticed that, while the proposed A. R. E. A. formula

$$I = \frac{100}{1 + \frac{L^2}{30,000}}$$

passes above practically all of the plotted points for spans of 200 ft. or less, it drops below two of them at a span length of 300 ft. In my opinion, it gives results that are too low for long-span bridges. For instance, in a 600-ft. span the percentage it provides for the truss-chords is only 7.7, while by my formula it is 22 for single-track structures and 12.2 for double-track structures.

For short spans the new A. R. E. A. formula and mine for single-track structures coincide at a length of 16 ft. and again at a length of 166 ft.; but between these two lengths my formula is as much as 11 points lower, and averages about 7½ points lower over the whole distance of 150 ft. As my curve is above almost all the plotted points, I claim that my formula is better than the proposed A. R. E. A. formula in that it tends to economy of metal.

In considering the advisability of a general adoption of the proposed A. R. E. A. impact formula with its somewhat extravagant employment of metal for short spans, it must be remembered that the day of the electrification of main-line railroads is not far distant, and that, as far as we know at present, the impact from electric locomotives is only about one-third as great as that from steam locomotives. When the time comes for operating electric trains over bridges designed for steam live loads, there will, of necessity, be a large surplus of strength in short spans and in the floor systems of all spans; consequently, it behooves us to keep down the said surplus as much as we consistently can—and we should not be doing so by adopting for impact the new A. R. E. A. formula.

J. A. L. Waddell,
Kansas City, Mo. Consulting Engineer.

Earthwork Computations Simplified

Sir—The common average-end formula for volumes for n stations used in earthwork computations may be written in three ways, as follows:

$$\frac{A_0 + A_1}{2} l_1 + \frac{A_1 + A_2}{2} l_2 + \ldots . \frac{A_{n-1} + A_n}{2} l_n \quad (1)$$

$$A_0 \frac{l_1}{2} + A_1 \frac{l_1}{2} + A_1 \frac{l_2}{2} + A_2 \frac{l_2}{2} + \ldots . A_n \frac{l_n}{2} \quad (2)$$

$$A_0 \frac{l_1}{2} + A_1 \frac{l_1 + l_2}{2} + A_2 \frac{l_2 + l_3}{2} + \ldots . A_n \frac{l_n}{2} \quad (3)$$

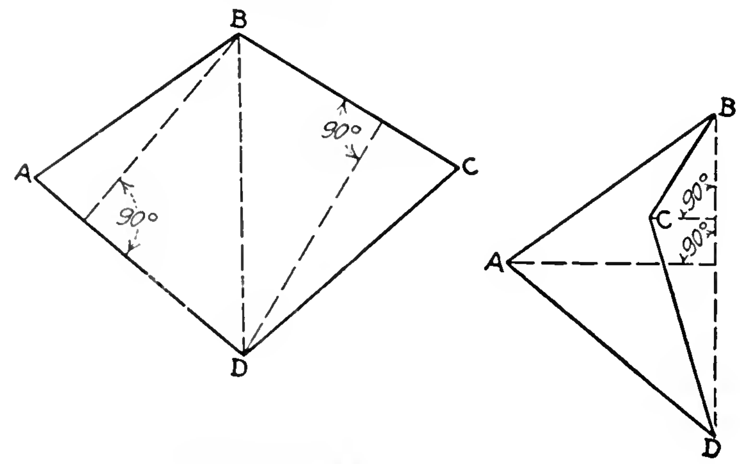
By formula 1 each section will have two areas to be added and volumes computed. By formula 2 two volumes for each station, and for substations one or two multiplications and the addition of volumes are required.

By formula 3, however, one volume is computed for each station, and never but one multiplication for a substation. The volume recorded for any station will be the section area for the station multiplied by half the distance from the previous station to the one next following. This "half distance" will of course be 100 ft. for full stations. Tables of volumes of level or three level sections 100 ft. long may be used. For calculations based on irregular areas, taken with the planimeter or otherwise, the formula is especially simple.

The writer's experience prompts the suggestion that the time saved by the use of formula 3 would justify its more extensive employment. J. H. Dorroh,
Dean, School of Engineering,
University of Mississippi.
University, Miss.

To Compute Area of Four-Sided Figure

Sir—It seems to have escaped the notice of writers of textbooks on surveying, and of computers generally, that the area of any four-sided figure may be obtained and the traverse checked in a much shorter way than by latitude and departure and the D.M.D. method. The



AREA BY SUM OF TRIANGLES

double area of any quadrilateral not containing a reëntrant angle is equal to the sine of any angle into its adjacent sides plus the sine of the opposite angle into its adjacent sides. Thus, from the diagram:

2 × Area = A D × A B sin A + C D × C B sin C

For the case of a reëntrant angle, note that in using angles A and C, the double areas of triangles A B D and C B D, respectively, are obtained. The area is then half the difference of the two products.

If now we take the other two angles of the quadrilateral, B and D, and their adjacent sides, we shall obtain the same double area, provided the traverse is correct, thus checking the first computation and the traverse at the same time.

By the D.M.D. method we should have arranged nine columns and 42 items. This method requires only about one-fourth the labor. C. K. Averill.
Bridgeport, Conn.

Quarantine Against Influenza in Alaska

Quarantine against influenza is said to have kept the disease out of Fairbanks and Nenana, Alaska. According to a statement in the *Alaska Railroad Record*, the official publication of the Alaska Engineering Commission, every person in each city had to wear on hat or coat a blue ribbon lettered "Health Department," which was purchased from the department for a fee of $1, or $2 for a duplicate in case of loss. Persons failing to obtain and wear the ribbon were subject to arrest and quarantine confinement. Civilian sentries guarded all the trails, and persons entering either city were detained five days in quarantine, being then permitted to proceed if no symptoms of the disease had developed. The fees went toward the expense of guarding the trails and quarantining travelers.

HINTS FOR THE CONTRACTOR

DETAILS WHICH SAVE TIME AND LABOR ON CONSTRUCTION WORK

Simple Heating and Ventilating System for Contractor's Hospital

By Dr. J. M. Stadter
Wilmington, Del.

Even distribution of stove heat and uniform ventilation without drafts were secured in a knocked-together construction camp hospital by the simple arrangement of stovepipes and wind shields illustrated by the accompanying view. The hospital was a two-story timber building about 90 x 20 ft., with a ward on each floor.

Exactly similar heating and ventilating arrangements were provided for the two wards. The illustration shows the lower ward. About 65 ft. of the length of each ward was occupied by cots, the remaining 25 ft. at one end being partitioned into toilets, chart room, locker and bathroom.

Wood-burning stoves, A and B in the illustration, were set about 40 ft. apart in the 65-ft. space occupied by cots. The pipe from each stove was carried up to the ceiling at CC, and then along the ceiling about 26 ft. toward the other stove, to DD, and thence to EE, and through the walls to outside tile chimneys. With dampers set near the outside walls this arrangement gave about 40 ft. of pipe radiation from each stove, and gave a very even distribution of heat—usually difficult with stoves.

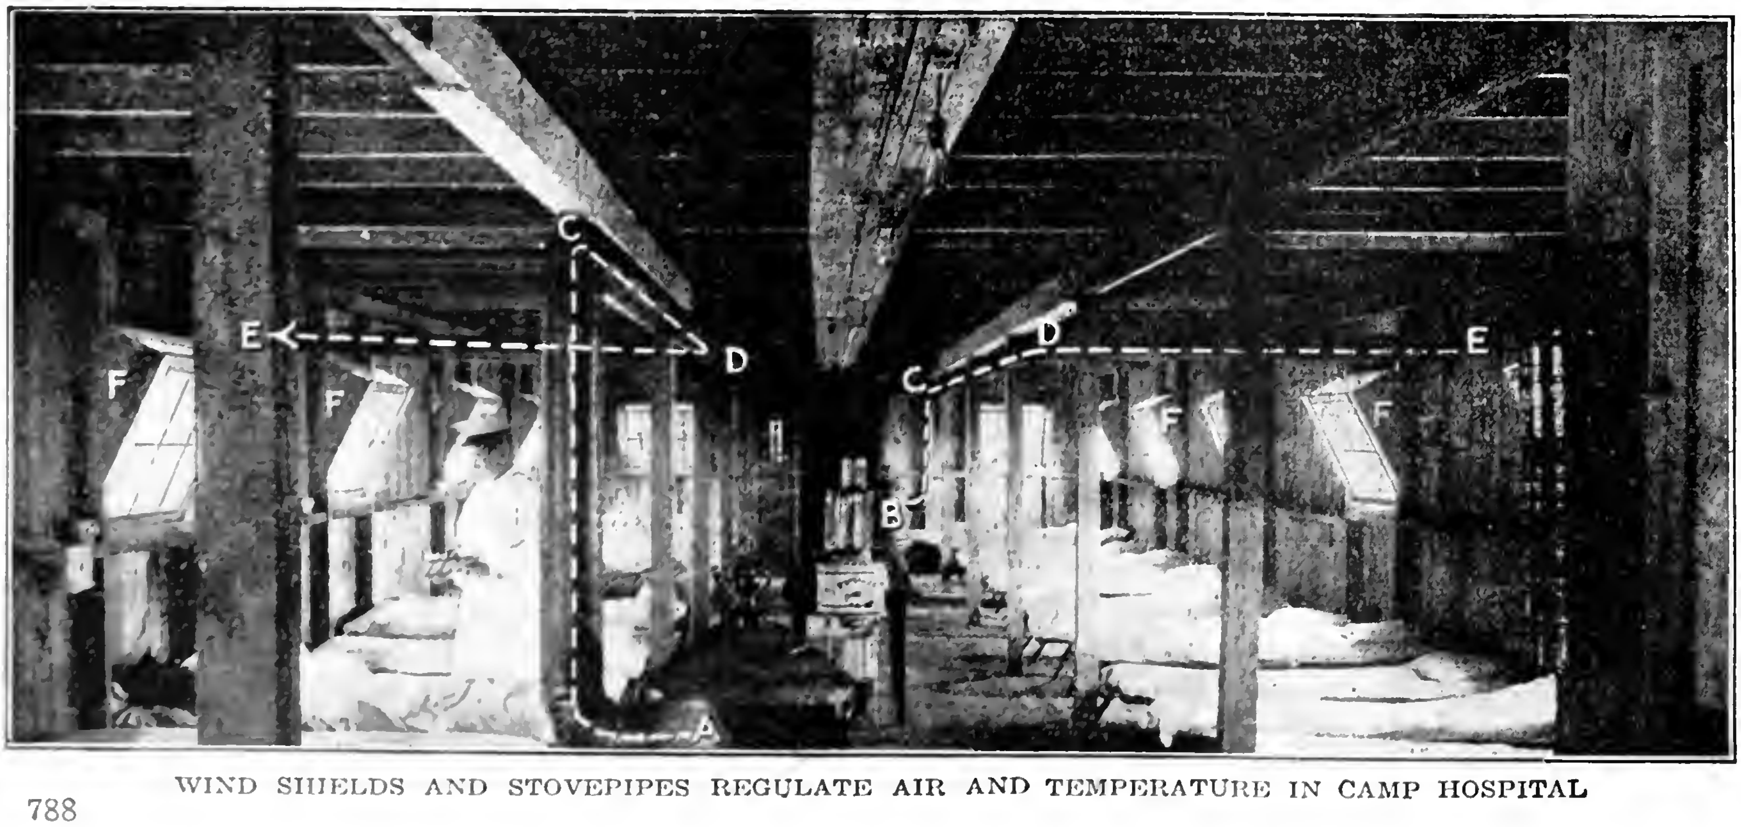
Ventilation was accomplished by equally simple means. Single sash were used for the windows and were hinged at the bottoms to swing into the room. Galvanized-iron shields were then fitted to each window as shown at FF. The air entering was deflected toward the ceiling, and a good circulation was secured without direct drafts on the cots.

This hospital has the noteworthy record, for a contractor's hospital, of having handled 285 cases of influenza, of which 124 cases were serious, with only four deaths. The hospital was constructed and equipped for operation in 48 hours. It was built at Union Park Gardens, a housing project of the Emergency Fleet Corporation located near Wilmington, Del.

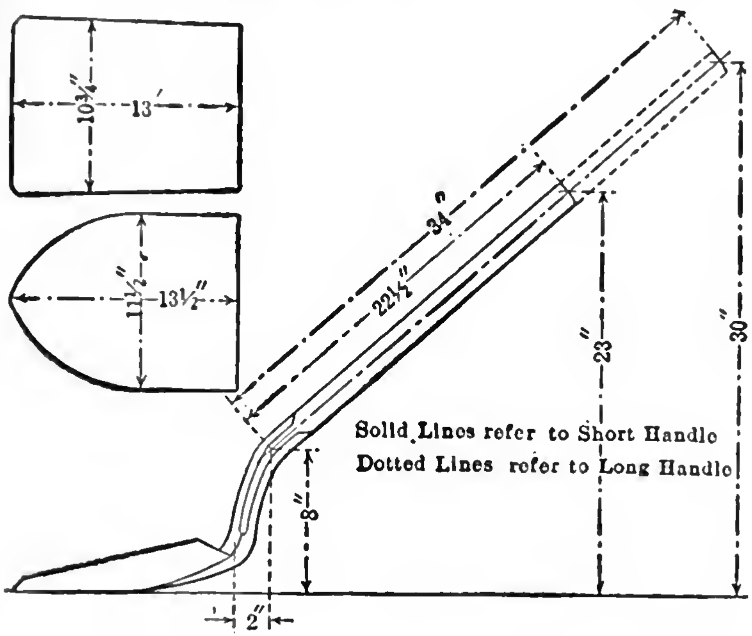
Other Articles in This Issue of Interest to Contractors:

Scoops Found Slower Than Shovels For Handling Ore

Best results applicable to construction operations such as mucking rock tunnels and loading broken stone have been determined in shoveling ore at the Tyrone, N. Y., mines of the Phelps-Dodge Corporation. Investigation was confined largely to comparison of work with No. 2 scoops and No. 4 shovels, under various conditions of loading. For jobs of less than four hours' duration a greater tonnage can be handled with a scoop, but for longer jobs the shovel is greatly superior, since, as the day progresses, the percentage of time required for resting becomes greater with the scoop than with the shovel. In general, for shovels smaller



WIND SHIELDS AND STOVEPIPES REGULATE AIR AND TEMPERATURE IN CAMP HOSPITAL



DESIGN OF SHOVEL BEST ADAPTED TO MINING WORK

than No. 4 (21-lb.) the tonnage handled per shift is, approximately, directly proportional to the shovel capacity. The design of shovel determined as best is shown by the drawing.

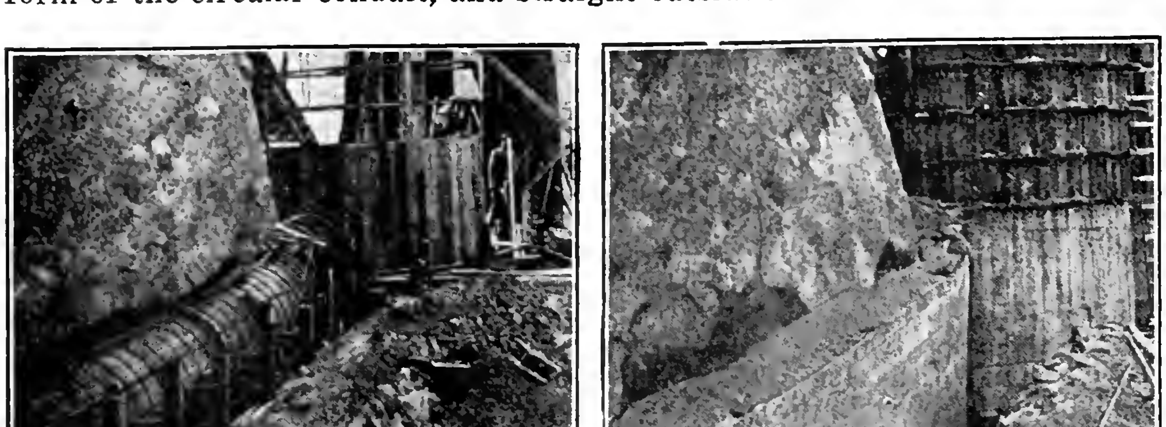
Other instructive facts brought out by the tests were: Owing to poorer light and air, greater humidity, increased temperature and other conditions prevalent underground, the tonnage handled is 20½% less than on the surface. Decrease in shoveling speed due to 1-ft. increase in distance of throw was 2½% for the scoop and 1.8% for the shovel; underground the corresponding percentages were 4.4% and 3.2%. Of a 7½-hour actual working day the men are shoveling only 82½% of the time, the remaining time being spent in nonproductive occupation. This figure is the average of several hundred man-shifts. In loading wheelbarrows a throw of 3 ft. gave the best results. In loading cars 42 in. high the best distance to maintain between car pile was four feet.

These data are from a paper by G. T. Harley, efficiency engineer, Phelps-Dodge Corporation, published in *Engineering and Mining Journal* of Mar. 15 and 23, 1919.

Wood Core Is Inside Form for Monolithic Concrete Conduit

CONDITIONS at the Gibraltar dam, near Santa Barbara, Calif., made it desirable that the concrete intake conduit should run from the intake tower upstream, beneath the shoulder of a projecting rock bluff, and through a tunnel to a point below the dam. In building the part under the overhang a bench was cut out of the rock, a wood core was placed for the inside form of the circular conduit, and straight outside forms were placed for the outside concrete wall, which was offset from the wall of the bluff.

The inside core form, of circular section resembling a wood-stave pipe, was made up of 1 x 3-in. strips nailed to circular segments and the reinforcement was attached to the core. Concrete was then poured in between the core and the outside forms. After the concrete had set the wooden core was broken up on the inside, and pieces were taken out at the intake tower end of the conduit. The contractors on the work were Bent Bros. and W. A. Kraner, the latter being in personal charge of construction.



AT LEFT, FORMS INSIDE OF CONDUIT; AT RIGHT, STRAIGHT WALL IS THE OUTSIDE OF CONDUIT

Loose Bolts for Temporary Bridge Deck

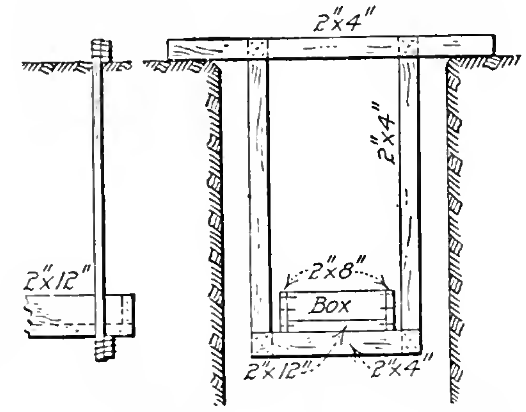
DROP bolts which resemble loose drift bolts are used in constructing temporary bridge decks on the Alaska Ry. When material for the timber trusses is not available, the deck is laid, on the falsework bents on which the permanent structure is to be erected later on, and the fastening must be such that the deck can be taken down readily and without damage to the timbers. The bolts are ½ in. and ¾ in. in diameter and 10 to 14 in. long, and the holes for them are bored to a diameter ⅛ in. larger, so that the bolts drop in easily. W. J. H. Fogelstrom is bridge engineer of the Alaskan Engineering Commission.

Portable Trench-Excavation Platform Saves Shoveling Time

By M. R. Lewis

United States Reclamation Service, Boise, Idaho

FOUR men move the shoveling platform (illustrated by the accompanying drawing) in the time it takes to walk the distance of the move, or in about one-fifth the time taken to move the ordinary trenching platform. Platforms are always necessary in making deep trenches by hand. In trenching by machine they are frequently needed for cleaning up the bottom by hand.



HANGING SHOVELING PLATFORM EASILY MOVED BY FOUR MEN

Usually, such a platform is constructed by placing a shallow box or two or three planks on the trench braces, or on wood struts wedged across the trench. To move the platform when the trench is not sheeted requires 10 to 15 min., the time needed to take down both braces and replace them a few feet farther along the trench.

The platform illustrated sets in yokes hung from the trench edges. By using the projecting ends of the top pieces of the yokes, as handles, four men lift and move the whole assemblage in one operation.

This device was used by J. A. Hoskins & Co., contractors for the Malheur Drainage District at Ontario, Ore.

NEWS OF THE WEEK

New York, April 17, 1919

Railroad Administration Plans Use of Inland Waterways

In a letter to Senator Fletcher of the United States Senate Interstate Commerce Committee, Director General of Railroads Hines has announced the policy of the Railroad Administration in the matter of inland waterways. The nub of his statement is in the following paragraph: "The attitude of the Railroad Administration with respect to the relation between water and rail competitive rates is that the rates should bear a relation to each other proportionate to the cost and desirability of the service by the respective routes and methods of transportation."

He further states that the rate structure in the United States is so complicated and of such standing that the adjustment of one portion of it inevitably affects all the others, so that there seems to be little prospect of any reduction in the rate along the waterways. What can be hoped is that there will be an easier provision for transshipment by means of through waybills and through rates. There seems to be no prospect that the Railroad Administration will do anything to foster the traffic along the New York State Barge Canal, for Director General Hines says: "The administration has agreed, if the traffic justifies it, that it will establish joint rates between responsible independent canal lines and rail carriers under Federal control by connecting points on the canal."

In answer to one of Senator Fletcher's questions Director General Hines states that in the event of the railroads returning to private ownership, in his opinion it will be desirable to continue the Federal control of the waterways under some Government agency.

Employment

For the convenience of engineers returning from military life, and others, there are listed below agencies which may be helpful to those who are seeking employment:

Engineering Societies Employment Bureau; secretary, 29 West 39th St., New York City.

American Association of Engineers, 29 So. La Salle St., Chicago. Service to members only, but Army or Navy engineers in uniform who are eligible to certified membership may join without payment of entrance fees or dues while in uniform and for six months after discharge.

Engineers' Service Bureau, maintained by the Joint Council of Engineering Societies of San Francisco, Engineers' Club, 57 Post St., San Francisco. Only applications by mail or wire will be considered.

The Federal director of the United States Employment Service in New York State announces the receipt of a letter from J. P. Morgan & Co., in which $100,000 is offered for the purpose of continuing the work of the service up to July 1 of this year. The Professional and Special Section in New York will therefore be continued, but will be located at the main office, 469 Fifth Ave., New York City.

New East River Tunnel In Service

Rapid-transit operation through the new pair of tunnels under the East River at New York City, extending from Old Slip, Manhattan Borough, to Clark St., Brooklyn Borough, was inaugurated on the morning of Apr. 15. The tunnels are part of the new west side subway, formed of that portion of the old subway extending north of Forty-second St. along Broadway, and the new Seventh Ave. subway extending south from Forty-second St. through Seventh Ave., Varick St. and West Broadway to South Ferry, and branching east along Park Place, Mail St., William St. and Old Slip to the tunnels. In Brooklyn the tunnels extend to Borough Hall and connect with the old subway. At that point trains of the east side and west side subway systems meet, the former reaching Brooklyn via the original Battery tunnels, whose easterly continuation is in Joralemon St., while the west side system uses the new Clark St. route. The present extension of the west side subway across the East River thus completes the separation of the old subway into the parts south and north of Forty-second St., and the joining of these parts with the new Lexington Ave. and Seventh Ave. subways to form independent east and west side systems.

Six rapid-transit tunnels under the East River remain to be opened to traffic: Two connecting Whitehall St., Manhattan, with Montague St., Brooklyn; two connecting Fourteenth St., Manhattan, with North Seventh St., Williamsburg; and two connecting Sixtieth St. with the Queensboro Plaza.

Federal Highway Council Formed

Pursuant to the intent of resolutions passed by the Highway Industries Association, following the Highway Congress held in Chicago last December, the Federal Highway Council was organized in Chicago, Apr. 8. The work of securing the coöperation of other organizations and their representation in the movement to promote a national highway system, and to create a Federal highway commission, has been going on for months under the auspices of a joint committee, headed by the Highway Industries Association; until now some 775 civic and commercial organizations throughout the country have indorsed the plan.

The meeting in Chicago decided that the work should be placed under the direction of a board of directors and the customary officers, supported and advised by an advisory committee composed of the leaders of the principal highway organizations.

Following the discussions which determined the type of organization, the Townsend bill, introduced in the last Congress and providing for the creation of a national highway system and a Federal highway commission, was considered and indorsed in all substantial features. A number of constructive suggestions were made, such as one fathered by A. R. Hirst, state highway engineer of Wisconsin, calling upon the Federal Highway Commission to maintain the existing road surfaces on all roads designated as parts of the national highway system as soon as they are taken over. These suggestions were passed along as matters for the consideration of the committee which drafted the bill.

The officers elected are as follows: Chairman, S. M. Williams; secretary-treasurer, H. G. Shirley; vice-chairmen, Coleman duPont, David Jamieson, Charles P. Clifton, Lewis J. Hill, A. H. Blanchard and C. F. Adams.

Freight Reduced on Road Materials Consigned to Government

A reduction in freight rates on road-building material to be used on Federal, state, county, parish, township or municipal Government road work has been decided upon by Walker D. Hines, director general of railroads. This decision was reached after a consultation with the Departments of Agriculture, Commerce, and Labor. The reduction will not be allowed, however, unless the material is consigned to, and the freight thereon is paid by, the particular Government authority using

the material. The reduction will be 10c. per net ton, but a minimum charge of 40c. per net ton will be charged, except where the regular published rate is less than 40c. at the present time.

This ruling will authorize all railroads under Federal control to apply reduced rates on carload shipments of broken stone, slag, shells, chatts, cherts, sand and gravel, from May 1 to Dec. 31, 1919, where the material is to be used as outlined above. These reduced rates may be applied on shipments consigned to the Governmental unit but in care of a contractor, provided the freight is paid by the Government, and provided proper certification is made that the shipments are for the use of, and the reduction in rate will accrue to, the Government. Responsibility for administering this ruling rests with each railroad hauling such material.

Money for Hudson River Tunnel Appropriated

On Apr. 11 Governor Smith of New York signed a bill making an appropriation of $1,000,000 for beginning construction of a vehicle tunnel under the Hudson River between New York and Jersey City. A New Jersey bill authorizing the construction of the tunnel has been signed by Governor Edge. The work will be in charge of the Interstate Bridge and Tunnel Commission, 115 Broadway, New York City.

Designs Largest Concrete Arch

Minneapolis will have a concrete bridge with the longest reinforced-concrete span in the world, if the designs recently made by City Engineer F. W. Cappelen are adopted. This new bridge will be across the Mississippi River on the line of Franklin Ave., will have two end spans of 60 ft. each, two side spans of 200 ft. each, and a center span of 400 ft. The largest reinforced-concrete arch today is the Risorgimento Bridge across the Tiber at Rome, with a span of 100 m., or 328.1 ft. There was designed to cross Spuyten Duyvil in New York City some years ago a concrete arch, commonly known as the Hudson Memorial Bridge, with a clear span of 715 ft., but the project never got beyond the design stage. The Minneapolis City Council already has a fund of $50,000 from the sale of bonds for the construction of the bridge, and it is stated that work will begin as soon as possible.

Pacific Coast Ship Contracts Reinstated

Reinstatement of canceled contracts for 25 steel vessels to be built for the Emergency Fleet Corporation by the Skinner & Eddy shipyard, Seattle, Wash., is reported. It is said that the price agreed upon is less than that fixed in the original contracts.

Defense Council Reorganizes Highways Transport Committee

Reorganization of the Highways Transport Committee of the Council of National Defense is announced by Grosvenor V. Clarkson, director of the council. Direct representation for the Bureau of Public Roads and the Bureau of Markets of the Department of Agriculture, the Postoffice Department and the Department of Commerce is provided for. It is believed that closer coöperation of the departments most vitally interested in the matters of highway transportation, forming a clearing house of action for all Federal interests concerned, will thus be brought about.

Problems growing out of the entrance of the motor truck into the commercial transportation field will be one of the particular problems which the Transport Committee will take up. In carrying on this work, it will coöperate with all transportation agencies, including the United States Railroad Administration, in the study of the various problems of speedy and economical delivery of goods. Special attention will be given to the relation of the rural motor express to interurban electric lines and waterway traffic, in the interest of all elements concerned. While the regional directors of the Highway Transport Committee will still be retained, the committee itself has been reorganized, as follows:

John F. Cravens, of the Council of National Defense, chairman; James R. Blakslee, fourth assistant postmaster general; John M. Goodell, consulting engineer, Bureau of Public Roads; James H. Collins, investigator in market surveys, Bureau of Markets; R. S. MacElwee, second assistant chief of the Bureau of Foreign and Domestic Commerce; Charles W. Reid, executive secretary, and Grosvenor V. Clarkson, director of the council, member ex officio.

The committee will be assisted by the Highways Transport Committee Advisory Board, consisting of William Phelps Eno, of Washington, D. C.; A. H. Blanchard, of New York; C. A. Musselman, of Philadelphia; Raymond Beck, of Akron, Ohio, and John T. Stockton, of Chicago.

Government Bureaus Do Not Agree on Steel Prices

Reduced prices for steel and iron, proposed by the Federal Industrial Board and agreed to by the steel producers, have been unsettled by the refusal of the Railroad Administration to approve them as being reasonable prices. Director General Hines has stated that he does not consider that there was any power conferred on the Industrial Board to impose any prices upon the Railroad Administration, and that the representative of the Railroad Administration who was in attendance in the conference which fixed the prices at no time approved of the decision. On behalf of the Industrial Board, Chairman G. N. Peek in a public statement defends the price established by the board and complains that Director General Hines is unreasonable in stating that in his opinion the prices are too high. Mr. Peek says the situation has become so involved it must be settled by the President.

Conference on City Planning in Buffalo May 26-28

The eleventh annual national Conference on City Planning will be held May 26-28 at Niagara Falls and Buffalo, under the auspices of the American and Canadian cities and towns of the Niagara frontier.

The conference will meet two days at Niagara Falls and will then consider city-planning problems of growing industrial districts. There will also be discussed the problem of regional planning and the regulation of railroads as affecting civic development. On the third day of the meeting in Buffalo, residental zoning and civic centers will be discussed.

Flavel Shurtleff, 19 Congress St., Boston, is secretary of the conference.

Better Pay for Oklahoma Engineers

Authority for salaries of $4200 per year for the county engineers of Tulsa and Oklahoma Counties was one result of an endeavor of the Oklahoma Society of Engineers to persuade the legislature to increase the pay of county highway engineers in general. It was proposed to change the pay from $5 per day, which the present law grants for time allowed by the county commissioners, to a sliding scale of salaries based upon county valuation. A bill was drawn originally to apply to Tulsa County only, but it was shown that some counties, in order to keep their engineers, were paying them (for extra services) $720 per year in addition to the $5 per day allowed by law.

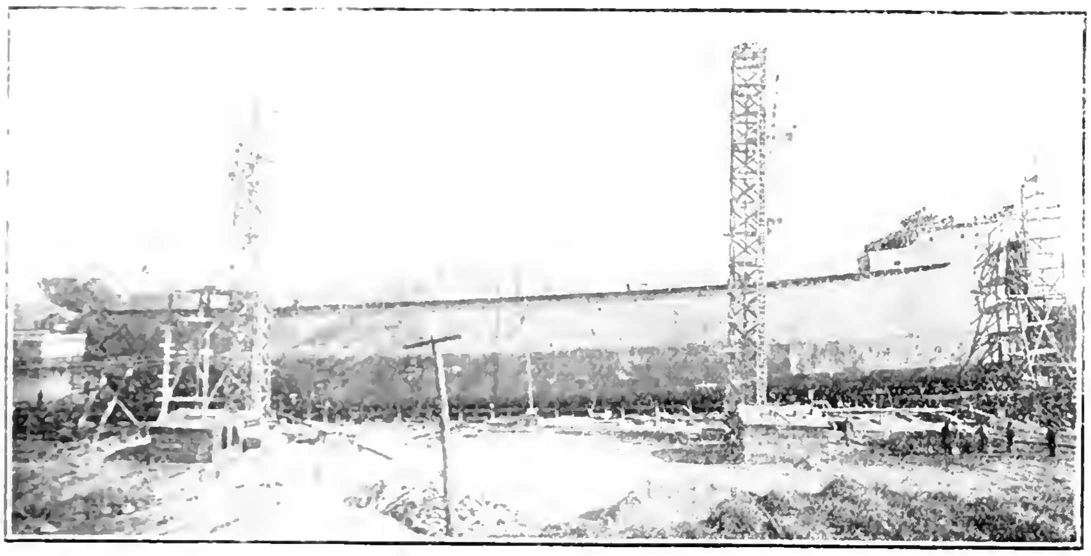
The amendment as proposed by the society was to legalize present salaries and to provide future salaries of $1800 for counties having less than $10,000,000 valuation, $2100 up to $20,000,000, $2400 up to $30,000,000, $2700 up to $40,000,000, $3000 for over $40,000,000; and not exceeding $4200 for counties having over $50,000,000 valuation. It provided also for inspectors on bridge and road work.

Ford "Eagle" Built in Ten Days

On Apr. 12 the shipbuilding plant of the Ford Motor Co., at River Rogue, near Detroit, launched its "Eagle" boat No. 59 in 10 days after the keel was laid. This represents an outdoing of the 21-day operating schedule for which the plant was designed (see *Engineering News-Record* of Oct. 17 and 31, 1918, pp. 698 and 788) as the ship-assembly shop contains 21 building stations and the program was to launch a boat a day at the period of full production. The first "Eagle" was launched in July, 1918.

Third American Concrete Ship Ready to Launch

Some time toward the end of April the United States Shipping Board concrete ship "Polias," which is shown practically completed in the accompanying view, will be launched at the yard of the Feugner Shipbuilding Co., on Long Island. This ship was described in detail in *Engineering News-Record* of Dec. 12, 1918, p. 1058. It is a 3500-ton vessel and is the third oceangoing concrete ship to be launched in this country. The "Faith," which was launched about a year ago, has successfully completed nearly 20,000 miles of ocean travel. The "Atlantus," the 3000-ton vessel which was launched at Brunswick, Ga., in December, 1918, is now being outfitted and should be ready for service in a short time. The "Polias" has been ready for launching for some time, but on account of difficulties in dredging the offshore slip, it has been held on the ways.



3500-TON CONCRETE SHIP READY TO LAUNCH AT FLUSHING, L. I.

Preliminary Report on Portland Elevator Subsidence

The committee of engineers appointed by the Portland Commission of Public Docks to report on the subsidence of the concrete municipal grain elevator being built at Portland, Ore., has presented a preliminary majority and minority report. The majority report, signed by Chairman H. C. Holmes, G. C. Mason, R. A. Cummings and G. W. Beschke, states that the storage annex should be supported by a spread foundation, and that this work can go on while the contractor is completing the structure. It is their opinion, furthermore, that the track shed can be left alone without any treatment whatsoever, the subsidence being very slight. The main report relates to the operating house, the part of the structure which has sunk the most. The report says there are two solutions which could be considered: First, to wreck the present structure and move the site of the operating house to a point south of the track shed, where it would be built upon a spread foundation; second, to complete the present operating house and to carry concrete cylinders under it to gravel.

The minority report, signed by W. R. Phillips, states that in the opinion of the signer the ground surrounding the storage annex is not sufficiently stable to carry the load of the annex upon a spread foundation. Nor does Mr. Phillips think that the proposed new site for the operating house would be stable. It is his opinion that the subsidence is still continuous. He therefore recommends that concrete cylinders be sunk to the underlying gravel under all of the buildings. This would require 63 cylinders for the storage annex alone.

No action has been announced as yet. The board of engineers is soon to present a final report.

New State Commissioner of Highways Appointed in New York

Confirmation by the New York State Senate makes effective the appointment by Governor Smith of Capt. Frederick Stuart Greene as state commissioner of highways. He succeeds Edwin Duffey, who was appointed by Governor Whitman. There has been considerable controversy as to whether Mr. Duffey's term has expired. When he was appointed originally, the term of John N. Carlisle, then commissioner, had not yet expired. The term would have expired Apr. 29, 1918.

At the expiration time Commissioner Duffey was not reappointed, but merely held over. Attorney General Newton offered the opinion that his term expired on the aforesaid date, and as there had been no new appointment the present Governor was at liberty to make one.

Captain Greene is a resident of Nassau County and has had extensive experience in engineering and general construction work. Since 1905 he has been vice-president and general manager of the Waterproofing Co. of New York.

During the war he was a captain in the 302d Engineers and served in France.

Idaho State Government Reorganized

Centralization of executive power and responsibility in the Governor of Idaho is effected by a bill which recently became a law. With the exception of the elective officials provided for by the Constitution and the officials of the Department of Education, all the various commissions, bureaus, etc., of the administrative branch of the Government of Idaho are done away with by the bill. In their place there are set up the following nine departments: Agriculture; commerce and industry; finance; immigration, labor and statistics; law enforcement; public investments; public welfare; public works; reclamation. A single commissioner will head each department. For some of the departments other officers are provided for by the statute. All of the officers named in the act are to be appointed by the Governor and may be romoved at his discretion. The salary of each commissioner will be $3600 a year. Several departments will deal with engineering matters: The department of law enforcement will register architects, surveyors and civil engineers. The department of public works will take over the work previously done by the state highway department, by the trustees of the capitol building, and by the Heyburn Park board of control. The department of reclamation will take over the duties of the State Engineer and of the state board of land commissioners, except as to the duties of the latter in holding, leasing and selling state lands. The act provides that the director of highways in the department of public works must be a civil engineer of not less than five years' experience in road building, and that the director of water resources in the department of reclamation must be a hydraulic engineer with not less than five years' experience in the practice of irrigation engineering.

Patent Office Employees Organize Society

For the purpose of advocating certain reforms in the administrative branches of the United States Patent Office, the employees have been organized under the name of the Patent Office Society which, it is claimed, will bring about a higher efficiency in the system. Committees on legislation and publicity have been appointed with a view to educating the public to the necessity for an immediate improvement of the present Patent Office system and to push Congressional enactment to broaden the scope of the office.

The plan includes the separation of the Patent Office from the Department of the Interior and provides for an executive officer who shall be an industrial and efficiency expert, the position eventually to be that of a cabinet officer when the department shall have assumed the proportions to warrant such a distinction.

The society proposes the establishment of five bureaus—namely, a bureau of information and education, a bureau of patents and publications, a bureau of utility, a bureau of validity examinations, and a bureau of priority of inventions.

The society is publishing a monthly journal in the interest of the principles being advocated in the reorganization of the Patent Office. The officers are as follows: President, M. H. Coulston; vice-president, J. H. Lightfoot; secretary, Bert Russell; treasurer, W. F. Avery.

Low Price Asked for Building Fabricated Ships

An offer to build 12,000-ton steel vessels for the price of $149 per ton deadweight capacity has been made to the Shipping Board by the Submarine Boat Corporation, Newark, N. J. These vessels would be powered for 12 knots speed, with either reciprocating engines or geared turbines. The vessels would be 473 ft. long and 62 ft. in beam, and draw 28½ ft. The Newark Bay yard is at present building 5000-ton ships for the Fleet Corporation, using bridge-shop fabrication. Enlargement of the ways would be necessary to permit building the larger ships. It is proposed to reconstruct eight ways, and the price made is contingent on the ordering of 16 vessels. According to E. N. Hurley, chairman of the Shipping Board, steel ship prices in 1916 ranged from $50 to $69, while recent prices have been $185 to $225 per dead-weight ton.

Members of National Societies Have Association in Cuba

What may prove to be a forerunner of similar association in this country is seen in the Association of Members of American National Engineering Societies in Cuba, recently organized to provide for activities "to foster the interests of the various national engineering societies represented on the island" and to promote the discussion of engineering and technical topics of local interest. Not the least attractive of the proposed activities are the dinners or smokers for the promotion of good-fellowship and for showing hospitality to members of the American societies temporarily visiting in Cuba. Luther Wagoner, president, suggests that since there is no danger of prohibition in Cuba there may be many visitors after July 1, who will be welcome.

Filters Added and Water Softening Proposed at Minneapolis

Having enlarged its mechanical filtration to 24 units, with a total capacity of 96,000,000 gal., Minneapolis is now considering plans for water softening. The plant was put in operation in 1913. A previous enlargement was completed in 1917. W. N. Jones is in charge of filter design and construction and F. W. Cappellen is city engineer.

Connecticut Electric Railways Bankrupt

Of the 828 miles of electric railways in Connecticut, 98% are either in the hands of a receiver or are insolvent, according to the report of a special commission made to the legislature Apr. 1. So bad is the situation that operations on many of these lines must be partially or completely suspended unless substantial temporary relief is afforded by the present legislature. The commission enumerates twelve causes that have contributed to create the financial difficulties. Besides the decrease in the value of the nickel railway fare and the great increase in cost of fuel, supplies and wages, the commission points out that a large part of the traffic formerly enjoyed by the electric railways is now carried by privately owned automobiles and by the unregulated jitney omnibuses. As a means of meeting this critical situation and enabling the companies to continue in operation, which is a public necessity, the commission recommends the release of the companies from the payment of state taxes and assessments for bridges and street paving. Motor omnibuses should be under state control so far as schedules, routes and rates are concerned, and should be compelled to give bonds for damages to injured persons. The electric railway companies should be permitted to abandon portions of their system which are unprofitable and to operate motor-vehicle service where desired. Bills have been drawn to carry out these recommendations and also providing for a loan of state funds, amounting to not more than $2,000,000, to electric railway companies to tide them over the present critical situation.

City To Buy Dredged Fill from Government

New land is to be made by the City of Jersey City, N. J., on the Hackensack River, from fill which is to be dredged from the river by the United States Government. The city commissioners have just passed a resolution authorizing the city to purchase from the Federal Government enough of the dredged fill to make about 50 acres of new land 5 ft. above the present river level. The agreed price is 10c. per cubic yard, and the estimate provides for the removal of about 400,000 cu.yd. of material.

New Assistant to Secretary of Interior Appointed

John W. Hallowell, member of the firm of Stone & Webster of Boston, who has been in close touch with engineering matters for the past 18 years, has been appointed the new assistant to the Secretary of the Interior, and will have under his immediate charge the Bureau of Mines, the Reclamation Service and the Alaska Ry. Mr. Hallowell has been associated with Stone & Webster for 16 years, specializing in the financial side of public utilities and other engineering projects.

Two years ago he joined the staff of the Food Administration, from which he resigned recently after his return from abroad, his last work being a survey of the industrial situation in Belgium and northern France. He succeeds H. A. Meyer, who resigned to become associated with the Prairie Oil & Gas Company.

Industrial Conference Addressed by Prominent Men

At an editorial conference held under the auspices of the New York Business Publishers' Association in New York City on Apr. 11 some of the most prominent men in the country discussed the pressing industrial problems now before the country. Dr. Charles P. Steinmetz, consulting engineer of the General Electric Co., made a keen analysis of the various proposals for industrial coöperation. Dr. Charles A. Eaton presented a forceful address on the subject of industrial democracy, and John Calder, consulting engineer, formerly general manager of the Remington Typewriter Co., treated the subject of "Recent Advances in Industrial Management."

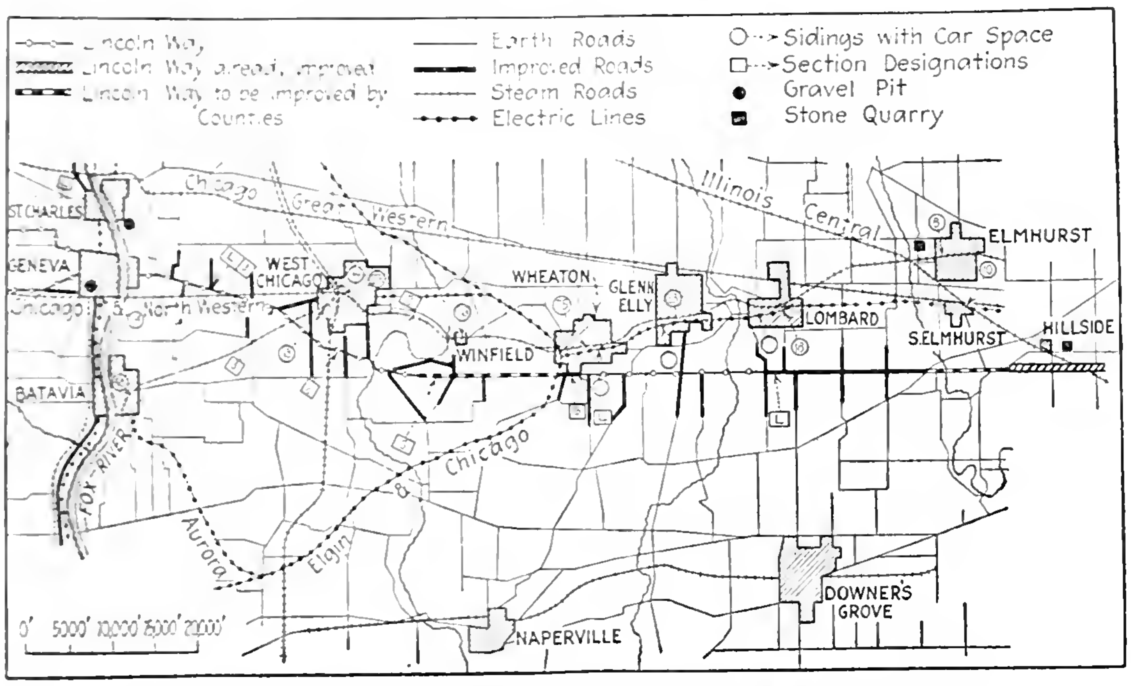
The necessity for organization in the settlement of labor disputes was the subject of an address by V. Everit Macy, chairman of a committee on adjusting wages in private shipbuilding plants during the war, and now president of the National Civic Federation. Four papers were presented on the subject of financial problems: "Post-War Financial Problems," by Francis H. Sisson, vice-president of the Guaranty Trust Co., New York; "Problems of Our Foreign Trade," by G. A. O'Reilly, foreign trade expert of the Irving National Bank, New York; "Prices Yesterday, Today and Tomorrow," by O. P. Austin, chief statistician of the National City Bank of New York, and "Stabilizing the Dollar in Purchasing Power," by Prof. Irving Fisher of Yale University.

Surveys for Large Washington Irrigation Project

An appropriation of $100,000 for surveys of the Columbia irrigation project, embracing some 2,000,000 acres to be put under water in Washington, has been made by the state legislature. Water would be taken from Pend Oreille River at Albany Falls, just over the line in Idaho. Federal coöperation through the United States Reclamation Service is hoped for. The studies are being made under the direction of the Columbia Basin Commission, the chairman of which is Marvin Chace, state hydraulic engineer. It is reported that A. J. Turner, Seattle, has been appointed chief engineer, and J. C. Ralston, Spokane, consulting engineer to the commission, and that headquarters will be in Spokane.

Pits and Quarries Mapped for Bidders on Road Work

Transportation routes and deposits of materials are mapped for the benefit of contractors who will submit bids and obtain contracts for 115 miles of the Dixie and Lincoln Highways to be built in Illinois in 1919. The fragment of the Lincoln Highway map reproduced here indicates the nature of the information depicted. Accompanying the maps are lists giving the car capacity of each railroad siding, and the character of the materials from each quarry and pit, together with the names of the operators. On the Lincoln Highway work, for example, 40 sidings are listed at 31 towns and cities, and on the Dixie Highway 31 sidings at 27 locations. For both contracts some 60 pits and quarries are listed. Clifford Older is chief state highway engineer.



MATERIAL DEPOSITS AND TRANSPORTATION FACILITIES MAPPED FOR ILLINOIS ROAD CONTRACTORS

Funds Available For Extensive Road Work in Oregon

A total of about $30,000,000 is to be available for highway construction in Oregon during the next three years. Plans have been made for beginning immediately an extensive construction program. All of the work except the forestry roads will be under the direction of the State Highway Commission. Herbert Nunn is chief engineer.

The funds included in the total figure mentioned come from several sources. Before the legislature met this year there was a total of $3,500,000 in unexpended bonds remaining from the bonds authorized in 1917, and authority was given by the legislature to sell bonds for $10,000,000 more. The ¼-mill tax is expected to net the road fund about $250,000 this year, while the tax on gasoline and distillate (1c. per gallon on the former and ½c. per gallon on the latter) will add $400,000. The net share from the auto-license department will be about $450,000 more. Federal funds for post and forestry roads to be used under the coöperative plan will also be forthcoming.

There are to be two road-bond issues on the ballot at the election in June, one for a property tax of one mill per annum for paying half the cost of local roads in those counties which will raise an equal amount, and also a measure providing for a military highway to be built along the full length of the Oregon coast, with $2,500,000 of state funds matched by an equal amount from Federal funds. The last project is the only one concerning which there is any doubt.

The plan for the expenditure of these funds calls for the completion of some 4000 miles of state highways. Of these, about 790 miles are to be hard-surfaced. On the coast roads concrete is specified wherever paving is to be done. On other parts of the system the type of road will depend on the prices bid, the alternative being bituminous pavement on macadam base. The concrete will be 6 to 7 in. thick, the 6-in. section being used in the dryer eastern part of the state, while the 7-in. depth is considered necessary west of the mountains. The pavements are to be laid 12, 16 and 18 ft. in width, depending upon the amount of travel; 80% will be 16 ft.: 15% 12 ft. and 5% 18 ft. wide., all with 2-ft. crushed-rock shoulders.

Michigan Votes for Highway Bond Issue of $50,000,000

Aproval by the voters of Michigan of a highway bond issue of $50,000,000, assures the construction of the 5000-mile system of intercounty roads described in *Engineering News-Record* of Feb. 20, 1919, p. 399. The system is planned to reach every county in the state.

While the road-bond issue voted on Apr. 7 was carried by a large majority, it is significant that the constitutional amendment which would have provided for the sale and manufacture of beer and wine was rejected. It will be remembered that the brewing interests tried to tie these two propositions together during the campaign.

Kansas Plans State-Aid for Roads

State aid for highway construction in Kansas is provided for by a constitutional amendment passed at the recent session of the state legislature, and this will be submitted to public vote at the general election in 1920. If it is carried it will permit the state to pay 25% of the cost of road construction, not to exceed $10,000 per mile and not to exceed 100 miles in any one county, except that this may be 150 miles for counties having an assessed valuation of over $100,000,000. The amendment provides also that the state may reimburse the counties which build roads after March, 1919, if the legislature so desires. It is pointed out that this constitutional amendment is more of a legislative act than a part of a constitution, but it was all that could be obtained from the recent session of the legislature.

The outlook for road work in Kansas during the coming season is said to be good. The Federal-aid funds will be taken care of with an equal amount from the counties. It is estimated that this, with a considerable amount of other work, will involve about $8,000,000 per year for the next two years. High prices are delaying progress, but with 50% aid it is hoped to get a good percentage of the work under way at an early date. Contracts have been let for five sections of road, and other contracts will soon be ready for letting. The State Highway Commission, however, has received so small an appropriation that it will have some difficulty in handling the work. M. W. Watson is acting state highway engineer.

Iowa Has Extensive Road Program

Hard surfacing of the intercounty road system, which consists of approximately 6000 miles of the most important roads in the state, during a period of 10 to 12 years, is provided for in a bill now before the Iowa legislature. Provision for bond issues in limited quantities by the counties is included, but bonding is not advocated or recommended, except in a few counties where the work should progress more rapidly. The bill covers the establishment of a primary road fund composed of the automobile fees and the Federal-aid money received each year. This fund is to pay 75 per cent. of the expense and the remainder is to be assessed against the adjacent property, for 1½ miles back on each side of the road.

Under the first Federal-aid law Iowa has 27 projects estimated to cost $105,630. These total 394 miles, principally of grading and draining. It is expected that they will be put under contract soon, and that work will be started early in the summer. Bids on two or three of these have been rejected as being too high. There are also projects aggregating $1,000,000, in progress in 13 other counties, for which contracts may be let and work started this year.

Civil Service Examinations

New York.—Junior assistant engineer, State Engineer and Highway Department, $1200-$1440 per year, May 24. Apply to State Civil Service Commission, Albany, N. Y. File applications before May 24.

New York.—Bridge designer, Public Service Commission, First District, $1501 to $2100 per year. Apply to State Civil Service Commission, Albany, N. Y. File applications before May 24.

For United States Civil Service examinations listed below, apply to United States Civil Service Commission, Washington, D. C., or to any local office of the commission, for form 1312.

United States.—Engineer-draftsman, Apr. 22, $1500 to $1800 per year. File Application before Apr. 22.

United States.—Transitman, $100 to $125 per month, and surveyor, $125 to $200 per month, Apr. 23-24. File applications in time to arrange for examination at place selected by applicant.

United States.—Expert patent investigator, $1800 to $2400 per year, and technical patent expert, $2400 to $3600 per year, May 20.

United States.—Highway bridge engineer, $1800 to $2100 per year, junior highway bridge engineer, $1200 to $1600 per year, Bureau of Public Roads and Rural Engineering, May 21. File applications in time to arrange for examination at place selected by applicant.

United States.—Engineer in forest products, $1860-$3000 per year; assistant engineer in forest products, $1200-$1800 per year, Forest Products Laboratory, Madison, Wis., May 27. File applications before May 27.

United States.—Chief of road survey party, $1800 to $2100 per year, transitman for road surveys, $1200 to $1800 per year, highway draftsman, $1200 to $1800 per year, Bureau of Public Roads and Rural Engineering, May 29. File applications before May 29.

United States.—Scientific assistant in public health work, Public Health Service, $1500-$2500 per year, June 3. Apply for form 2118, to be filed before June 3.

United States.—Senior engineer and senior architect. Interstate Commerce Commission, $1800-$2700 per year, June 10. File applications before June 10.

United States.—Assistant material engineer, Bureau of Construction and Repair, from $4.48 to $6.40 and upwards per diem. No date specified. Applications should be filed without delay.

United States.—Junior recreational engineer, Forest Service, Denver, Colo., $1800 to $2400 per year, May 6. Apply for Form 2118.

United States.—Statistician, Department of Interior, $1800 per year, May 13. Apply for Form 2118.

Engineering Societies

Calendar

Annual Meetings

NATIONAL FIRE PROTECTION ASSOCIATION; 87 Milk St., Boston, Mass.; May 6-8, Ottawa, Can.

AMERICAN ASSOCIATION OF ENGINEERS, 29 S. LaSalle St., Chicago; May 13-14, Chicago.

NATIONAL CONFERENCE ON CITY PLANNING; 19 Congress St., Boston; May 26-28, Niagara Falls and Buffalo.

AMERICAN WATER-WORKS ASSOCIATION; 47 State St., Troy, N. Y.; June 9-13, Buffalo, N. Y.

AMERICAN SOCIETY OF CIVIL ENGINEERS; 29 W. 39th St., New York; June 17-20, St. Paul-Minneapolis.

AMERICAN SOCIETY FOR TESTING MATERIALS; University of Pennsylvania Philadelphia; June 24-27, Atlantic City, N. J.

AMERICAN CONCRETE INSTITUTE; 6 Beacon St., Boston; June 27-28, Atlantic City, N. J.

The Rochester (N. Y.) Engineering Society will hold a meeting Apr. 25 in conjunction with the regular monthly meeting of the local section of the American Institute of Electrical Engineers. The speaker will be Prof. Vladimir Karapetoff, of Cornell University.

The Engineers' Club of Philadelphia will be addressed by Prof. George B. Pegram, dean of the School of Mines, Engineering and Chemistry, Columbia University, on "A Broader Type of Training for Engineers," at the weekly luncheon Apr. 22.

The Engineers' Society of Milwaukee held a joint meeting with the Milwaukee sections of the national engineering societies Apr. 16, at which George R. Lawrence, president of the Lewis-Lawrence Aëroplane Co., Chicago, presented an illustrated paper on "Flying Today and Tomorrow."

The Engineers' Club of Trenton, N. J., was addressed Apr. 10 by H. C. Eddy, senior inspector of traffic, Public Utility Commission of New Jersey, who spoke on "The Development of the Electric Railway."

The Brooklyn Engineers' Club will be addressed at the meeting Apr. 17 by Maj. W. McI. Wolfe, who will speak on "The Work of Engineer Troops in France." At the Apr. 24 meeting, to be held in the Sperry Building, Manhattan Bridge Plaza, Brooklyn, Elmer A. Sperry, of the Sperry Gyroscope Co., will speak on "The Sperry Searchlight" and will give a demonstration of the searchlight on the roof of the building, if weather permits.

The Engineers' Society of Northeastern Pennsylvania will hold its regular monthly meeting at Scranton, Apr. 17. Maj. L. S. Doten will speak on "Sewage Disposal in Army Camps."

The Engineers' Club of Cincinnati will be addressed Apr. 17, by W. W. Freeman, president of the Union Gas & Electric Co., on "Power Problems of a Modern City and Their Solution."

Personal Notes

G. A. TOMLINSON, director of inland waterways and canals, United States Railroad Administration, has resigned and will soon go to London to become resident director there of the American Shipbuilding Co., which controls a number of shipyards on the Great Lakes.

J. R. WEST, for the past three years professor of railway and structural engineering, Pei Yang University, Tientsin, China, has been appointed engineer-in-chief of the Min River Conservancy at Foochow, China, for the purpose of regulating and deepening the Min River to permit steamers engaged in coastwise trade to reach the wharves at Foochow.

LEROY D. GIFFORD, formerly construction engineer, California State Highway Commission, and recently of the 19th Regiment C. A. C., has returned to civil life and is engaged in establishing a chemical manufacturing plant at Anaheim, Calif., to specialize in citrous byproducts.

CAPT. L. R. MACKENZIE, U. S. A., recently engineer of roads on the staff of the commanding general, port of embarkation, Newport News, Va., has been appointed district engineer in charge of the new district office of the Portland Cement Association at Des Moines, Ia.

EDWIN R. WEBSTER, for several years assistant engineer on the Iowa and Dakota divisions of the Chicago, Milwaukee & St. Paul R.R., in charge of construction and maintenance work, has taken up private practice in general civil and sanitary engineering and has opened an office at 327 S. La Salle St., Chicago.

CHARLES H. HURD, consulting engineer, Indianapolis, whose resignation from the Board of Sanitary Commissioners was noted in *Engineering News-Record* of Apr. 3, 1919, p. 693, has been apponted supervising engineer of construction for the commis-

sion. He will have charge of the building of the new city sewage-disposal plant. Mr. Hurd went to Indianapolis as chief engineer of the Indianapolis Water Co., later becoming its vice-president.

CAPT. ERLE P. DUDLEY, Engineers, U. S. A., who recently returned from overseas, has received his discharge from the service and has resumed his work with the Bunker Hill & Sullivan Mining & Concentrating Co., Kellogg, Idaho.

ROBERT GARDNER, assistant superintendent of the water department, Lowell, Mass., has been appointed superintendent of the department, succeeding Robert J. Thomas, who has resigned to become New England representative of the Gamon Meter Co., Newark, N. J., as noted elsewhere.

MAJ. ROBERT A. ALLTON, Field Artillery, U. S. A., who has received his discharge from the Army, has resumed his position with Samuel A. Greeley, hydraulic and sanitary engineer, Chicago.

CHARLES B. BALL, chief sanitary inspector for the Department of Health, Chicago, has been granted leave of absence to go to France as an adviser in the work which the Y. M. C. A. is undertaking for housing and city planning in the devasted districts.

H. E. PHELPS, assistant sanitary engineer, United States Public Health Service at Petersburg, Va., has resigned to become highway engineer for Moreland and Bennett Counties, at Pine Bluff, Ark.

LIEUT. RAYMOND G. CLINITE, Corps of Engineers, U. S. A., who recently received his discharge from the service, has resumed his work as assistant topographer, United States Geological Survey.

CAPT. WILLIAM T. HUBER, Engineers, U. S. A., who was recently discharged from the service, has become field engineer for the Portland Cement Association, in charge of western New York territory.

BURT A. HEINLY, formerly associated with William Mulholland, chief engineer for the Department of Public Service, Los Angeles, has entered the employ of the California Willite Road Construction Co., Los Angeles.

CAPT. C. A. JENNINGS, Construction Division, U. S. A., has received his discharge from the service and has returned to the technical staff of the Wallace & Tiernan Co., New York City, to resume charge of the Chicago office. While in the Army his work was done in the supervision, operation and maintenance of water-purification and sewage-treatment plants in various camps.

JOHN T. GEPHART, JR., for the past three years county engineer of Fayette County, at Uniontown, Penn., has resigned to enter a state position at Harrisburg.

ENSIGN EDMUND A. PRENTIS, JR., U. S. N. R. F., has been placed on inactive duty by the Navy Department and has resumed his connection with the Underpinning & Foundation Co., New York City.

CAPT. HARRY C. KITTREDGE, Engineers, U. S. A., who recently received his discharge from the service, has been appointed superintendent of city construction, Rochester, N. Y.

D. C. FENSTERMAKER has been appointed district engingeer, Chicago, Milwaukee & St. Paul R.R., with headquarters in Chicago.

A. C. BLAIR, Lyons, Kan., has been appointed to the State Highway Commission, succeeding E. R. Moses, resigned.

E. C. MCCULLOUGH, assistant road engineer of Fayette County, Uniontown, Penn., has been appointed connty engineer, succeeding John T. Gephart, Jr., as noted above.

CAPT. JOHN A. MCLEAN has been appointed city engineer of Crookston, Minn., succeeding A. Hunt, who resigned on account of poor health.

W. S. LOZIER, chief project engineer, United States Shipping Board, Housing Department, Philadelphia, has returned to Rochester, N. Y., to resume private practice.

CAPT. CHARLES L. COULSON, 2nd Canadian Division, at present in England awaiting demobilization, has been appointed city engineer of Welland, Ont. The City Council will endeavor to obtain his release from military service as soon as possible.

ROBERT J. THOMAS, for thirty years superintendent of the waterworks department of Lowell, Mass., has been appointed New England representative of the Gamon Meter Co., Newark, N. J. He is succeeded by Robert Gardner, as noted elsewhere.

JOHN R. ALLEN, dean of the College of Engineering and Architecture, University of Minnesota, has been appointed director of a national bureau for heating and ventilation research. His work will be done in connection with the research laboratory maintained by the United States Bureau of Mines in Pittsburgh. Although the formal contract has not yet been announced, it is understood that he will select his staff, which is expected to begin work in August. Dean Allen went to the University of Minnesota from the University of Michigan in 1917.

SAMUEL A. GREELEY, hydraulic and sanitary engineer, announces that he has moved to new offices at 39 W. Adams St., Chicago.

OBITUARY

CURTIS DOUGHERTY, chief engineer, maintenance of way and structures, Southern Railway System, West, died in Cincinnati Mar. 30. He was born in 1863 and was graduated from Washington University, St. Louis, in 1886 with the degree of C. E., shortly afterward entering the chief engineer's office of the Wisconsin Central Ry. From 1888 to 1892 he was assistant engineer, Chicago & Western Indiana R.R. at Chicago, and for the following nine years was roadmaster of the Chicago division of the Illinois Central R.R. He afterward became superintendent of the Springfield division of the Illinois Central at Clinton, Ill., and in 1907 was appointed assistant chief engineer, Cincinnati, New Orleans & Texas Pacific Ry.-Alabama Great Northern R.R. From 1910 to 1917 he served as chief engineer of the two railroads. In 1917 he was appointed chief engineer, maintenance of way and structures, Southern Railway System, Lines West.

MARSHALL TEN BROECK DAVIDSON, president of the M. T. Davidson Co., pump manufacturers, died in Brooklyn, N. Y., Apr. 10. He was born in 1837 and was educated in the public schools and the Academy at Hudson, N. Y. In 1857 he entered a marine-engine machine shop in New York City and later went to sea as assistant engineer. He served as a chief engineer in Army transport service during the Civil War. After the war he engaged in business as a contracting mechanical engineer and in 1878 commenced the building of the Davidson steam pump and pumping engine. He constructed the pumping machinery for the old City of Brooklyn and the high-service pumping engine at the Prospect Park reservoir, as well as the machinery for the water-works extension at the Millburn station.

CHARLES E. WESTLAND, who became assistant to the hydraulic engineer, Turners Falls Power & Electric Co., after his release from the Reserve Officers' Artillery Training School at Fortress Monroe, died at Turners Falls Apr. 5. He was graduated recently from the Massachusetts Institute of Technology.

Special Pneumatic Device for Cutting Rivet Heads

A pneumatic rivet cutter for use on structural steel work and in repair shops is shown in the accompanying view. It consists of a long barrel with compressed air connection at one end and a chisel at the other, the stem of the chisel being held by a coiled spring which draws it back after each stroke. A plunger travels freely in the

RIVET CUTTER IN USE ON STRUCTURAL WORK

barrel or tube, and a small bypass pipe connects the ends of this tube. Two men are employed, the one at the rear operating the valve and the one at the front keeping the chisel against the rivet head.

In operation, air is admitted first through the bypass pipe to the chisel end of the tube and drives back the plunger, the shock being absorbed by a coiled spring. Air is then admitted at the other end of the tube and drives the plunger forcibly against the stem of the chisel. Another turn of the valve exhausts the air charge and admits air again through the bypass to drive back the plunger for another stroke. The force of the blow can be regulated by the valve. Air pressure of 40 to 90 lb. may be used, the higher pressures being the more effective. A punch can be inserted in place of the chisel for backing out the rivets.

In the larger size the stroke is 40 in., and the weight of the machine complete is only 65 lb. A smaller size will cut rivets up to [illegible] in. in diameter. These two sizes are known respectively as the "Red Devil" and the "Baby Devil." They are made by the Rice Manufacturing Co., Indianapolis, Ind.

Manufacturers of Electric-Furnace Products Organize

An organization to be known as the Electric Furnace Association was formed at a meeting called at Niagara Falls Mar. 21-22. Representatives of a large number of companies manufacturing electric-furnace equipment, accessories, etc., and electric-furnace products were present. The following officers were elected: President, Acheson Smith, of the Acheson Graphite Co., Niagara Falls; Secretary, C. G. Schluederberg, Westinghouse Electric Manufacturing Co., Pittsburgh.

Building Materials and Machinery For South America

According to a recent report issued by the Department of Commerce, the time is ripe for the sale of construction materials and machinery in several South American countries. This is notably the case in Chile, Peru and Ecuador. The Chilean public is generally favorably impressed with American goods and considers them more up to date than those from Europe.

Large amounts of public improvements are contemplated in these countries, which are more prosperous than before the war, and, having become more progressive, they desire all manner of sanitary fixtures, etc. A publication entitled "Construction Materials and Machinery in Chile, Peru and Ecuador," covering this subject in detail, may be obtained from the Superintendent of Documents, Government Printing Office, Washington, D. C.

Business Notes

Charles F. Ames & Co., Ltd., 90 West St., New York City, announces that they have been appointed to act as the New York sales department of the Platt Iron Works of Dayton, Ohio, handling the pumping and power-plant equipment of the latter.

The Chicago Pneumatic Tool Co. has disposed of its Giant truck department and will confine its operations hereafter to its pneumatic-tool, electric-tool, air-compressor and oil-engine lines. The truck business, consisting of the Chicago Heights plant, with all stocks, inventories, agencies and branches, has been transferred, and the purchasers will continue the business, probably under the title of the Giant Truck Corporation. The tool company also announces that F. V. Sargent has been appointed district manager of sales for its Boston territory, succeeding F. S. Eggleston. The headquarters will be at 182 High St., Boston, Mass.

The Turner Construction Co. has opened an office in Philadelphia in the Presser Building, 1713 Sansom St. It will be a complete unit of the parent organization.

The Advance Machinery and Supply Co., of Denver, Colo., announces that Lieut. F. A. Koenig, recently discharged from the coast artillery service, has joined its organization as sales engineer.

The Trailer Manufacturers' Association of America, the reorganization of which was reported in *Engineering News-Record* of Mar. 6, 1919, p. 499, has announced the appointment of H. W. Perry as general manager. Mr. Perry has been associated with the National Automobile Chamber of Commerce for the past nine years, was secretary of the commercial-vehicle, good-roads, legislative, and export committees, and recently has been manager of the statistical and information department, with offices at Washington. The offices of the association will be located in New York City.

E. I. du Pont de Nemours & Co., Wilmington, Del., announce the following changes in the personnel of their organization: T. E. Doremus has been transferred to the export division of the company as general Eastern manager, with headquarters in Shanghai, China; E. R. Galvin has been appointed manager of the sporting powder division to succeed Mr. Doremus.

Trade Publications

The Central Foundry Co., 90 West St., New York City, has issued a pamphlet containing instructions for laying Universal cast-iron pipe and connecting up the joints. There are 11 pages, $2\frac{3}{4}$ x $4\frac{1}{2}$ in., with illustrations.

A set of five catalogs has been issued by the Chain Belt Co., of Milwaukee, Wis., covering the various sizes of Rex mixers. Of these catalog 95 is a general pamphlet covering all the sizes. Catalogs 101, 102, 103 and 104 contain descriptions with methods of using various types recommended for building and paving work. The catalogs are illustrated with line cuts and half tones and are $7\frac{1}{2}$ x 10 in. in size.

The C. H. & E. Manufacturing Co., Inc., has issued bulletins Nos. 2 and 3. No. 2 covers power pumps, while No. 3 covers hoists, elevators, mortar mixers and engines.

The Edward F. Terry Manufacturing Co., Grand Central Terminal, New York City, has issued Bulletin No. 3, devoted to cargo cranes. This bulletin contains fifteen $8\frac{1}{2}$ x 12-in. pp. and illustrations on the methods of loading ships by the use of traveling cranes.

"Concrete Chutes and Equipment" is the title of bulletin No. 200 recently issued by the Ransome Concrete Machinery Co., Dunellen, N. J. It covers a complete line of chutes and other auxiliary concreting equipment, is $8\frac{1}{2}$ x 11 in. in size, contains 51 pages and is illustrated.

"Blueprint Suggestions on Haulage, Loading Stations and Mixer Equipment for Road Work" is the title of a book recently issued by the Koehring Machine Co., Milwaukee, Wis. The pamphlet is $9\frac{3}{4}$ by $5\frac{3}{4}$ in. and consists of 10 pp. of reading matter and nine charts, showing the layout for different kinds of machinery on road operations. These charts are in blueprint form and are folded in to fit the size of the booklet

DEVOTED TO CIVIL ENGINEERING
AND CONTRACTING

E. J. MEHREN *Editor*   CHARLES WHITING BAKER *Consulting Editor*

Volume 82   NEW YORK, THURSDAY, APRIL 24, 1919   Number 17

Keeping Faith With Those Who Died

THERE is a far-reaching appeal in the attractive poster which is a supplement to this issue of *Engineering News-Record*. Primarily, of course, its object is to preach the need for a full subscription to the Victory Liberty Loan, but the reader who draws only this inference gets only part of the message. Liberty is appealing to everyone, employer and employed, to keep the faith—and that appeal extends to every feature connected with or flowing out of the war. We must keep faith

By oversubscribing the Victory Loan;

By doing justice to every worker and by meeting with patience and in a spirit of compromise the troublesome industrial problems ahead;

By rendering a fair day's work for a fair day's pay;

By insisting that the way of sound progress is by evolution, not revolution;

By making, each in his particular job, whatever sacrifices are necessary to bring about that reign of justice for the attainment of which our sons and brothers suffered and laid down their lives.

Light Aggregate Promises To Compete With Stone

WHAT is virtually a new structural material is made possible by the light-weight concrete aggregate whose properties and methods of manufacture are outlined on another page. Structural concrete rarely requires the weight that generally is necessary or at least useful in mass concrete or masonry. Every pound that is gained without loss of strength is a saving multiplied many times in the reduction of other members proportioned to carry dead as well as live load. Ten months of experimenting have demonstrated that a satisfactory artificial aggregate can be made almost anywhere in this country, and that the technique of its manufacture, while not easy to be learned, can be developed in many types of kiln. The crucial element yet to be determined is its price, and a favorable reply to this question will be eagerly awaited by structural engineers. If such a material can be put down on the job at competitive figures, the stone and gravel men will soon find that their selling problem has taken on new difficulties.

Typhoid Honor Roll Continues To Lengthen

NOTHING can be more gratifying to the sanitary engineer and few things more satisfactory to public-health men generally than the continued decline of typhoid fever. No fewer than 22 cities in 1918 won a place on the provisional typhoid fever honor roll suggested for cities by *Engineering News-Record*, in the issue of Oct. 18, 1917, p. 723. The standard then set tentatively was a rate of 5 per 100,000 or less. Six more cities gained places on this roll in 1918 than in 1916. Some years ago a typhoid rate of 20 or under per 100,000 was considered creditable, and anything over that as indicating, though not proving, a polluted water-supply. In 1918 there were only five cities in the above-20 class, compared with eight in 1916. The detailed figures on pp. 812-813 deserve study, especially by engineers and health officials in cities whose rates are still high. The need for most watchful attention in 1919 will be great, in view of the possible spread of typhoid by demobilization. During the latter part of 1918 and early in 1919 typhoid in our Expeditionary Forces, although still low, increased considerably, as noted in *Engineering News-Record* of Apr. 3, 1919, p. 677. As the forces return there may be among them a sufficient number of carriers, even if not of sick or to-be-sick cases, to spread innumerable typhoid germs in this country. The wise health officer will be on the lookout, ready to act the moment there is the slightest evidence of an increase in typhoid.

The Electric Railway Versus the Motor Truck

RECENTLY the executive secretary of the Highways Transport committee, in addressing a meeting of motor-truck salesmen, pleaded earnestly for coöperation between motor-truck interests and the electric railways, pointing out that the latter were in a bad way financially and needed help in order that the investment represented might be conserved. All will agree with him that it will be a national loss if widespread financial disaster overtakes the electric railways, urban and interurban. Also, when coöperation can produce economies there should be coöperation. The burden, however, is not so much on the motor-trucking interests as on the electric railways. The latter were first in the field. They had a great opportunity to develop intercity express service, and, by and large, had not the business acumen to grasp it. Now they must not whine when a new type of carrier, with great intrinsic merits and under skillful promotion, comes in to preëmpt the field which in great part might have been theirs. Their efforts must be directed not to recommendations of coöperative discussion but to actual demonstrations of economy in freight carriage. The burden is clearly upon the electric railways, not on the operators and advocates of motor trucks. Theoretical discussions have some value as contributions to engineering knowledge, but they do not take the place of demonstrations and records of fact in the application of new methods in this workaday world.

An Influential but Unobtrusive Organization

THE publication elsewhere in this issue of the remarkable address on prices by O. P. Austin, chief statistician of the National City Bank, New York, makes opportune the mention of an organization which in an unobtrusive way is having a very definite influence on the industrial life of the nation. The organization in question is the Editorial Conference of the New York Business Publishers' Association, composed of the editors of the leading technical and trade papers published in New York City. The purpose of the conference is to consider problems that affect industry and business generally, to the end that the editors may have available the best information obtainable in formulating their policies. During the war, for example, there were two conferences at Washington, at which members of the cabinet and heads of important bureaus laid before the editors the main features of important war activities, while at the New York conference at which Mr. Austin's paper was read three big topics were set for discussion —post-war finance, industrial coöperation and foreign trade. These were discussed by the most eminent men obtainable. Besides Mr. Austin, the financial problems were covered by Francis H. Sisson, vice-president of the Guaranty Trust Co. and Prof. Irving Fisher. Dr. Charles P. Steinmetz, V. Everit Macy and Dr. Charles A. Eaton discussed industrial coöperation, while G. A. O'Reilly presented the problems of our foreign trade. While there is no thought of imposing opinions and policies on the editors, the influence of the organization is nevertheless potent, for it is an instrument by which there is constantly made available to the editors the very best thought on urgent general problems.

Cost-Plus Contracts Do Not Encourage Low Labor Output

STUDENTS of cost-plus contracting—and that means almost every engineer and contractor—will be interested in the evidence of its cost efficiency which is presented by Henry C. Turner of the Turner Construction Co., on page 815 of this issue. It is good management and not the form of contract which determines the efficiency of labor in construction; it was floating labor and shortage of trained workmen which caused the low records of labor output in war construction. Seldom has any fact in construction practice been demonstrated more convincingly than these are shown by Mr. Turner's article. For the first time cost comparison of percentage and lump-sum contract work is made.

War construction accomplished much in educating the construction industry to the possibilities of cost-plus contracting. Unfortunately, it also did much to cast suspicion on this form of contract. War construction was wastefully extravagant in the expenditure of labor. Workmen of all classes were most inefficient. Unit costs of construction ran high. These facts may not be denied. They are being charged to the cost-plus contract. If this charge is not to hold good in the opinion of the building public, the true reasons for inefficiency of labor in war construction must be demonstrated. The article here considered comes closer to furnishing the unimpeachable evidence required for complete demonstration than any utterance heretofore made.

Presentation of the precise figures of comparison is left to the article itself. Two broad conclusions stand out from the detail. One is that in a properly organized construction company there is no difference in efficiency in labor engaged in percentage work and that engaged in lump-sum work. The second and equally important conclusion is that there is no reason or justice in forming an opinion as to the advantages of percentage or lump-sum work based on war construction experience.

Wider Use of Standards Should Be Promoted

WHY is it that in some cases important standards of engineering design and practice fail to be used generally even by members of the technical associations that formulated and adopted them? We speak of those standards, such as rail sections, which acquire their greatest value only through practically universal use.

Doubtless inertia is one large factor in the case. Pride in personal designs and prejudice against the standards are others. Positive or well defined objections also play a part, of varying magnitude.

If these are the principal causes operating against the standards, certain obvious remedies are available. For inertia and prejudice the remedy lies in insistent promotion or education, not only as to individual standards, but especially as to the broad advantages of uniformity and the necessity of some amount of compromise or even sacrifice to produce these advantages. Where specific objections are urged against the standards these objections must be analyzed and the reasons for allowing them to outweigh the advantages of uniformity must be brought into the light of day. By means of such methods it is possible to make headway in extending the use of the standard, and thereby transform a potentially valuable document into a productive asset.

A moment's consideration of the special case of rail sections may be illuminating. In touching upon the subject of standardization in his presidential address to the American Railway Engineering Association, C. A. Morse referred to the unnecessary number and variety of rail sections and stated that at the present time 12 sections of 100-lb. rail are being rolled. It is beyond all probability that each one of these is superior to all the others under the conditions of the road or roads using it. On the contrary, it is safe to say that the difference between some of the sections is comparatively or absolutely insignificant, so that other sections would give equally good service. In regard to such cases, it would be pertinent to ascertain the extent to which these special sections are used, and the reasons for not substituting standard sections. Some of the reasons would doubtless appear weak in the light of expert analysis.

Special sections mean extra expense and trouble at the mills. Orders for them cannot be filled from stock, as can those for standard rails, but must wait until the mill has time to change the rolls. Such changes also involve time and money, spent to no useful purpose. In fact, if large amounts of several special sections should be ordered at the same time during a busy period they would constitute a distinct bar to rapid and economical production or output. The same remarks apply to railway splice bars and to many other manufactured parts.

Technical associations having standards should promote their use by informing consumers of their advantages and by finding and combating the objections urged against them.

Expiration of the Norcross Flat-Slab Patent

ON APRIL 29, 1919, the famous Norcross patent, U. S. No. 698,542, on reinforced-concrete flat-slab floors expires, and with it, according to the present legal status of the case, goes the right of the Flat Slab Patents Co., the present owner of the patent, to charge a royalty or to issue a license for the construction and use of a flat-slab floor. This right has been generally recognized since the 1918 decision in the Lauter Piano case, and by many admitted since the 1914 Drum vs. Turner decision. It has been so recognized, however, not because engineers believe those decisions to be just or reasonable, but because it became evident that the complicated legal patent procedure had firmly established the Norcross patent as the basic patent on flat slabs and that it would be futile to try to override the precedent of two original Circuit Court decisions, with several confirmatory later decisions.

It is not the intention of this journal now to enter into a discussion of the evidence and procedure which marked the various Turner-Norcross patent cases. The printed record of those cases occupies many volumes, and only one who was forced to do so would attempt to wade through it. Certainly, the various engineering experts on both sides, whether intentionally or not, succeeded in obscuring the real issue and in confusing the judges as to the technical questions involved. It is of interest, though, to note that the two cases are founded on diametrically opposite principles. According to the Drum-Turner decision, Norcross showed invention in his novel arrangement of steel in a flat-slab floor, although obviously flat-slab floors had been previously patented and built. The later Lauter decision held that Turner's patent infringes Norcross' because its difference in placing reinforcement does not constitute invention. In other words, the first case sets up Norcross as a basic patentee on analogous grounds to which the second case denies invention to Turner. To confuse matters, in a later decision the Drum-Turner court specifically stated that it considered the Norcross invention to lie in a floor without supporting beams, not merely in the location of the reinforcing rods.

In practically all of the other reinforced concrete patent cases there has been a growing movement toward consistent thought. Arrangement of reinforcement to meet stresses is now fairly definitely established as mere engineering design and not invention. On such a basis neither Turner nor Norcross was entitled to a patent, because both developed through ready processes of engineering thought a type of structure established by record if not by extensive practice. A flat reinforced-concrete slab, supported on four columns, antedated both patents. Whether the designers and builders of these earlier slabs understood the actions that took place in the structure or designed correctly to meet those actions, is not pertinent if there was sufficient suggestion in them to permit an engineer skilled in structural design to adapt the principle to meet acceptable theory.

The progress of the litigation and the subsequent success of the Norcross patent, with its levying a tax on hundreds of structures, was a legal victory entirely and not an engineering one. No one doubts that Turner developed a commercial flat-slab floor, though few agree with his highly optimistic views on the strength of his floors. On the other hand, the Norcross case bore every evidence of lying only in a paper patent put forward to fight Turner's claims for invention and his prospective, if not actual, demands for royalty. Neither patent, in the views of most engineers today, was anything but a step forward in design, and the enforcement of a tax to be paid to either one of the patentees on the ground that his was a broad basic patent was bound to be resented as a legal imposition, although unfortunately there was no redress when once the courts had made their decision.

The Concrete in the Teaching of Engineering

DISCUSSIONS of engineering education have been so frequent recently that one is inclined to pass them by and to await the action of the colleges before indulging in more theory. However, we believe that engineers will read with more than ordinary interest the clear, forceful presentation of the plea for the concrete teaching of engineering made by Professor Morrow on page 827 of this issue. His views on his major topic are not altogether novel, but he repeats them with a strength and conviction that throw them into higher relief than in any presentation that has come to our attention.

Briefly, he pleads that the fundamentals of engineering—physics, chemistry, mathematics, etc.—should be taught in the applied manner. He would show through the concrete how things are done, and then seek the causes. Obviously, the teaching of the fundamentals would not follow after the engineering experiments themselves, but would go hand in hand with them. The same thought dominates the coöperative system of education as developed at Cincinnati, but it is clearly apparent that the method proposed by Professor Morrow can be applied at institutions far removed from industrial centers. It is a difference in spirit rather than equipment that is determinative in his scheme.

The danger, as we see it, in the plan he proposes is that which inheres in any scheme of education which stresses practice rather than theory; namely, that the student may be inclined to apply the quantitative standard not merely to the engineering works with which he deals, but to all other factors in life. It may be answered that even the abstract teaching of science has the same tendency, but we are inclined to believe that the stressing of principles which comes in the older method of teaching has somewhat the advantage as to this feature over Professor Morrow's scheme.

In criticising Professor Morrow's proposals we are not to take his attitude on the teaching of the engineering fundamentals as the whole of his plan, for when the latter part of his paper—that referring to the humanities—is taken into consideration, the first objection to the materialistic tendency of his proposed method of teaching engineering is largely removed. The problem is one of spirit just as much as method. An engineering faculty with little sympathy with the humanities could work much mischief, in the way of turning out one-sided men, with a plan such as Professor Morrow's. On the other hand, if the leaders are cultured men with a clear vision of the type of student they wish to turn out—young men prepared to take their places not merely as engineers but as citizens—the concrete teaching of the engineering subjects would be mellowed by the correct emphasis upon ideals.

History and Properties of Light-Weight Aggregates

Burnt Clay or Shale, Producing Material Full of Nonconnecting Cells and Making Concrete of High Strength and Light Weight, Developed by Government's Concrete-Ship Engineers

LIGHT-WEIGHT aggregate made from an artificially burnt shale or clay is now being used for the concrete on all of the Government concrete ships. The concrete so made, in rich mixtures and with a fine-ground cement, weighs from 100 to 118 lb. per cubic foot, and tests in compression from 3500 to 5500 lb. per square inch at the end of 28 days. Furthermore, it is impermeable, readily workable, and, so far as has been ascertained, has no defects not common to concrete with any of the more generally used aggregates. This artificial aggregate has been developed by the concrete ship section of the United States Emergency Fleet Corporation, but until now no definite statement of its method of manufacture or of its properties has been given out. *Engineering News-Record* is permitted here to make public the present knowledge of the material.

Early in the study of the concrete ship it became evident that to compete commercially with wood and steel the concrete must be lighter than the 150 lb. per cubic foot of the structural mixture commonly used. Naturally, low-weight concrete meant a low-weight aggregate. Many investigations were made into the possibilities of slag and various light, natural aggregates, such as volcanic scoria, pumice, etc., all of which are of a vesicular nature; that is, full of small nonconnecting cells which reduce weight. In pursuance of these studies it was found that certain clays or shales could be burnt so as to produce a light-weight vesicular product similar in appearance and qualities to the volcanic basalts, but more uniform in character and therefore better fitted for aggregates.

Accordingly, experimental work was started at the Bureau of Standards in the early summer of 1918 on quantity production of this material. The first working plant was a down-draft beehive kiln near Birmingham, Ala., where enough aggregate was turned out to supply the 3000-ton "Atlantus," launched in December at Brunswick, Ga. Experiments were also carried on in a portland cement rotary kiln at Ragland, Ala., and initiated at a railroad tunnel kiln at Perth Amboy, N. J., local clays and shales being used at each, but neither progressed beyond the experimental stage. Later, however, two contracts were let for quantity production for the big concrete ships under way; one to the Atlas Portland Cement Co., which makes the aggregate in cement kilns at Hannibal, Mo., and one to the Los Angeles Pressed Brick Co., which made the aggregate in dome kilns formerly used for burning brick. Both plants are now producing aggregates, the Hannibal plant supplying the ships at Wilmington, N. C., Jacksonville, Fla., and Mobile, Ala., and the Los Angeles kilns those at San Diego and San Francisco. In all, 25,000 tons of the aggregate will be required for the present Government program.

The new light-weight aggregate, as has been stated, is an artificially burned clay or shale uniformly filled with small nonconnecting cells. Speaking nontechnically, it is a bloated brick; that is, the basic clay or shale from which it is formed, when subjected to a temperature of about 1800° to 2000° in a kiln, becomes plastic and sears over on the surface, a coating being formed there which retains the gases generated by the decomposition, under heat, of the contained compounds. This expanding gas blows the brick or the clay ball full of holes and bloats it to several times its original size.

Various clays and shales are of the proper quality and consistency for such an aggregate. The material from which the aggregate is made should be rich in compounds of metallic oxides, carbon, sulphur, sodium, potassium or other equivalent compounds, some of which, when the material is subjected to heat, will either act as a flux in reducing the more refractory compounds or will give off gas at the desired time, or both. The use of clay or shale containing a relatively high percentage of calcium carbonate or magnesium carbonate should be avoided, as such undesirable elements, after being subjected to a temperature sufficiently high to change their form, would be detrimental to the product. The ratio of the fluxing constituents to the nonfluxing constituents can vary within wide limits, but ratios indicating fusibility at comparatively low temperatures may be commercially preferable.

LIGHT-WEIGHT AGGREGATE AS IT LOOKS BEFORE IT IS REDUCED TO PROPER SIZE FOR CONCRETING

This material was made at the Los Angeles Pressed Brick Company. Lettered brick near middle of bottom of view is of standard size.

Such material is widely distributed, having been found in Alabama, New Jersey, Missouri, New York and California, and used commercially in the production of aggregates in those localities. An analysis of a typical clay or shale of which such aggregate is made is as follows:

	Per Cent.		Per Cent.
S_1O_2	60	SO_3	1
Fe_1O_3	8	CO_2	2
Al_2O_3	19	Alkalis	3
CaO	1	Water	5
M_gO	1		
		Total	100

Such composition is found both in shales and clays. Both can be used in the manufacture of the aggregate, although the process of manufacture is slightly different. Either one weighs about 100 lb. per cubic foot in its natural state.

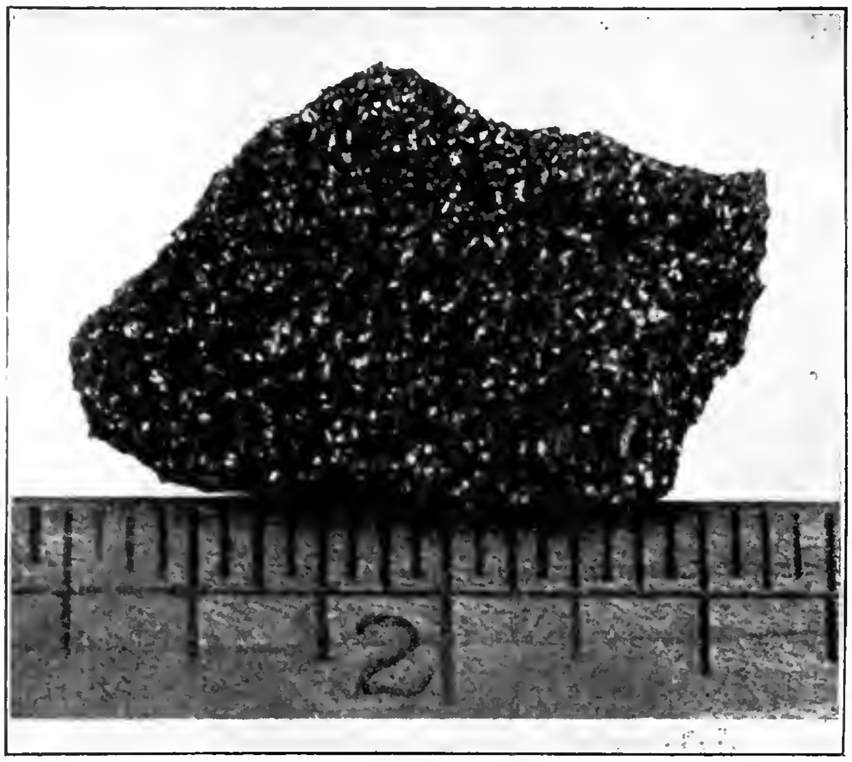
In general, in the production of the aggregate, the raw shale or clay must first be reduced by means of suitable crushers or disintegrators to a fineness so that all of it will pass through about $\frac{3}{16}$-in. openings. The purpose of this reduction is to obtain uniform texture and to prevent striations or laminations which might otherwise result in the finished material. It is then burned in a kiln, according to either the wet or dry process as noted hereinafter, is taken from the kiln either in large balls or in the bloated brick, and is then crushed to the required sizes for the aggregate which, in the concrete-ship work, is not larger than passing through a $\frac{1}{2}$-in. round opening.

The aggregate burned in the stationary brick kilns is prepared as an ordinary brick for the burning. Such a product used on the Brunswick ship was made at the brick plant of the Copeland-Ingles Shale Brick Co. at Alton, near Birmingham, Ala. This material was burned in an ordinary type of down-draft dome brick kiln. The raw material, which was a shale, was prepared as for common, stiff-mud brick, and after drying to a less degree than is the practice for the production of common brick, was placed in the kiln, set rather close in columns, leaving space for swelling, and fired rapidly. The resulting product was more or less oxidized on the surface, and lacked the uniformity possible by other methods of burning. However, most of the product was quite satisfactory. The bricks, when sufficiently cool, were taken from the kiln, crushed and screened. The coarse aggregate was that which passed the $\frac{1}{2}$-in. screen and was retained on the $\frac{3}{16}$, the fine aggregate that passing the $\frac{1}{16}$-in. screen to dust. The tests of the concrete made from this aggregate are given in Table III. Local coal was used for the fuel in the kilns.

While burning the aggregate at Alton, experiments were also made in burning the same material in a rotary kiln at the plant of the Coosa Portland Cement Co. at Ragland, Ala. In the experiments, the shale from Alton and the shale from the cement company's land were both used. There was practically no difference in the products of the two materials, neither was there much difference in the analysis of the shales. In this experiment the shale was prepared by passing it through Fuller mills and then directly to the kiln in the form of both a dry powder and a slurry. Bricks, also, were made at Alton and shipped to be burned in the rotary kiln, with quite satisfactory results. From the experiment, though it was not extensive enough to establish the fact, it would seem that somewhat better results might be expected from the use of a slurry than from the use of a dry feed. Some very excellent material was produced during this experiment, made in an ordinary cement kiln 8 ft. in diameter by 125 ft. long, using powdered coal as fuel. None of this material was used in the ships.

Further experiments were made at certain other places, both with tunnel kilns and with ordinary brick kilns, but none of the material was used in practical work.

Later a contract was entered into with the Atlas Portland Cement Co. to produce light aggregates in its plant at Hannibal, Mo., using shale found on the property. The raw material here was reduced to a fineness of approximately 100% through a 50-mesh screen, and introduced into a large cement rotary kiln in a dry state, with powdered coal as fuel. This burned ball coming through the rotary was passed directly into a crusher while hot and sorted at the distribution end of the kiln. Crushing the material while hot and malleable produced particles of a spheroid shape with few of the sharp corners which distinguish the cold-crushed material. In this product there is a rather large quantity of extra hard, burned small particles, which are screened out before the larger particles are crushed. These hard fines weigh considerably more than the more porous product, but on account of the expense of production they are being used in the ship work. As noted in the tables and descriptions further on, they tend to increase the weight of the concrete a few pounds over that of the concrete made from the brick aggregate. The product of the Hannibal mill is now being shipped to the Atlantic and Gulf yards.



PIECE OF CRUSHED LIGHT-WEIGHT AGGREGATE SHOWS FIXTURE

The scale shown in the view is to one-sixteenth of an inch

Still later an agreement was made with the Los Angeles Pressed Brick Co. to produce the aggregate in semi-muffle and down-draft kilns, using oil as fuel. In this plant the material is pugged and mixed with water and forced through brick machines and burned as ordinary brick. There is being produced here a remarkably light and satisfactorily strong material, as shown in the data in Table IV. It is being used on the San Diego and San Francisco ships.

The aggregate as used in the concrete ships is as a rule being divided into two sizes, the coarse material, that which passes through a screen having $\frac{1}{2}$-in. round openings and is retained on the screen having $\frac{3}{16}$-in. round openings, and the fine material, that which passes through a screen having $\frac{3}{16}$-in. round openings. In the ships the concrete is mixed in the proportions of one part cement, two-thirds part fine aggregate, and one and one-third parts coarse aggregate, although in some of the yards these proportions have been changed to slightly different mixtures which are noticed in the various strength tests given herewith. The early speci-

TABLE I COMPRESSION TESTS OF LIGHT-WEIGHT AGGREGATE CONCRETE MADE AT HANNIBAL, MO.

Tests made on 6x12-inch cylinders at mill. Mixture = 1 part Atlas portland cement, ⅔ part fine aggregate, 1 part coarse aggregate.

fication for the concrete was that the 1: ⅔: ⁴⁄₃ mixture with sufficient water to produce a consistency drop of 9 in., according to the test noted in Mr. Davis' paper in *Engineering News-Record* of Mar. 27, 1919, p. 603, shall develop in seven days a minimum strength of 2500 lb., using standard American portland cement. In the ship the special fine-ground cement, passing 90% through the 200-mesh screen, is being used. The tests, as given in the accompanying tables, indicate that the 2500 lb. would be a safe minimum for the seven-day test, with 4000 or even 4500 lb. per square foot for the 28-day test. The early specifications for the weight of the aggregate were that the coarse material should not weigh more than 37 lb. per cubic foot. This is somewhat lighter than the average material produced.

Tests are given in the various tables herewith. Table I represents the mill test of the concrete aggregate made at Hannibal, mixed to a 1: ⅔: 1 proportion. These are compression tests on 6 x 12-in. cylinders and represent material shipped to Mobile, Jacksonville and Wilmington. The screen analysis of only one of the aggregates is given, but this is fairly representative of the group. From this it will be seen that the fine aggregate made at Hannibal averages about 67 lb. per

TABLE III. COMPRESSION TESTS ON LIGHT-WEIGHT AGGREGATE MADE AT ALTON, ALA.

Tests on 6x12-inch cylinders poured with ship at yard.
Portland cement passing 90% through 200-mesh sieve.
Consistency drop averages 8½ inches.

Mix	Age	No. of Spec.	Wgt. Lb. Cu.Ft.	Compression Lb. Sq.In.	Modulus of Elast. at 1500 Lb. Sq.In.
1:⅔:4/3	1 mo.	2	115.7	3042	2,866,000
1:⅔:4/3	1¼ mo.	14	114.2	3774	2,608,000
1:⅔:4/3	60 days	14	111.6	3836	2,398,000
1:2	1 mo.	2	128.1	4375	3,080,000
1:2	1¼ mo.	5	122.0	3740	2,608,000
1:2	60 days	15	121.0	4493	2,733,000
1:1	1 mo.	3	124.3	4055	2,720,000
1:1	60 days	2	125.2	6195	2,355,000
1:⅔:4/3	59 days	4	112.0	4425	....
1:⅔:4/3	35 days	3	124.0	4280	....

cubic foot in weight and the coarse aggregate about 43 lb. per cubic foot, that the seven-day compressive strength is about 2500 lb. per cubic foot, the 28-day compressive strength averages 4417 for 61 tests, and that the weight of the concrete for the same number of tests is 114.2 lb. per cubic foot. The low compression for 28 days is 3246 and the high 5397, with only two testing below 3500 and eight above 5000. The low weight for the wet concrete is 112 lb. and the high 117½ pounds.

Table II gives the result of cylinders taken from the actual pourings of the various Atlantic and Gulf ships of concrete made with the Hannibal aggregate. From these it will be seen that the 28-day test of a 1: 1: 1 concrete made up of the aggregates of the sizes noted before averages well above 5000 lb. per square inch, and that the weight is somewhat higher than the weight of the mill-tested concrete of the 1: ⅔: ⁴⁄₃ mixture, running around 116 lb. per cubic foot. This, however, is the weight immediately after pouring, and other tests have shown that this decreases 3 or 4 lb. in the 28-day test. Table III shows the tests of various proportions and various ages of the dome-kiln aggregate used in the "Atlantus" at Brunswick, Ga. The strengths are not quite as high as the others given, but the weights are about the same. Tables IV and V give the results of some of the tests of the Pacific Coast aggre-

9¾	7	3393	104.9
9⅜	7	3447	108.4

Last four mixes have 1 ½% diatomaceous earth by weight of cement, added to overcome the tendency of the concrete to segregate.

gates. In experimental mixtures not noted here the material dropped as low as 92 lb. per cubic foot in weight, and averaged below 100 lb. Tests on the concrete as poured in the ships show that while the weight is not quite so low it is somewhat less than with the Eastern aggregates and the strength is satisfactory.

There has not been sufficient time to make long-time tests of the light-weight concrete, but a few such tests, noted in Table VI, show values as high as 7200 lb. at 3 months, and for the standard consistency of the other tests a strength of 6483 lb. for the same period.

Some concern is occasionally expressed as to the permeability of a concrete made with this material. A number of tests have been made, and they all show that such a concrete is as low in absorption and in permeability as concrete made with an apparently more dense aggregate. The material is not porous. While full of holes, it must be remembered that they are nonconnecting holes, so that there is no reason why water should pass through such a concrete, assuming that the aggregate itself is of a dense material. Very few strength tests on the aggregate itself have been made. Recent tests at the University of Pennsylvania laboratory show that in 1-in. cubes it has an average compressive strength of about 1500 lb. per square inch, with values in test ranging from 1000 to 2500 pounds.

Commercial production of the aggregate except for the Government ships has not been started, though there are prospects that one or both of the Government contractors will continue production after the ship requirements are satisfied. There is a company in Kansas City, under the direction of Stephen J. Hayde, which is manufacturing a somewhat similar product known as Haydite. This material was used in the concrete superstructure of the freight car recently exhibited in Chicago. Haydite was developed some years ago as the

TABLE VI. THREE-MONTHS COMPRESSION TESTS OF LIGHT-WEIGHT CONCRETE

Commercial cement with a variation of workable consistencies. Mix=1:2/3:4/3

aggregate for sand-lime brick and is produced in a vertical kiln.

The technique of the manufacture of the aggregate is necessarily complicated, as the value of the resulting product depends so much on the quality and moisture content of the raw material, the nature of the preliminary treatment, the degree of heat, and many other details. There is no claim that perfection has been reached in the brief time in which experiments and quantity production have been under way, but the aggregate is uniform and satisfactory in quality and there is every hope that its commercial manufacture is possible. Costs today are not consistent, and are not therefore of much use to those contemplating the use of the aggregate for structural purposes. It seems, however, that the aggregate should be produced at the mill for $3 or $4 per cubic yard, which will weigh in the crushed state about as shown in Table I and in the ball or brick, uncrushed, about 60 lb. per cubic foot.

The studies, tests and production of this aggregate have all been carried out under the direction of Rudolph J. Wig, head of the concrete ship section of the Emergency Fleet Corporation, with C. W. Boynton and W. D. Richardson, specialists in immediate charge of the work. Credit should also be given to A. V. Bleininger, ceramic chemist of the Bureau of Standards, for laboratory burns of various clays to determine suitability for the purpose.

Will Name Bridges After War Heroes

As memorials to soldiers who lost their lives in France, the City of Hutchinson, Kan., is to name some new concrete bridges just being built after specific men. A granite cornerstone inscribed with the soldier's name, regiment, and military record will be placed at each end of the bridge. Five bridges have been so designated for the present year.

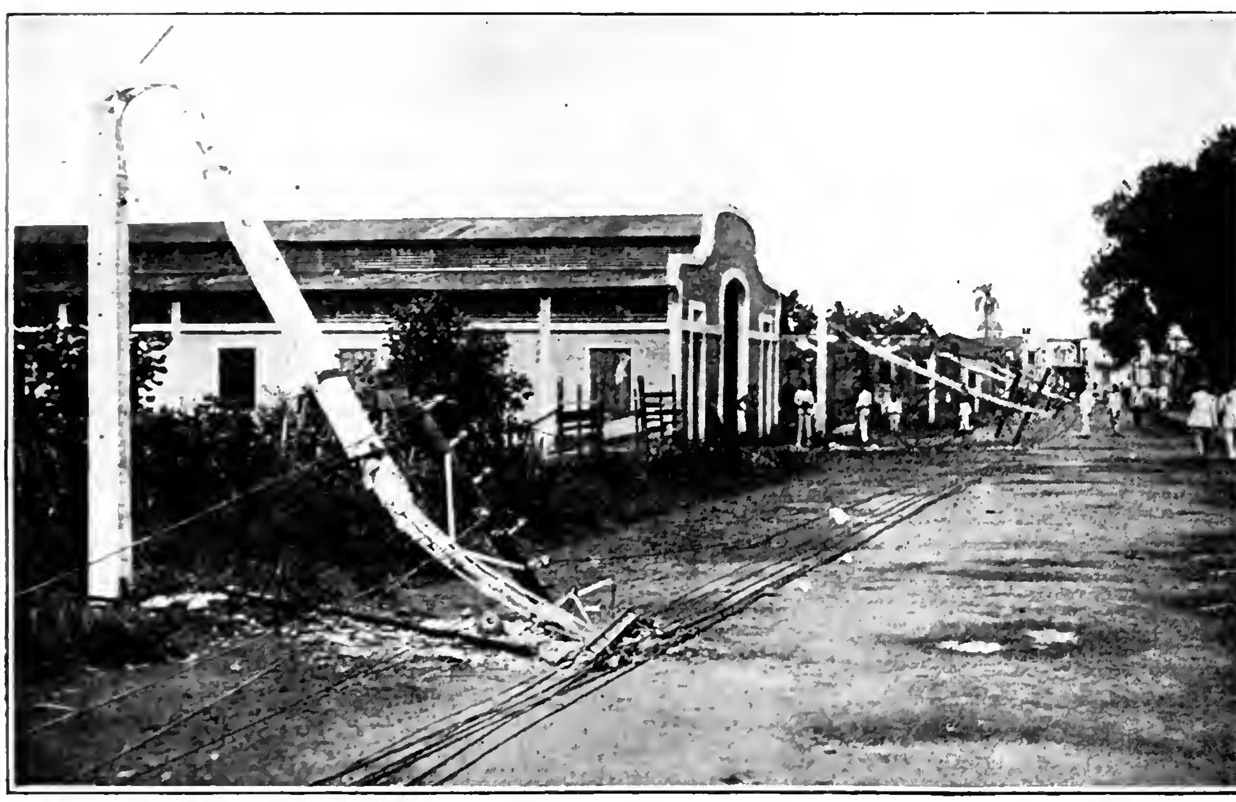
Effect On Structures of Recent Porto Rico Earthquakes

Wood Frame Proves Safest for Buildings, With Well-Built Reinforced Concrete Next, But Articulated Construction Is Poor

By M. L. Vicente and C. F. Joslin

Professor of Civil Engineering and Assistant Professor of Physics, Respectively, College of Agriculture and Mechanic Arts, Mayaguez, P. R.

Earthquake-resisting construction, which is a decided necessity in some sections of the world, can best be studied from the behavior of existing structures in a serious earthquake. Opportunity has been afforded the authors during the past six months to observe closely the effect of the successive earth shocks to which parts of Porto Rico were subjected in that period. On the calm and typically hot tropical morning of Oct. 11, 1918, there occurred in western Porto Rico a severe earthquake shock, lasting some 50 sec. and accompanied by distinct subterranean rumblings. All communication with the outside world and with the rest of the island was temporarily cut off, the property loss was about $3,000,000 throughout the island, while the loss of life was nearly fourscore. At the time of the first earthquake the writers were in their classrooms in the engineering building of the college in Mayaguez. This building, of modern reinforced-concrete construction, did not collapse, but all chemicals were thrown violently to the wooden floors, and soon the building was in flames.



LINE OF CONCRETE POLES BROKEN—ONE-STORY CONCRETE BUILDING INTACT

This first earthquake was followed shortly by a tidal wave some 15 ft. high which swept in from the sea and mainly concentrated itself at the head of the harbors of Mayaguez and Aguadilla. This wave destroyed several hundred huts along the shore, in which many of the poorer classes lived. The monetary damage was slight, but over a thousand persons were rendered homeless by the wave, which aroused so much terror among the lower classes that they started in droves for the highest nearby hills.

The first earthquake was followed by sharp quakes which occurred every few hours for a full week. It was the continual fear and uncertainty as to the outcome of these lesser quakes which kept the inhabitants in a state of terror and made it most difficult to obtain men who would help in the necessary reconstruction work. At midnight, Oct. 25, two weeks after the first earthquake, the western part of the island was visited by a second severe earthquake. There was but little property damage done by this shock, mainly because most of the damage had been done that could be done. Two and a half weeks after this second quake occurred the third severe earthquake, on the afternoon of Nov. 12. This earthquake was most discouraging; it took the heart out of many men who had considered the earthquakes as over and who had practically decided to rebuild. There have been a multitude of short, sharp tremblings ever since the first earthquake in October, decreasing in intensity, duration and frequency, but occasionally punctuated by more severe jolts of longer duration. At the present writing, Mar. 18, 1919, there have been no sharp tremblings of any kind for over 10 days.

The cause of the earthquake was left for seismologists to fathom. The most generally accepted belief is that the first earthquake was caused by the sudden falling or slippage of great masses of rock under the ocean surface in the Mona Passage, which lies between the western coast of Porto Rico and eastern Santo Domingo. Inasmuch as the cities of Mayaguez, Anasco and Aguadilla, which were most severely hit by the earthquake, are all on the western coast, and as the earthquake diminished in intensity and effect toward the eastern end of the island, this theory sounds quite plausible. The later earthquakes were apparently caused by further slippage and settlement of large rock masses in the same locality.

The writers were appointed by the assistant commissioner of the interior to act with the municipal engineer in an endeavor speedily to make the city safe for life and property. For two and one-half weeks the committee was busy in dynamiting dangerous walls and towers, erecting temporary bridges, making temporary roads and shoring up property wherever feasible. Opportunity was obtained in this work for observing certain effects of the earthquake on various structures.

The damage done in Mayaguez was pitiable, because so much of it could have been avoided. The great majority of houses, except in the heart of the city, are of simple wood construction, an absolutely safe type of structure in earthquake regions. The wooden house creaks, rocks and sways, but it does safely resist the most severe earthquakes. Shortly after the first earthquake it was very evident that no one felt secure for the night unless he slept in a tent, out of doors, or in a wooden house.

Another type of construction common here is a one-story native brick store or dwelling. We have not seen one such building which has satisfactorily withstood the earthquake. Most of them went completely to pieces. There are several reasons for the universal failure of brick structures. The bricks used here are made locally in almost prehistoric fashion. Yokes of oxen are made to work the clay with their hoofs; the bricks are handmade and burnt in crude kilns. These bricks are naturally very porous, of low compressive strength and of varying poor quality. The native brick is 1 in. thicker and 1 in. wider and longer than the typical American brick. In laying brick, joints ¾ in. thick are often found in what is considered first-class brickwork. The mortar is generally of lime and sand—rather dirty, smooth sand. Failures in brick structures were often due to lack of coherence between bricks. Very often in tearing down walls the bricks could be lifted loose by hand.

It was continually noticed that brick walls supporting roof or floor beams held up better than unloaded walls. The common type of overhanging brick cornice is an unwise design in earthquake regions. Save in rare cases, these cornices broke off and fell into the street, sometimes carrying the lower wall with them in their fall. Brick arches of all types were subject to failure. To see an intact brick arch of any type was unusual. In nearly every brick arch seen or inspected the key had either dropped several inches or had dropped out entirely. Much of this was due, of course, to the poor

TYPICAL FAILURE OF KEYS IN BRICK ARCHES.

CONCRETE WALLS OF COLLEGE BUILDING INTACT BUT CRACKED AT INTERSECTIONS—FIRE GUTTED BUILDING

quality of brick and mortar used. In general, it was evident that walls parallel to the direction of the earthquake waves, northwest to southeast, were more seriously damaged than were walls running perpendicular to the direction of these waves.

A number of buildings were made of wooden framing, filled in with brickwork. The brickwork had to be removed, but the woodwork was undamaged and was used for framework in rebuilding the house of wood. Many instances were noticed where floor and roof timbers embedded in brick walls had practically rotted away at the ends to within ½ to 1 in. of the edge of the support. In fact, this condition was so typical in the larger dwellings that the authors felt that had not the earthquake exposed these rotting timber ends, in a few years some of the floors would, under a normal load, suddenly have collapsed, with loss of life and property. No attempt had apparently been made to protect the wooden beams in any cases against the effects of the alternate wet and dry seasons.

Concrete, when properly designed and inspected, makes a dependable construction. The largest building in Mayaguez, a four-story reinforced-concrete structure belonging to the Redemptionist Fathers of the Roman Catholic Church and built by an American contractor, withstood all the earthquakes. It was used as a temporary hospital for those injured in the earthquake. It was noted in this building that the plastering on the walls was in some cases from 1½ to 2 in. thick where presumably the walls had been cast out of plumb. Wherever the plaster was over ½ in. thick it cracked loose from the concrete wall during one of the three earthquakes. This building had doors leading from the building onto the balcony from the middle of each floor. About 2 ft. above each door, and midway between the top of the door and the bottom of the door immediately above it on the floor above, were left ventilation holes in the concrete wall some 10 in. in diameter. The location of these holes was unfortunate. The concrete cracked from the top of one door to the ventilation hole, from the upper edge of the ventilation hole to the bot-

tom of the door on the next floor and thus through the door to the next ventilation hole. In other words, as these doors were all in the same vertical line from the top of the building to the bottom, and as the ventilation holes were also in the same vertical line, as a result of the earthquake cracks have connected these openings and the building has practically been divided into two parts along this center line. In general, however, this building stood the earthquake in good shape, and no material damage was done anywhere. It stands as conclusive proof that well constructed reinforced concrete can stand up in earthquake territory.

A number of buildings constructed of so-called reinforced concrete collapsed at the first severe shock. These buildings were poorly designed, were slighted on cement and carelessly erected. The most flagrant case was "La Hababera," a large two-story cigar factory. The walls were 6 in. thick and reinforced with vertical round ½-in. rods spaced about every foot. The concrete could be easily picked apart with no danger of dulling the end of the pick. The sand used was obviously too smooth and unwashed. The absence of cement was conspicuous. The collapse of this structure was a lesson to everyone who saw it, and local contractors will be more careful henceforth in choosing their aggregate. Some fifty persons were killed in this building.

The electric light wires for the city were carried on reinforced-concrete poles, some 30 ft. high and tapering from a 9 x 9-in. cross-section at the bottom to a 6 x 6-in. section at the top. A great many of these poles broke completely in two some 15 ft. from the ground. This was due in many cases to large masses of wall falling on the tense wires. It seems that the reinforcing was somewhat of a handicap, because the steel separated the inside core from the outer part of

TYPICAL FAILURE OF SECOND-STORY BRICK WALL AS A UNIT

the section of the pole. The rods were ½ in. square twisted rods, with hoops every foot vertically. As the sand was not particularly clean, the bond to the steel was poor, and the reinforcing merely served to prevent the concrete inside the steel reinforcing cage from properly bonding with the outer concrete. A hollow circular pole would have been more sturdy.

The authors are fully convinced that reinforced concrete and wood are suitable materials for construction in earthquake countries. There are no structural steel buildings in this section, and no opportunities were therefore afforded for observing the behavior of this construction. In concrete work all contractors in the western part of Porto Rico are handicapped by the

ROOF OF BRICK LAID FLAT ON 1 x 2-INCH WOOD STRIPS AND JOINTED WITH GROUND CORAL

want of sharp, clean sand. In San Juan the ocean sand is fairly reliable, but on the western coast sea sand is entirely too smooth and fine. The other alternative material is the river sand, which is rather coarse, very dirty and not very sharp. The stone is river stone and gravel, strewn with old brick bats. For these reasons the use of the smooth bar for reinforcing work is highly undesirable in this section of the island.

The greater part of the loss of property in the earthquake and practically all the loss of life could have been avoided by reliable construction so far as materials, workmanship and design are concerned. All concrete walls should be well tied by horizontal reinforcement at all corners and intersecting walls. Continuous stretches of wall of any type are unwise without tie walls or other precautions against vibration.

Calls on Water Consumers Analyzed

In one year the water department of Oak Park, Ill., made calls equivalent in number to 88.7% of the 7683 accounts it has on its books. Of the 6802 calls, 13.34% were to turn on services for new customers, 12.25% were calls on delinquents, 11.79% to shut off services and close account, 8.46% because of meters not registering, 7.2% for special reading of meters, 6.45% to shut off water-supply from vacant houses, 5.35% to investigate leaks on account of high bills, 4.98% for periodical tests, 4.68% for meter leaks, 4.45% to investigate miscellaneous complaints, 3.38% to read meter for new tenants, 2.12% to locate service boxes, 2.16% to turn off water from delinquents, 2.1% on account of frozen meters, 1.81% for repairs made by laborers, 1.54% for "no water" complaints, 1.5% to check consumption, 1.37% to re-read meters, 1.37% for service leaks, 0.87% to inspect meter boxes, 0.62% on consumers' call for test, 0.60% for special shut-off at request of consumer, 0.38% to repair fire plugs, 0.25% to inspect premises found without meter, 0.29% to repair meter dials, 0.22% to reset incorrectly installed meters, and 0.1% for repairs made by inspectors.

Prices Yesterday, Today and Tomorrow

An Analysis of the Factors—Scarcity Demand, Advance in Wages and Inflation—Responsible for the Present High Price Level

A paper by O. P. Austin, statistician of the National City Bank of New York City, read before the Editorial Conference of the New York Business Publishers' Association, Apr. 11, 1919.

THE purpose of this address, as implied by its title, "Prices Yesterday, Today and Tomorrow" is an attempt to look into the future and determine, if possible, the probability as to the course of prices. That there have been great and continuous advances during the war period we are painfully conscious, and in the five months since the cessation of hostilities we have failed to experience the reduction which some had fondly hoped would come with the close of the war. In a few instances there have been slight reductions but in others there are still advances, and the index figures on foodstuffs in New York today are actually higher than those on Nov. 5, when the whole world so joyously welcomed the apparent termination of the great conflict which had raged for fifty-one months.

To attempt to determine what is likely to happen in the future we must try to find the cause of the things which have happened in the past, and also to see whether this cause is or is not likely to continue in the near future. When prices began to advance in the opening of the war, we could readily see that the upward movement was due to the urgent demand for the food and raw material required by the enormous armies which had been put into the field, and this cause has been designated the "scarcity demand," but when we found the advance extending to many articles in which there was no scarcity and which were not used by the armies or utilized in the manufacture of their requirements, we began to realize that a part of the advance must be due to some cause other than mere war or scarcity demands.

Edgar Crammond, the distinguished British statistician and economist, in an address before the London Institute of Bankers on Mar. 26, 1919, stated that the three facts which would tend to make the fall in prices a very gradual one are: (1) the vast increase in the amount of paper money; (2) the huge increase in the amounts of public debts of the belligerents; (3) the determination of labor to maintain wages and improve the standard of living.

Price Advances World-Wide

Raw silk, for example, for which the war made no special demand and which was produced on the side of the globe opposite that in which the hostilities were occurring advanced from $3 per pound in the country of production in 1913 to $4.50 per pound in 1917, and over $6 per pound in the closing months of the war. Manila hemp, also produced on the opposite side of the globe and not a war requirement, advanced in the country of production from $180 per ton in 1915 to $437 per ton in 1918. Mechanically ground wood pulp, not a war requirement, advanced as our publishers are aware, from $14 per ton in the opening months of the war to $35 per ton in the opening months of 1916, and the grade known as "chemical bleached" advanced from $50 per ton at the beginning of the war to $160 per ton in January, 1919. Goatskins, from China, India, Mexico and South America advanced from 25 cents per pound in 1914 to over 50 cents per pound in 1918 and yet goatskins were in no sense a special requirement of the war. Pig tin, produced by Chinese labor in the Malayan Peninsula and the Dutch East Indies and not to a very great extent a war requirement sold in the country of production in 1914 at 30 cents per pound and in the same markets at 75 cents per pound in the closing weeks of the war. Sisal grass produced in Yucatan advanced from $100 per ton in 1914 at the place of production to nearly $400 per ton in 1918, and Egyptian cotton, a high-priced product and thus not used for war purposes, jumped from 14 cents per pound in Egypt in 1914 to 35 cents per pound in 1918. Even the product of the diamond mines of South Africa advanced from 60 to 100 per cent in price per carat when compared with prices existing in the opening months of the war.

The prices which I have quoted to you are in all cases those *in the markets of the country in which the articles were produced* and in most cases at points on the globe far distant from that in which the war was being waged. They are the product of countries having a plentiful supply of cheap labor and upon which there has been no demand for men for service in the war. The advance in the prices quoted is in no sense due to the high cost of ocean transportation since they are those demanded and obtained in the markets of the country of production.

Labor Doubled in Price During War

Why is it that the product of the labor of women and children who care for silk worms in China and Japan, of the Filipino laborer who produces the manila hemp, the Egyptian fellah who grows the high-grade cotton, the native workman in the diamond mines of South Africa, the Mexican peon in the sisal field of Yucatan, the Chinese coolie in the tin mines of Malaya, or the goat-herd on the plains of China, India, Mexico or South America has doubled in price during the war period? The articles enumerated were in no case for use in the war and the prices are those in the country of production and thus not due to the increase in ocean freights or dangers of over-sea transportation. The advance has been general, world-wide. In a few articles in which an over-production was occurring in which the demand fell below normal the advance was not so strongly marked but there is scarcely an article in the long list of those entering world markets in which there has not been an advance, no matter how distant its place of production from that in which the war was occurring or how little the war's demands for it or for the labor by which it was produced.

Surely there must have been some general underlying causes for this world advance, this simultaneous demand by people of all classes and in all parts of the globe for higher prices for their products irrespective of their relation to war requirements. While we may be willing to accept the immediate demands of the war as a partial explanation of the advance in the prices of foodstuffs and certain manufacturing material and manufactures we must look farther for the cause of the similar ad-

vance in articles upon which the demands of the war could have had no direct bearing. It is true that a marked advance in the price of one important class of products does cause an advance in the prices demanded for other articles which must be exchanged for those in which the advance has already occurred, but it does not seem probable that the advance due to scarcity of a comparatively few of the world products required for war could have been the chief cause of the doubling of prices in practically every article produced in every part of the world, many of which had not the most remote relation to war requirements.

Underlying Causes

Apparently the principal causes of the advance in prices during the war were, stated in their chronological order, first, "scarcity demand"; second, the advance in wages presumably due to the increased cost of living and demand for labor, and, third, the large increase in world circulating media, or to put it in a single word, "inflation." Prof. A. C. Miller, member of the Federal Reserve Board, an authority whose views are entitled to high consideration, in a recent address before the American Academy of Political and Social Science named as the two chief causes of the advance in prices, "scarcity demand" and "inflation," adding that "there is so much evidence of an artificial abundance of money in comparison with the things that are purchasable by it that the abundance of money must be credited *with at least* an equal influence in explaining the high prices which have prevailed."

What were the articles for which the war created a scarcity demand? Food, clothing, transportation facilities, and material for the battlefield. How much did it add to the world's demand for these articles? Of course, the percentage of increase in demand for strictly war materials was very large, but was there really as great an increase in demand for other materials, food, clothing, and transportation facilities as we are accustomed to imagine? Let us assume that the number of people participating in the war was forty million, which is probably more than those in the field at any one time. Do we realize how small a share those forty million were of the world's consuming population? Less than two and one-half per cent. We think of forty million as a large number of people to feed, and so it is, but it must be remembered that the number of people in the world who must be fed and clothed and supplied with transportation facilities every day of the year is 1,800,000,000 or forty-five times as many as the highest number in the military service at any time during the war. Of course the soldiers were better fed than are many of the people in certain sections of the world, but even if their per capita consumption was four times as much as the average it would still represent but a small percentage of the world's daily food consumption. And it must be further remembered that all these forty million people in the armies had been consumers of food before the beginning of the war, not to quite as great an extent perhaps as after entering the activities of the military service, but it cannot be assumed that the war added forty millions to the world's consumers of food and clothing. Nor can it be properly assumed that the withdrawal of these millions from the industries actually reduced to that extent the world's producing power, for four millions of these were already in the military service and the places of the other thirty-six million were to a considerable degree filled by others who had not been up to that time actively engaged as producers.

Much of the material used in preparing the supplies for the battlefield was "switched" from the usual lines of industry, for there was an immediate cessation of railway construction, building operation, and a thousand industries which formerly required manufacturing material and as a result of this cessation of activities the material formerly used by them became available for war purposes.

It thus appears on close analysis that the "scarcity demand" created by the war was not as great in food, clothing, or manufacturing materials as has been pictured, while the fact that fifteen millions are still under arms minimizes the reduction in military demands which had been expected.

One factor often mentioned in the attempt to determine the causes of high prices is the advance in wages of labor, but the fact that the increase in compensation of labor was in most cases given because of the fact that the cost of living had already advanced at least somewhat minimizes the relative importance of this factor in attempting to discover the real causes of the general world-wide advance in prices. And it must also be remembered that several million persons who had not been engaged in the industrial and business world came to the assistance of those engaged in these duties during the war.

Inflation

Where, then, shall we turn in the search for the principal cause of the general advance in prices of articles produced the world over and their relation to the demands of the war? What other cause can we find after giving due consideration to the scarcity demand, the destruction by war and the increased cost of labor? The most prominent among the possible or probable causes is the theory advanced or accepted by the historians, economists, statisticians and financiers of the world that inflation in currency is usually accompanied or closely followed by an advance in prices; and, as already indicated, so high an authority as a member of the present Federal Reserve Board, Prof. A. C. Miller, has recently declared that "the abundance of money must be credited with at least an equal influence in explaining the high prices which have prevailed."

I wonder if we do fully realize the quantity of paper money which the responsible governments of the world have put afloat since the beginning of the war. Thirty-six billion dollars. The paper money in existence in the fifteen principal countries of the world at the beginning of the war was less than eight billion dollars and at the end of the war was over forty-four billions, an increase of thirty-six billions in fifty-one months, and this does not include any of the eighty billion dollars' worth of paper currency issued by the Bolsheviki in the eighteen months of their control in Russia. Thirty-six billion dollars of new paper money added to the circulation of the world by fifteen responsible governments in a little over four years of time.

We had been inclined to charge up the advance in prices occurring prior to the war to the fact that eight billion dollars' worth of gold was turned out by the mines of the world in the twenty years following our famous gold and silver campaign of 1896. But here are thirty-six billion dollars' worth of paper promises

to pay turned out as legal tender money by fifteen responsible governments in a short four-year period.

Do we realize how vast a sum is this thirty-six billion dollars' worth of paper currency which has thus been put into circulation in such a brief time? It is more, *in its face value*, than all the gold and all the silver turned out by all the mines of all the world in the 427 years since the discovery of America.

True, much of this paper money is now more or less depreciated in its value as compared with gold, the world's accepted standard, but the fact that it has behind it not only a certain amount of the yellow metal but also the pledge of the governments by whose authority it was issued renders it at least an accepted medium of exchange in the countries of its origin, while the fact that nearly every neutral country of the world has meantime increased its paper currency and national indebtedness, permitting its gold to pass from circulation into the vaults of its banks as a security for the paper circulation, tends to widen the field affected by this inflated currency.

In addition to these vast sums of legal tender currency turned out by fifteen responsible governments of the world, these same governments have at the same time made an even more spectacular advance in their issue of another series of promises to pay, which while not legal tender in the ordinary sense of the term, do form a more slowly moving mass of currency. By this I mean the one hundred and eighty billion dollars' worth of bonds or other forms of national obligations issued by the governments of the world in the past four years, for national debts of the world have advanced from forty billion dollars at the beginning of the war to two hundred and twenty billions at its close. And while these bonds or other governmental promises to pay money at some future date are not legal tender currency in the ordinary sense of the term they do pass current in the financial world and prove a basis upon which money may be readily obtained by their holders, and to this extent are an addition to the world's circulating medium.

Bank Deposits Greatly Increased

Still another increase in circulating media is found in the enormous growth in bank deposits, which of itself increases circulation through the increased use of checks, especially in countries such as the United States where the check forms so large a share of the daily business transactions of the country. Bank deposits in fifteen principal countries of the world have grown from twenty-seven billion dollars in 1913 to approximately seventy-five billions at the present time, the ratio of increase being about the same as that of currency.

These increases, in circulation, indebtedness, and bank deposits, while occurring chiefly in the countries participating in the war have also extended to many other countries, especially in Europe, where the six principal neutrals have during the war period increased their national debts one billion dollars, their note circulation over a billion dollars and their bank deposits by about one billion.

Thus in a short four and one-half year period world paper money has increased thirty-six billion dollars, world evidences of national indebtedness one hundred and eighty billion dollars and world bank deposits nearly fifty billion dollars. Most of this enormous increase has occurred in "uncovered" paper. The gold mines of the world have turned out less than two billion dollars' worth of the precious metal during the war period and most of the world's gold, which formed fifty-five per cent. of world circulation at the beginning of the war, has passed into the vaults of the governments or their great banks as a basis for their paper currency, and now bears a relation of but about twenty per cent. to the flood of paper money in circulation, and this proportion of gold to paper varies widely when the respective countries are compared.

If the world's historians and financiers and economists and statisticians are right in their general belief that an advance in prices usually accompanies or closely follows inflation in currency, and especially in paper currency, can we be surprised at the world-wide advance in prices which we have witnessed during the past four years in which world currency and bank deposits trebled and national debts quintupled?

Prices of Tomorrow

We come now to the third and final question, that of prices of tomorrow. May we expect a material reduction in general prices in the near future? And in trying to determine this we must see whether the causes which brought about the advance during the war period are likely to be removed.

The chief causes of the advance seem to have been the "scarcity demand," the higher cost of labor, and the increase in circulating media.

The "scarcity demand" came on the very first day of the war, for most of the countries entering that struggle found that the demand upon them would be far in excess of their supplies either of foodstuffs or military requirements, and as the weeks and months and years progressed this fact was more strongly impressed upon them.

During the closing year of the war the ammunition factories of the various participating countries were able to meet to a great extent the requirements of their own armies but in the matter of foodstuffs the "scarcity demand" still continues with little prospect of abatement at least in the near future. The number of mouths to feed in Europe has not decreased, and that continent, which has not for many years been able to produce its own requirements of foodstuffs, now finds itself with neglected soils, a disordered population and unable to return to normal production in the immediate future. In manufacturing materials, for which Europe has also been dependent upon other parts of the world, she will require abnormally large quantities at least in proportion to her attempts to manufacture, for her stocks of this class of merchandise are absolutely exhausted. In all parts of the world which have relied upon Europe and the United States for manufactures the shelves are empty and must be filled, and most of the manufacturing sections of Europe will evidently be slow in resuming the production of manufactures for exportation, and will have limited facilities for transporting or marketing them even if produced. So it seems that, although the demand for war material has terminated, the other features of the "scarcity demand" will continue at least in a somewhat modified form in the immediate future, especially as relates to world requirements of food, manufacturing material and manufactures, while developments thus far do not point to an early reduction in labor costs.

If we are right in assuming that a considerable pro-

portion of the world advance in prices is due to the enormous increase in world currency can we expect a marked reduction in prices until the cause, "inflation," is removed? Or, to put it in another form, that part of the advance caused by inflation can only be cured by deflation, by a reduction in the enormous stocks of currency which, as I have shown you, has trebled during the war, while that other form of slowly moving currency, governmental obligations, has quintupled.

Is it probable that these two forms of currency can be or at least will be reduced in the near future? The governments of the world, which were paying less than two billion dollars a year of interest on national debts at the beginning of the war are now paying and must continue to pay a total of over ten billion dollars a year in interest, and at the same time all other expenses of governments have advanced. Official estimates of the "budgets" or expense accounts of several of the principal countries for the coming fiscal year have already been announced and indicate that their necessary expenses in the first full year of after-war peace will be about four times as great as in the year preceding the war. The British budget for the next fiscal year is estimated at about six times as much as in 1913 and those of France, United States and Canada about four times as much as before the war. Present indications are that the governments of the world will be compelled to collect in taxes from their people about fifty billion dollars a year as against about twelve and one-half billions in 1913, or say a billion dollars a week as against a billion dollars a month before the war, *and* this does not include anything for "sinking funds" or other provision for reduction of outstanding debts. If this be true is it probable that the governments in those countries which have greatly increased their circulation and must now demand such enormous increases in annual payment of taxes will find it advisable or possible to reduce materially the amounts of currency available for such payments?

If the governments which have been the chief participants in the world increase of currency should fail to reduce materially that excessive supply, and if the world's demand for food, manufacturing material and manufactures is to continue at the present rate, are we justified in expecting a general reduction in prices in the near future? The question I think answers itself. There will, of course, be instances in which there will be material reductions, but in general terms the outlook for marked or rapid decline, at least in the near future, does not seem encouraging.

Typhoid in the Large Cities of the United States in 1918

Continued Downward Trend in Majority of Cities of More Than 100,000 Population — Eight Cities Under 3 per 100,000

NOTWITHSTANDING the unfavorable conditions of the war, typhoid fever continued its downward course in 1918, according to the seventh annual survey made by the *Journal* of the American Medical Association and published in its issue of Apr. 5, 1919. In 40 of the 60 cities surveyed the rate for 1918 was lower than that for 1917, and in 20 it was higher. Three cities had a rate of less than 2 per 100,000; eight were under 3. Twenty-two were below 5 and another 22 below 10. This leaves only 16 having a rate of 10 or more.

There is a general upward trend in the rates as the population of the cities increases, but as a rule each group shows a decline in 1917 compared with 1916, and in 1918 compared with 1917. Taking the 57 cities as a whole for which complete records are available, there is a constant decline year by year from 1910 to 1918, the two extremes being 19.59 and 6.23 per 100,000. It was in 1915 that the rate for the entire group went below 10.

The two cities at each extreme in 1918 were Chicago, 1.4, and Lowell, 1.8, contrasted with San Antonio, Tex., and Richmond, Va., at 54.3 and 65.3, respectively. The *Journal* in its article asks: "Will the chamber of commerce in that town advertise the typhoid rate in Northern papers, when presenting the claims of San Antonio as a winter resort?"

The accompanying tables, taken from the *Journal* already named, give all the tabular details of the results of the survey. In its editorial comment the *Journal* says it is fair to conclude that at least in many Northern cities further typhoid reduction will have to come largely through improvement in related rural and suburban conditions.

TABLE I. TYPHOID DEATH RATES IN CITIES OF UNITED STATES

Population estimates of the United States Census have been used for this and other tables. No estimates are made by the Census for Denver, Portland, Ore., Seattle and Spokane. The estimate for Washington is made by another plan. The number of typhoid deaths is given as sent to the *Journal* of the American Medical Association by local health officers and include deaths of non-residents.

(Deaths per 100,000 population)

	1918	1917	1916	Average 1911–1915	Average 1906–1910
GROUP 1: MORE THAN 500,000 POPULATION					
Chicago	1.4	1.7	5.2	8.2	15.8
Boston	2.5	2.9	3.5	8.0	16.0

Concrete Floor Stands Big Overload Without Collapse

Sheet Tin Piles Give Maximum Loading Six Times Design Load, and Though Beam-and-Girder Floor Cracks and Deflects It Does Not Fail

LOADS from four to six times those for which the floor was designed have just been put on a reinforced-concrete building in Long Island City, N. Y., through the almost criminal negligence of a warehouseing superintendent. The floor has cracked badly—so badly that the Superintendent of Buildings of Queens Borough has ordered the load mostly removed and the floors shored up, and has required that they be repaired. There was no definite collapse, however, nor is there any evidence of any adverse effect on the rest of the building, a remarkable testimonial to the effectiveness of this type of construction.

The building in question is known as the Kindel Bed Co. building. It is located in Long Island City in one of the boroughs of New York City. It is a four-story structure, and the section in question is 80 ft. wide and 218 ft. long. Transversely it is divided into three bays, the outer bays being 26 ft. 4 in. in span and the middle bay 27 ft. 4 in. In the other direction, columns are spaced 18 ft. c. to c. The floor is a girder, beam-and-slab type, 14 x 26-in. girders running lengthwise of the building and 8 x 22-in. beams being spaced 6 ft. c. to c. and spanning between the columns or the girders. The building was erected in 1916 and was designed for manufacturing purposes to have a load on this floor of 200 lb. per square foot.

CONCRETE FLOOR LOADED WITH BOXES OF SHEET TIN EACH WEIGHING 122 POUNDS

The original owners of the building had vacated it, and the second floor, through a series of leases, came into the control of a warehouseman in New York City. Some time early this year he began storing, on the floor, boxes of sheet tin being held for the Standard Oil Co. preliminary to shipment to the Far East. These boxes are of various sizes, but the main ones are 14 x $8\frac{3}{4}$ in. in plan and about 4 in. deep, and carry sheet tin

to such an amount that the gross load of the tin plus the box is 122 lb. This gives a loading of about 68 lb. per square foot. Apparently the entire floor, except a 4-ft. aisle down the inside of the column rows, was loaded with these boxes, some of which were piled as high as 20 deep. It is the opinion of observers that in some places the loads reached 1300 lb. per square foot and that the uniform load must have been equivalent to a load of 900 lb. per square foot over the entire floor, about 4½ times the design load.

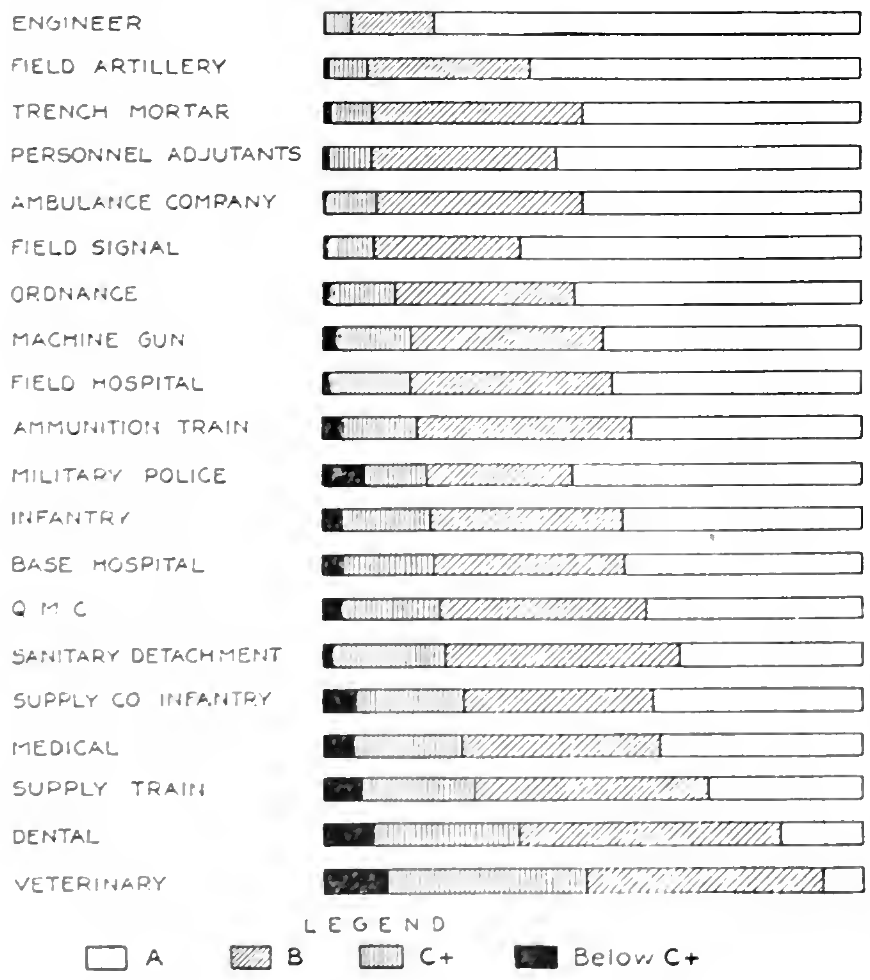
The first warning of trouble is reported to have been given by the night watchman, who heard ominous rumblings and crunchings which so disturbed him as to make him get outside of the building and stay out all night. The next day he reported the trouble, and it was found that many cracks were appearing in the floors. There was also a certain deflection, although this was not very considerable nor has it been measured. At any rate, Superintendent of Buildings Moore, immediately upon being informed of the trouble, put an "unsafe" order on the building and had a court require the survey demanded by New York law for such contingencies. Under the authority of this court order he removed enough of the load so that at present the floor is carrying somewhat over its designed amount. At the same time he strutted up those sections of the floor where the cracking appeared to be most dangerous. At present it is the intention to repair the floor or to replace it, although the exact method to be carried out has not been determined.

The cracks in the floor seem to indicate that a continuous beam action was carried clear across the three panels of the 80-ft. width. Cracks appear in the floor-slab of the interior panel about the point of inflection, and in some places are carried down a short distance into transverse beams.

Similar cracks around some of the columns appear in the longitudinal stringers, and in all cases the cracking seems to have been roughly circular around the heads of the columns.

Engineer Officers Rank First in Army Mental Tests

TYPICAL of the results obtained under the direction of the Division of Psychology, Medical Department of the United States War Department, is the chart reproduced herewith, which indicates that of all the classes of officers examined the engineer officers show the highest grade. The tests upon which the officers' ratings depend were prepared by a committee of the American Psychological Association and of the National Research Council, for the purpose of determining relative intelligence. While admitting that a man's value to the service should not be judged by his intelligence alone, it has nevertheless been thoroughly demonstrated that the intelligence ratings are useful in indicating a man's probable value to the Army service.



RELATIVE GRADES OF OFFICERS—ENGINEERS RANK FIRST

Letter ratings have been used as follows: A, very superior intelligence—this grade is ordinarily earned by only 4 or 5% of a draft quota, and is composed of men of marked intellectuality; B, superior intelligence—this class includes less exceptional intelligence than that in class A, and is obtained by 8 to 10 soldiers out of 100; C +, high average intelligence—this group includes 15 to 18 per cent. of all soldiers and contains a large amount of noncommissioned-officer material; C, average intelligence—includes about 25% of all soldiers; C —, low average intelligence—includes about 20 per cent. who, though below the average in intelligence, are usually good privates and satisfactory in work of routine nature; D, inferior intelligence—includes about 15%; and D — and E, very inferior intelligence. The comparison in the diagram is for officers only.

Engineers in United States Public Health Reserve

By recent Congressional legislation providing for a United States Public Health Reserve, provision is made for commissioning a corps of sanitary engineers, epidemiologists, chemists and other nonmedical men for a period of five years, with pay and allowances equal to those in the present regularly commissioned medical corps. Those wishing to be enrolled must be qualified citizens of the United States and must apply to the Surgeon General, United States Public Health Service, for permission to appear for examination. The grades and corresponding pay and allowances at Washington for sanitary engineers, under the legislation named, will be as follows: Assistant sanitary engineer, $2623 a year; associate sanitary engineer, $3200; sanitary engineer, $3976; senior sanitary engineer, $4651; directing sanitary engineer, $6325. Commissioned reserve officers will normally be on inactive duty without pay. They may be called to active duty for a period not exceeding one month annually for special training, and they will be subject to call in any public-health emergency. Under the new legislation men in the nonmedical branches of public-health will receive equal recognition with men in the medical branches of the service.

Labor Efficiency Good on Percentage Contracts

Carefully Kept Figures on Peace-Time Construction Contradict Common Charge Against This Form of Contract—Inefficient Laborers Rather Than Type of Contract Cause of Trouble on War Construction

BY HENRY C. TURNER
President, Turner Construction Company, New York

The editor asked the Turner Construction Co. the following questions:

1. Is it your experience that labor is less efficient in cost-plus construction?

2. If less efficient, is the fact due to the form of contract, or to some other cause?

Mr. Turner's illuminating reply is based on careful unit-cost records in all the contracts of the company during peace operations just prior to the war, and on a large amount of war-time construction. Not only does the company see no labor inefficiency in the cost-plus system but, as stated in detail, it thinks that this form of contract has many advantages.

DURING the year 1918 we were engaged almost entirely in Government work, carried on under the standard percentage with a limiting fee form of contract. To obtain a comparison between our experience with percentage and lump-sum work, it is, therefore, necessary to go back to the year 1917. In that year we find that we built 22 factories and warehouses of reinforced concrete, on which our contract exceeded $100,000 each, averaging $413,000 each. Of these 22 buildings 13 averaging $470,000 each in cost were built under a percentage form of contract and nine averaging $329,000 each in cost were built under a lump-sum form of contract.

While some of these buildings were more elaborate than others, they were all of the factory and warehouse type and enough alike to make an average comparison of units between the percentage group and the lump-sum group possible. Some of the buildings considered were flat-slab and others beam-and-girder, and later in this analysis will be noted the influence of this fact on the units obtained. Attention will also be drawn to the effect which the height of a building has on the unit cost of floor forms, etc.

For purposes of comparison of cost, three labor units have been selected covering the three principal divisions of the work included in such construction.

Item 3-F. Cost of carpenter and labor work per square foot of floor required for placing and removing floor forms, including all hoisting and miscellaneous work in connection therewith. This item does not include the cost of making the forms before they are used for the first time and, therefore, a comparison is possible as between buildings having a different number of stories.

Item 22. Cost of labor per cubic yard for all labor in connection with the mixing and placing of concrete. An average of this unit will give a very fair comparison.

Item 30. Cost of all labor per ton for receiving, handling, bending and placing steel reinforcement. As the labor conditions under which this work is done are different in the metropolitan districts from the conditions existing outside of these districts, one comparison is made between jobs located in the metropolitan districts and another comparison is made between the jobs outside of such districts.

There is also included in the table the amount of money spent for all labor disbursed under Item 19, "General Expense," expressed as a percentage of the total payroll for the job. This is done to show that the units obtained on the 3-F, 22 and 30 Items were not influenced by incorrect charging of labor to General Item 19, thereby reducing the amounts properly chargeable to the cost of forms and placing concrete and steel.

The results of the comparison are given in the accompanying tabulation:

COMPARISON BASED ON A STUDY OF COST UNITS ON ALL FACTORIES AND WAREHOUSES COSTING OVER $100,000 BUILT BY TURNER CONSTRUCTION CO. IN 1917

TOTAL NUMBER, 22

	Average unit on 13 percentage jobs	Average unit on 9 lump sum jobs	Percentage jobs were cheaper by	Lump sum jobs were cheaper by
Item 3-F. Cost per square foot of placing and removing floor forms	5.75c.	6.25c.	8%	
Item 22. Cost per cubic yard of mixing and placing concrete	$1.02	$1.04	2%	
Item 30. Cost per ton of receiving, bending, fabricating and placing steel reinforcement on jobs in the metropolitan districts	(10 jobs) $15.71	(4 jobs) $14.89		5%
Item 30. Cost per ton of receiving, bending, fabricating and placing steel reinforcement on jobs outside of the metropolitan districts	(3 jobs) $9.01	(5 jobs) $8.87		2%
Item 19. General expense. The amount charged to this miscellaneous item is expressed as a percentage of the total payroll	1.8%	2.3%		

EFFECT OF VARIOUS ITEMS

The items will be taken up separately; comparisons are made under Item 30 for jobs located within the metropolitan districts and for jobs located outside of such districts.

Placing and Removing Floor Forms—There is some difference in the cost per square foot for the 3-F item as between flat-slab and beam-and-girder construction. By a coincidence it happens that 14% of the floor area in the percentage jobs was beam-and-girder and 86% was flat-slab, while in the lump-sum jobs 13% was beam-and-girder and 87% was flat-slab. Because of this similarity the comparison made between the average units on the percentage work and on the lump-sum work is not influenced by any difference due to the slightly greater cost of beam-and-girder forms over flat-slab forms. The column spacing was near enough the same in all of the buildings, so that any difference due to this element may be disregarded. The 3-F item has a tendency to be lower in buildings having a greater number of stories, because the 3-F unit for the first floor is nearly always higher than the 3-F unit for floors above the first. As all of the buildings studied are five stories, or over, in height, with the exception of two, which are four stories, the influence of the element of height is very slight. It is to be noted that the next to the lowest 3-F unit obtained on any of the 22 buildings was at the Beckers Aniline & Chemical Building,

which is only five stories high, and the units made on the two four-story jobs are each below the average. It is believed that a comparison of the 3-F unit as between the percentage group of jobs and the lump-sum group is a fair comparison and means that if anything our organizations on the percentage had the jump on the lump-sum job organizations for this item.

Mixing and Placing Concrete—With equal efficiency on the two classes of construction the averages of Item 22 should run very close together, and such is the case, the difference being only 2% in favor of the percentage organizations.

Receiving, Bending, Fabricating and Placing Steel Reinforcement in Metropolitan Districts—The lump-sum jobs beat the percentage jobs by 5%, and this difference is probably justified by the more difficult conditions affecting this Item 30 that existed on the percentage group of buildings.

Receiving, Bending, Fabricating and Placing Steel Reinforcement on Jobs Outside of Metropolitan Districts—The lump-sum jobs beat the percentage jobs by 2%. The comparison is a fair one and should be a true indication of efficiency.

General Expense—The amount of money covered by the classification in Item 19 is very small compared with the other items used in the table. The only reason for tabulating the item was to show by its smallness that improper charges had not been made to this general item, thereby reducing the charges of payroll made to Items 3-F, 22 and 30.

Low Costs Not Confined to One Type

If lowest units made on these 22 jobs are sought it is found that the lowest unit in placing and removing floor forms was made on the Belleville job, a percentage contract, and that the next lowest unit was made on the Beckers Aniline & Chemical Co. job, also a percentage contract. The lowest unit made in placing concrete was on the Bush Service Building, a percentage contract, and the next lowest was at the United Cigar Stores Building, which was also a percentage contract for the Bush company. The third lowest was at the Belleville job, which was a percentage contract, and the next was at the Winchester Woolen Mills, a lump-sum contract. The lowest unit on placing steel reinforcement, outside of the metropolitan districts, was on Endicott-Johnson, a lump-sum job, and the next lowest was for Belleville, a percentage job. In the metropolitan districts the lowest unit for placing steel reinforcement was at the Beckers Aniline & Chemical Co. percentage job, the next best was the Bush Service Building, also a percentage job.

It is believed that the figures justify the statement in reply to the first question that in a properly organized construction company there is no difference in efficiency in labor engaged on percentage work as compared with lump-sum work. So far as this company has ever been able to see, a good superintendent, or a good foreman, shows the same interest in his job whether it is on percentage or lump sum. This will always be the case if he works for a company which rewards him just as quickly for good work on a percentage job as for good work on a lump-sum job and penalizes him just as severely on one class of work as on the other.

Answering the second question—there seems to be no valid reason why labor should be less efficient on the percentage job than on the lump-sum job. A workingman is naturally primarily interested in his own welfare, and hence in the keeping of his job. If negligence and a lack of interest in his work lead to his discharge on the percentage job just as quickly as on the lump-sum work, while he finds that diligence on the percentage job is rewarded by advancement and continuous employment by the contractor, he will work just as hard on one form of contract as on the other.

There have been published recently a number of articles in which the position was maintained that percentage work has ruined the moral character of the American contractor and the American workingman. This company believes the opinions expressed in these articles are based either upon some unfortunate personal experience with the percentage form of contract, or are founded on observation made on the general run of percentage work during the war.

Many owners have had trouble over percentage contracts, just as many owners have had trouble over lump-sum contracts, but in nine cases out of ten the fault has been with the owner in not making sufficient investigation before he awarded his contract. There are plenty of good contractors to handle percentage work if the owner will only take the trouble to find them. Any owner intending to buy a piece of property will have a very careful search made of the title, and will have someone spend much time in investigation and study before he decides to purchase. Too often the owner will select a contractor because the contractor's selling agent sometimes knowingly, but much more often through lack of knowledge of construction work, will promise anything the owner wishes in the way of speed or price. Surely, the selection of a building contractor for the confidential position he occupies on percentage work is worthy of some study, but it is not infrequent for an owner to award a large percentage contract with less study and investigation than he would give to the purchase of a motor car.

Owner Should Study Both Systems

It is not difficult for the owner to get reasonable assurance that he is picking the right man for the job. In the first place, no contractor should be selected for percentage work unless he is very well known to the owner or has a very considerable record on such work. Let the owner ask the contractor for a list of all jobs he has built. Very likely several of these jobs were for persons known to the owner, in which case the investigation will be easy. If the entire list was for strangers, then let the owner pick about a dozen jobs similar to the project he has in mind and thoroughly investigate the contractor's record on all of the jobs so selected, having his representative make personal calls, where possible, to obtain the information. The price to any owner for satisfactory work on a percentage basis is the comparatively slight trouble of thorough investigation before the contract is let.

It is a fact that a considerable prejudice against the percentage or fixed-fee form of contract has arisen because of observations made on such work during the war. Conditions in the building industry were in many cases deplorable during the war, but these conditions would have existed in most of these cases had the work been on a lump-sum basis. The majority of the large Government operations were built far away from any labor market, which made it necessary to hire men in

the large cities and send them to these out-of-the-way places where they were housed in wooden barracks. In most cases the rates of wages established by the Government, and made obligatory on percentage contracts in such out-of-the-way places, were lower than the wages paid in the large labor markets in which men were recruited. As more work was always available in the large cities than the supply of competent mechanics and good laborers living in such cities could handle, there was no incentive for a good man to leave his home. The result was that these out-of-the-way jobs had to be built with so-called floating labor; there was no other way to get the jobs done. This labor in many cases was not physically fit to do a day's work and, in order to get the work done at all, it was necessary for the superintendents and foremen to exercise the greatest of forbearance.

War-Cost Additions Due to Inexperience of Workmen

The experience of this company during the 1918 war period illustrates the condition that existed. It was then building for the Government, at the same time, the Naval base in Brooklyn, the Army base in Brooklyn and the Navy and War office buildings in Washington. During the war, on account of the shortage of labor, the Government ordered a 10-hour day for laborers mixing and placing concrete, paying time and one-half for overtime. The labor rate in Brooklyn was $3.25 to $3.60 for eight hours, while in Washington it was $3.20 for eight hours. The cost of mixing and placing concrete per cubic yard on the naval base was $1.25, including a large amount of miscellaneous work, $1.19 per cubic yard on the Army base and $1.98 per cubic yard at the Navy and War buildings in Washington. The rate of wages per hour was lower in Washington than in Brooklyn, and the overtime affected jobs in both cities to an equal extent. The more difficult nature of the work in Washington would justify a difference of only about 20c. per cubic yard had the wage rates in the two cities been equal, hence an inspection of the unit costs on the three jobs shows the inefficiency of the workmen on the job in Washington as compared with the workmen in Brooklyn.

In Washington there was no home labor market and no quarters for housing men except temporary wood barracks. As a result, in order to keep the job supplied with the 1,400 laborers required, it was necessary to ship into Washington 4,000 of such men as could be gotten from New York, and in addition considerable numbers were obtained in other cities as far west as Chicago. It is to be remembered that it was very much easier to persuade fair workmen to go to Washington than to get such men to go to the small out-of-the-way places in which most of the Government plants were located. Inefficiency and resulting high units were, therefore, to be expected in such places, and they would have existed on the work of any honest contractor in the same degree had his work been done on a lump-sum basis.

Comparing the results obtained on the naval base and on the Army base in Brooklyn with the results the company was able to get in 1917, it is found that the cost of labor per hour of actual time worked was 18% higher in Brooklyn in 1918 than in 1917, due to an increase in the average rate from $3.12 per eight hours in 1917 to $3.35 per eight hours in 1918, and the effect of paying time and one-half for the two hours of overtime each day in 1918. Hence the units of $1.25 per cubic yard made on the naval base in 1918 and $1.19 made on the Army base in the same year are equivalent to units of $1.06 and of $1.01, respectively, if made on the same jobs in 1917. This comparison shows that there was no serious loss of efficiency during the war in the labor of placing concrete in the Brooklyn district, due to the fact that Brooklyn is a good labor market, and, therefore, the gangs were composed largely of experienced concrete laborers, many of whom had worked for the company for years.

To state the effect of the war condition on construction work in another way—the experienced workman in most lines of the construction industry continued to give good service during the war when working for his old employer, but there were not nearly enough of these experienced workmen to carry on the Government building program and it therefore became necessary to employ large numbers of men new to the industry. These men were frequently found inefficient. The effect of this dilution was felt to some extent in the large labor markets and to a considerable extent in places like Washington, but affected work in out-of-the-way places very seriously, because, the established Government rates of wages on percentage jobs being lower there than in the large labor centers, it was almost impossible to get good men to leave their homes to go to such places.

There is no reason or justice in forming an opinion as to the relative advantages of percentage or lump-sum work based on war-time experience. Where such a comparison is made, the person making it is generally comparing in his mind the efficiency of the percentage job he saw during the war with the efficiency of lump-sum jobs he may have seen carried on before the war, or if he does have in his mind one of the comparatively few lump-sum jobs built during the war, he forgets that the contractor on such a job was not subject to the Government wage scale and, therefore, by paying wages above that scale could get the pick of the men.

Two Types About Same During War

Comparing again the costs obtained on percentage and on lump-sum work, it is interesting to note that the average unit of $1.47 for labor per cubic yard of concrete on the naval base, Army base and Navy and War office buildings was only 1c. higher per cubic yard than the $1.46 unit made on the only large lump-sum job we built during 1918. On the three Government jobs, the average cost of Item 3-F was 8.03c. as compared with 9.19c. on the lump-sum job. The cost of placing steel reinforcement on the Government jobs in Brooklyn in 1918 averaged $21.32 per ton, which is a considerable increase over the 1917 average for percentage and lump-sum jobs of $15.26 obtained from the table. Approximately $3.97 of this difference is due to a 26% increase in the average hourly rate of wages paid, caused by a 9% increase in the rate per eight hours and the effect of overtime. The balance of the difference between the 1917 and the 1918 unit, amounting to $2.09 per ton, must be charged in part to the fact that on the Government work economy had to be sacrificed to speed to a certain extent, and in part to a falling off in the efficiency of the workmen.

The cost of placing steel reinforcement on the job in Washington during the war was $16.22 per ton. This is

an abnormally high figure for such work outside of the metropolitan districts and was due to the inefficient men obtained in Washington. Almost the entire experienced steel gang left and went to work for another contractor who had a lump-sum contract, because he paid wages above the scale fixed as a maximum by the Government for percentage work in Washington. This statement is not to be taken as a criticism of the other contractor. He had taken his contract before the full effect of war conditions was realized and had to get fairly efficient men or suffer a very severe loss.

The percentage and cost-plus-a-fixed-fee form of contract is of great advantage to the responsible contractor in helping him to secure work on an equitable basis, and is of equally great advantage in many cases to the owner, enabling him to get work started on important projects months before detailed complete plans and specifications could be prepared for lump-sum bidding.

It is felt that the importance of the subject has justified a frank statement of the facts as this company has found them, because in our opinion any general condemnation of the percentage contract is warranted.

Panels of Movable Weir Collapse Automatically

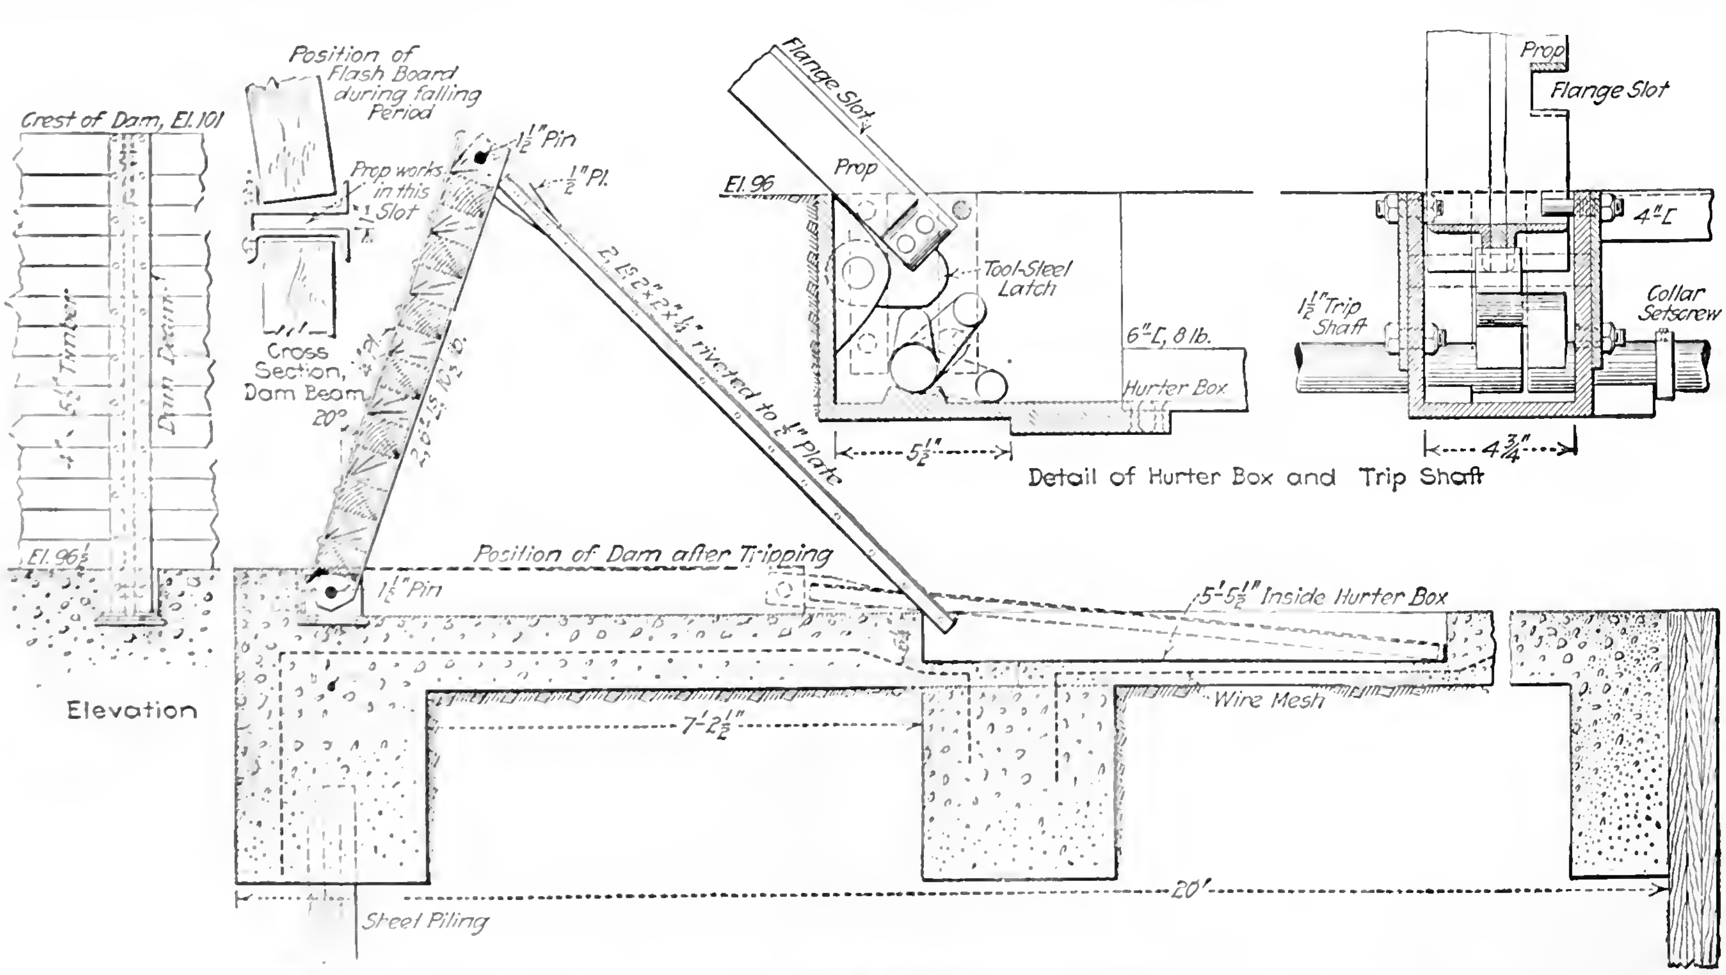
Tripping Started by Float in Chamber Filled as Flood Rises — Double Skimming Eliminates Sediment from Canals

FALLING flashboards trip those adjacent in succession in a collapsible dam built across the Huerfano River, Colorado, to divert water for irrigating 2500 acres of land belonging to the Butte-Mesa Reservoir Land Co. The tripping mechanism operates automatically should a great flood from a cloud burst unexpectedly raise the water 4½ ft. above the top of the panels. This probably will occur not oftener than once in ten years, when no attendant would be on hand to do the tripping.

The Huerfano River rises in the Sangre de Cristo Mountains, the crest elevations of which are 9000 to 14,000 ft. above sea level. The drainage area is 620 square miles, of which 170 square miles are above the 9000-ft. contour. The fall of the river is 50 ft. per mile at the dam site, increasing until 150 ft. per mile is reached at the foothills. Along the river the irrigation ditches usually have brush and stone diversion weirs. These storms occur mostly during the growing season, causing loss of crops, for reconstruction cannot be done until the low-water period.

The necessity for the adoption of a movable structure, as against a fixed weir, arose from the fact that the river is subject to sudden floods by cloud-bursts, which often convert it into a raging torrent. This condition calls for a structure that would allow the water to rise above the top, having no obstruction over the weir crest, and which may be immediately released automatically or by employees, so that the structure would fall to a horizontal (recumbent) position on the floor. This would leave no obstruction to the freedom of discharge of water, logs and débris swept down from above, and would free the entire cross-section area of the channel. It would also avoid the flooding of adjoining farm lands so far as protection may be given by the increased waterway through the weir.

With its steep slope and the flashy nature of the violent floods the river has great erosive and transporting power. Large quantities of débris are carried along the bed and in suspension. A fixed weir across such a stream would have given ground for claims for overflow damages, on the ground that the regimen of the stream had been entirely changed and that the running water would establish another channel condition. Finally, shoaling would extend upstream some distance from a beginning depth equal to the height of the weir to a point where the first grade is broken.

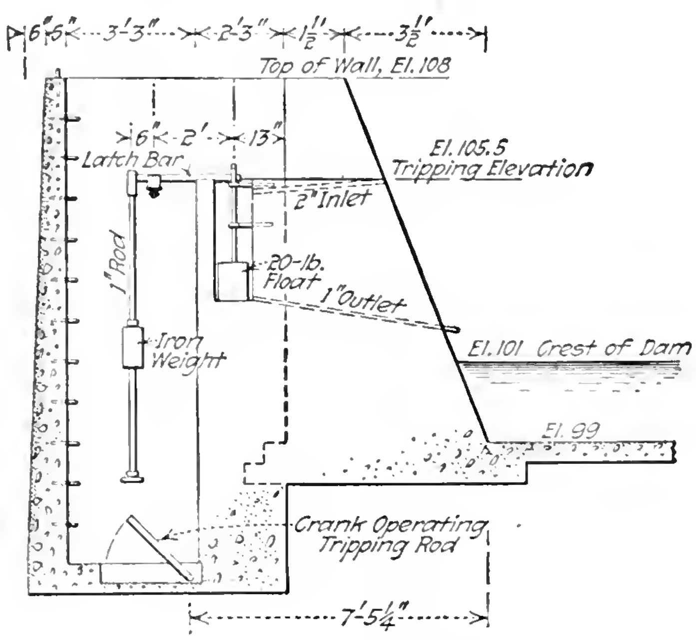


AUTOMATIC FLASHBOARDS DROP WHEN WATER IS 4½ FEET ABOVE CREST OF DAM

PANELS LIE PRONE BEFORE STATIC HEAD IN POOL CAN CHANGE TO VELOCITY HEAD—FIFTH PANEL PROPPED UP INTENTIONALLY

This contention might be hard to disprove before a local jury. With a movable weir, all danger from deposits of sand is removed, as they can be washed down the river when such result is required.

Location of the headworks was maintained at the site of the old diversion weir, and the elevations were



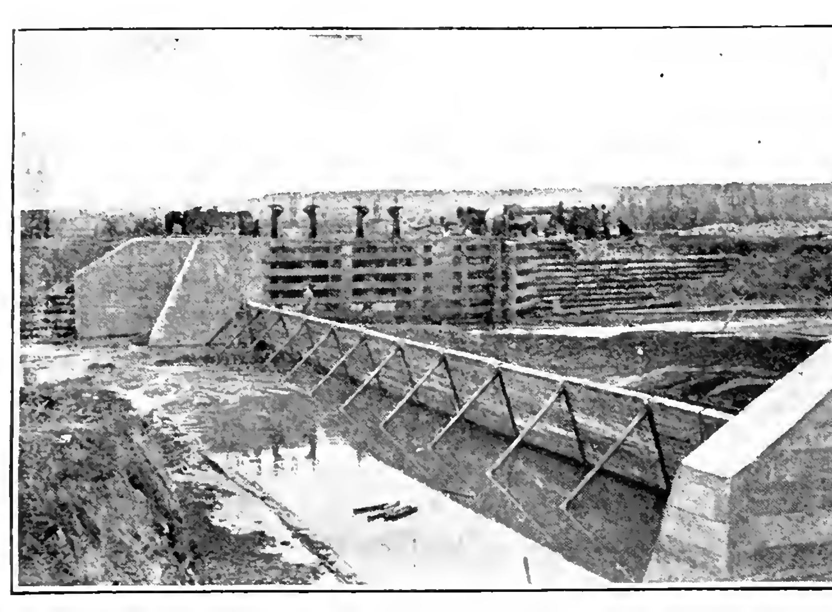
DETAIL OF AUTOMATIC TRIPPING CONTROL

controlled by the grade of the 2½-mile inlet canal, of 100-sec.ft. capacity, to the existing Homestead reservoir.

The diversion works consist of a reinforced-concrete apron, with steel frames for a movable weir, and having the headgates at right angles to the weir. The latter is 104 ft. long, divided into 13 panels, 8 ft. long and 5 ft. high, placed at an angle of 20 deg. from the vertical. The bed of the stream is composed of sand and gravel from 10 to 15 ft. thick, overlying a bed of hardpan. A row triple-lap sheet piling was driven in a trench excavated through the sand and one foot into the hardpan, extending entirely around the apron and abutments. The apron, 20 ft. wide, was placed flush with the river bottom. At the upper edge is a sill 6 in. high, behind which the bottom end of the frames forming the collapsible portion of the weir is hinged. The sill also protects the flashboards from injury when in the prone position. The posts are two channels, into which the horizontal flashboards are placed. These are supported by a hinged prop of angle irons, the foot resting upon a latch, which in turn is retained in place by a cam on the end of a tripping rod.

When the water rises 4½ ft. above the top of the weir an automatic mechanism will be put in operation by the admission of water to a float-well in the weir abutment. Raising the float releases a system of levers and allows a heavy weight to drop upon an extended arm of the first tripping bar. This turns the cam from under the latch of the prop, when the pressure of the water and the silt forces the panel to fall. In moving 1½ in. this panel strikes a crank on the next tripping bar. This action continues rapidly until all the panels are thrown down in succession.

Tripping may be done by an employee at any time, even under a small flow of water. Raising or replacing the panels forming the weir is not required until the stream has fallen to a normal stage, but it can be done in 1 to 1½ ft. of water if necessary. The steel frames are set up, then the boards are placed between them all the way across the stream at the same height above the apron before the head has much increased, and



TRASH RACK GRILLAGE BARS ENTRANCE TO HEADGATES

are pressed so closely together that but little leakage will take place between them. The fall of the weir is so rapid that the flashboards remain in place in the frames. The picture on p. 819 was taken of the operation for the first time of four of the gates, the fifth gate being braced up to save the trouble of resetting all the gates. The engineer snapped the shutter of his camera at the instant he saw the first gate begin to move, but the time lost in getting the actual exposure, $^1/_{100}$ sec., gave time for the first gate to go all the way down while the fourth gate had just started the warping motion taken by the flashboards. The water had not yet followed the gates.

A scouring sluice, at the end of the weir, with the floor at the same level as the apron, is fitted with a steel radial gate, 6 ft. wide and 5 ft. high. The purpose is to scour out any silt that may be deposited in the forebay between the headgates and the trash rack, and to regulate the water level as required.

Headgates to the canal are placed in a concrete wall at the end of the weir. They are of the overflow or skimming type, 9 ft. long and 6 ft. high, and are formed

LONG, NARROW SETTLING BASIN EASILY WASHED CLEAN —SANDY SLOPES SILTED SHOW BLACK

of three leaves each 2 ft. high, so arranged that one, two or three of the horizontal leaves may be raised, depending on the river stage. The leaves are of structural steel shapes and plates, operated by bevel-gear lifting devices, having two rising stem gate stands, connected to a common shaft on top. The top leaf is fastened directly to the rising screws by a 3-in pipe. A 2½-in. pipe inside of the first one is secured to the top of the middle leaf and ends just below the solid screw stem. Working inside of this latter pipe is a 2¼-in. cold-rolled steel rod fastened to the lowest leaf and extending just below the top of the middle pipe. By inserting wedges through the two outer pipes and the rod, all the leaves can be raised simultaneously to take water when the river is at its lowest stages. When it is raised so that the level is, say, 2 ft. higher, the gate is lowered to the floor and the wedge transferred to a slot passing through the two pipes, but just above the top of the solid rod. The bottom leaf then will not be raised when the gate is operated. Should the river rise another 2 ft. the gate is again lowered and the wedge removed, when the upper gate only may be lifted.

The sill of the gates is 3 ft. above the weir apron and 2 ft. below the top of the weir, which gives a sluiceway depth of 3 ft. in front of the gates, and a depth of water of 2 ft. through the gates before there is a flow over the weir. By this arrangement only surface water is taken from the river, and silt is prevented from entering the canal. The full supply can be obtained with only 2 ft. depth passing through the gates.

During low water, when the entire stream flow is diverted for the priority of an old ditch right, all the moving sand and silt go into the settling basin. Also, when the stream is in flood and turbid and turbulent a certain amount of silt unavoidably goes into the settling basin, where, meeting practically still water, the sediment is mostly deposited. The settling basin has a capacity of 55,000 cu.ft. and is that portion of the canal between the headgates and a steel radial sand or sluicing gate. It is 660 ft. long, and has a concrete bottom 6 ft. wide, with 1½ ft. vertical height, excavated slopes 1 on 1 and a grade of 1⅓ per cent.

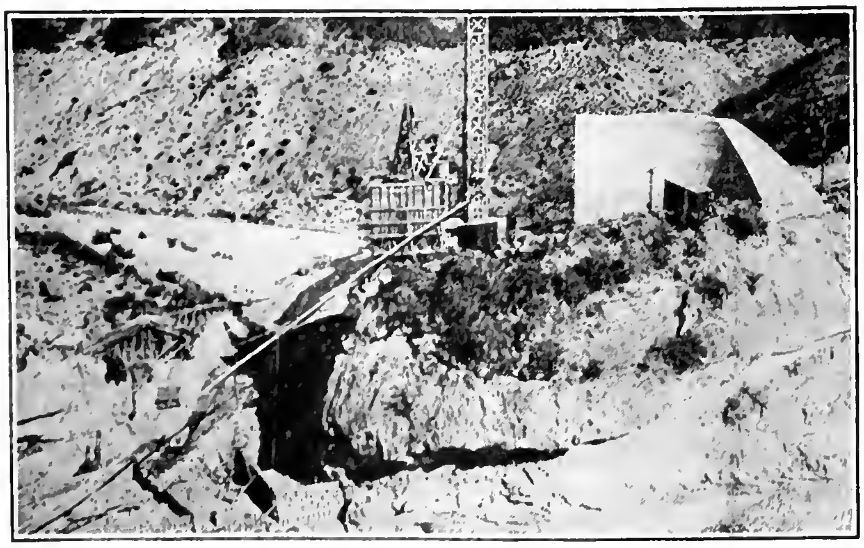
A 12-ft. weir to the inlet canal at the sand gate structure again skims the water from the top. There has been no deposit of river silt in the canal, which has a grade of 0.7 ft. per 1000 ft., since it was put in operation.

T. W. Jaycox, consulting engineer on the design and construction of these works, states that they have been in operation two years and have satisfactorily met the requirements.

Arch Dam Abutment Built Before Rest of Dam

BECAUSE one side of the cañon did not rise high enough to take the full height of the Gibraltar arch dam now being built for the City of Santa Barbara, Calif., an "artificial abutment" of concrete was placed one full year before the actual dam work was started, so that it would have a full set when the pressure began to act. As shown in the view, the abutment is a continuation of the arch curve of the dam and forms the inside face of the spillway just beyond.

Quinton, Code & Hill were consulting engineers on the work. The contractors are Bent Bros. and W. A. Kraner, the latter being in personal charge of construction.



"ARTIFICIAL ABUTMENT" TO ARCH DAM ALSO SERVES AS BUTTRESS BETWEEN MAIN DAM AND SPILLWAY

23rd Engineers Being Held to Repair French Roads

General Pershing Carrying Out Policy Insisted on by French Government—General Black Urges Patriotic Acceptance of Situation

By Wingrove Bathon
Washington Representative of "Engineering News-Record"

An investigation in Washington of the reasons why the 23rd Engineers are still being held in France, notwithstanding the fact that the armistice was signed more than five months ago and that these engineers are needed in the United States now for the building of roads at home, discloses the official information that the French Government has represented to Washington that the damaged highways in France in the sectors used by American troops should be rebuilt and repaired by the American engineers before they go home; that the United States Government has accepted that point of view; and that General Pershing is now carrying out that policy.

Coincidentally, however, Washington is expecting to hear soon by cable from Secretary of War Baker, now in France, as to what the 23rd may expect, following the passage of a resolution by the American Road Builders' Association creating a committee which took up the matter of the possible return of the 23rd with the Secretary of War through the Bureau of Public Roads and the Secretary of Agriculture, the Secretary of War having promised that he would personally present to General Pershing the matter of the return of the engineering regiments.

Basis of Men's Dissatisfaction

At the same time, the investigation above referred to brings forth the official request from Major General Black, chief of engineers of the Army, in Washington, that there shall be a cessation of complaint on the part of the men in the 23rd, who, he points out, "signed up for the war," bearing in mind, he says, that the President has not yet proclaimed peace, and that therefore the war has not yet actually ended. The complaints of the men, it may be here stated, are based principally upon the fact that they are doing pick-and-shovel work in many cases, when they were promised that they would not be obliged to do so, and that there would be labor battalions to do such work; also, that if they are not returned to the United States now, to go back into their old positions while the road-building season is on in the United States, they might just as well be kept in France until next winter.

The request for a patriotic acceptance of the situation mentioned in the preceding paragraph is made by General Black not only of the men in the 23rd, but it is made of the employers, and would-be employers, of the men in the regiment, many of whom have been urging the return of the regiment. The request is also made by General Black of the committee, referred to above, appointed by the American Road Builders' Association.

Finally, the request for a patriotic suspension of judgment and activity concerning the 23rd is made by General Black of *Engineering News-Record*, which was instrumental in recruiting the 23rd Engineers, and which, since the armistice was signed, has advocated the return of the 23rd.

The investigation at Washington to which reference has been made was undertaken as the result of many activities throughout the United States which have to do with the desire to get the highway builders and other engineering regiments home from France. These activities are growing, and others are on the point of springing up all over the country. They will undoubtedly find expression and championship on the floor of the Senate and the floor of the House of Representatives as soon as the expected extra session of Congress assembles. But the investigation was undertaken more especially because of the great number of letters received by *Engineering News-Record* direct from men of the 23rd in France, complaining of their condition, and asking the assistance of this journal in bringing them home, in the same sort of manner that the men of the 23rd accepted advice from *Engineering News-Record* in getting into the 23rd, and going to France to serve their country. These letters were offered to General Black, minus their signatures, so that there would be no question of the War Department being obliged to take official cognizance of unofficial complaints, although General Black pointed out that it was not necessary for him to see them, as the War Department has received many other letters on the same subject. At the same time, the following statement was made to General Black, in writing, over the signature of the editor of *Engineering News-Record*:

In the fall of 1917, under request from the officers detailed to raise a regiment of highway engineers, *Engineering News-Record* did its utmost through advertising to bring into the 23rd Engineers men of exceptional talent and ability as road builders.

This regiment is still abroad, and for the following reasons we beg leave to urge upon the War Department the advisability, in the interests of road building in this country, of the early return of these men:

1. As is commonly known, we are embarking on a highway-building program of exceptional magnitude, due to an endeavor not merely to catch up with work delayed by the war, but also to provide employment for returned soldiers. Highway building is an art that is learned only by long experience, and the roads to be built under this enlarged program will measure up to the needs and justify the expenditures only if there is available an adequate supply of engineers, contractors, superintendents and foremen. Engineering and contracting organizations with which we have been in touch in many parts of the country are urgently in need of the assistance of the specialists who left these organizations in order to join the 23rd Engineers. They were the men responsible for getting results in planning and in the field, and highway work is going to suffer severely if they are not here during the coming construction season to take charge of the new work.

2. In our publicity efforts to recruit the regiment we specifically stated, under direction of the recruiting officers, that only those men were wanted who were qualified to take charge of and to direct work, it being the expectation that prisoners and work regiments would be assigned to work under the men recruited in the 23rd.

3. While many of these men will find positions in highway work should they return after the construction season is well under way, naturally highway departments and contractors will try to complete their organizations at the

very opening of the construction season. In justice to these men, therefore, who showed their loyalty to their country by volunteering for service in the 23rd, we believe that they should be assigned for immediate return.

General Black's answer to the above has already been outlined in the opening paragraphs of this article. It may be stated, however, that he added that there is no likelihood, in his opinion, based on his information from General Langfitt, General Pershing's Chief Engineer in France, of the early return to the United States of the 23rd, or of any of the other regiments containing road builders. General Black is having very great difficulty in getting back from France his own staff engineer officers whom he needs here badly. In many cases he is unsuccessful, the answer to his inquiries and to the inquiries of General March, the chief of staff, from France, being that the officers wanted are "needed in France." With the policy which creates this need, of course not General Black, General March, General Pershing or any other Army officer is concerned; that is solely within the jurisdiction of the administration.

Typical Letters

It may be useful to quote one or two typical letters concerning the 23rd, on which this investigation was based. The following, from one of the men in France, is quoted in part:

Many thousand men, 85% of whom are experienced engineers, artisans, etc., in various occupations connected with the construction business, enlisted voluntarily in the 23rd Engineers for immediate service in France, with the understanding that men skilled in their particular business were urgently needed at the front. Your advertising stated particularly that only experienced men were wanted, and not pick-and-shovel men.

After spending five months in the United States this regiment was sent to France where, with the exception of the truck companies which are a part of the organization, fully 85% of these men have been since engaged constantly in nothing but pick-and-shovel work. These men are still doing pick-and-shovel work and only in rare instances has a man been assigned to the work for which he enlisted.

It seems to me that a grave injustice has been done, not only to these men who voluntarily gave up positions of trust and confidence and made many sacrifices for the great cause, but to the country at large, and more particularly to the conduct of the war, by taking these men from occupations requiring skill and experience and placing them at common labor.

A still more grave injustice will be done to those men if they are not returned to the United States by Apr. 15 or May 1 in time to take part in the season's activities in the world of practical construction.

These men are nearly all experienced, practical engineers and skilled workmen. They are still doing pick-and-shovel work in France. They gave their services voluntarily.

Do you not think that something should be done about it?

The following is from an employer in this country, interested in the return of the road builders, quoted in part:

I am sending you an extract from a letter received from a civil engineer in the 23rd Engineers, U. S. A., which speaks for itself. It looks as if it were up to you to urge the War Department to consider their early return. The extract is as follows:

"We sure are in a nice position here in France. We are in the intermediate section between the Army of Occupation and the S. O. S. Nobody knows where we are and I guess nobody at home is bothering Army officials as to when the 23rd Engineers is going to be shipped home, as we don't come from any one locality as a regular division does. I guess General Pershing thinks we have gone home. Just a brief word as to the gigantic undertakings we are undertaking. Yesterday I saw a $250 a month man peeling spuds. Today he was sawing wood to cook the spuds, and tomorrow I suppose he will be helping to dump the peelings on the garbage pile. That's what about 150 of us are doing. The rest are chasing niggers and hunting cooties and rabbits in their spare moments.

"The point is, in this regiment there are some 3500 good skilled men in various branches just stagnating over here. We, of all people, are not needed here at all. We were a technical, I was going to say *regiment*, but I supply the proper word, *mistake*, and not only that, we have been here and on the front for 12 long months, yet regiments and divisions over here, some only six months, are being sent home to gather together the shattered ends of their careers. I ask you, and through you those who may interest themselves in our return, aren't we entitled to a little consideration in the matter of an early return? I'm convinced that nothing can be done except from the home end.

"The *Engineering News-Record* threw tons of ink and paper around getting us into this and praising this regiment to the skies as being composed of such highly paid engineers, yet never a peep out of them today about getting these highly trained volunteer engineers home. Of course we did not come over here for the *Engineering News-Record* but it was through their call we responded, and now that it is over I think it is up to them to demand our early return. The only time we have ever begun to use the talent in this company is here, and that in making ourselves comfortable."

It appears to me as if there ought to be some agitation to get these boys home without delay. They were sent right out to the front a couple of weeks after they landed in France and worked on the roads under shell-fire until the armistice was signed. A lot of them are men who left good positions here and worked with pick and shovel through the campaign. They did not mind that while the war was on, but now they rightly think they ought to be released.

This is a plain statement of what is being said and done in various quarters as to the 23rd Engineers, except that it is necessary to add that no explanation is obtainable in Washington as to why the men were promised by Army officers that they would not be obliged to do pick-and-shovel work and that they are, and it ought to be said that the statement would not be a well-rounded whole if it did not contain the following explanation. It is a fact that the War Department in Washington does not specify the units which are to come home or the order in which they are to come, and that the first information the War Department has concerning which units are to come home and the order of their coming is received by cable from General Pershing. The policy on which that is based is due to the fact that upon the signing of the armistice the War Department was besieged by politicians in the United States demanding the early return of their own home contingents. To get out of that political tangle the whole matter of the order in which units should come home was left to General Pershing, who, in turn, adopted the policy that the units which could be spared first should come home in the order in which they went abroad. In other words, those who went overseas first should come home first, bearing in mind the need for their respective services in France, based on the policy of the administration. Inquiry in Washington does not seem to develop any prospect that there will be undue delay in sending home engineers recruited from many states simply because they have no one single spokesman, and the case of the Rainbow Division, recruited from many states, and now on the way home, is cited as proof that there is no such likelihood.

New Orleans Army Base Improves Facilities of the Port

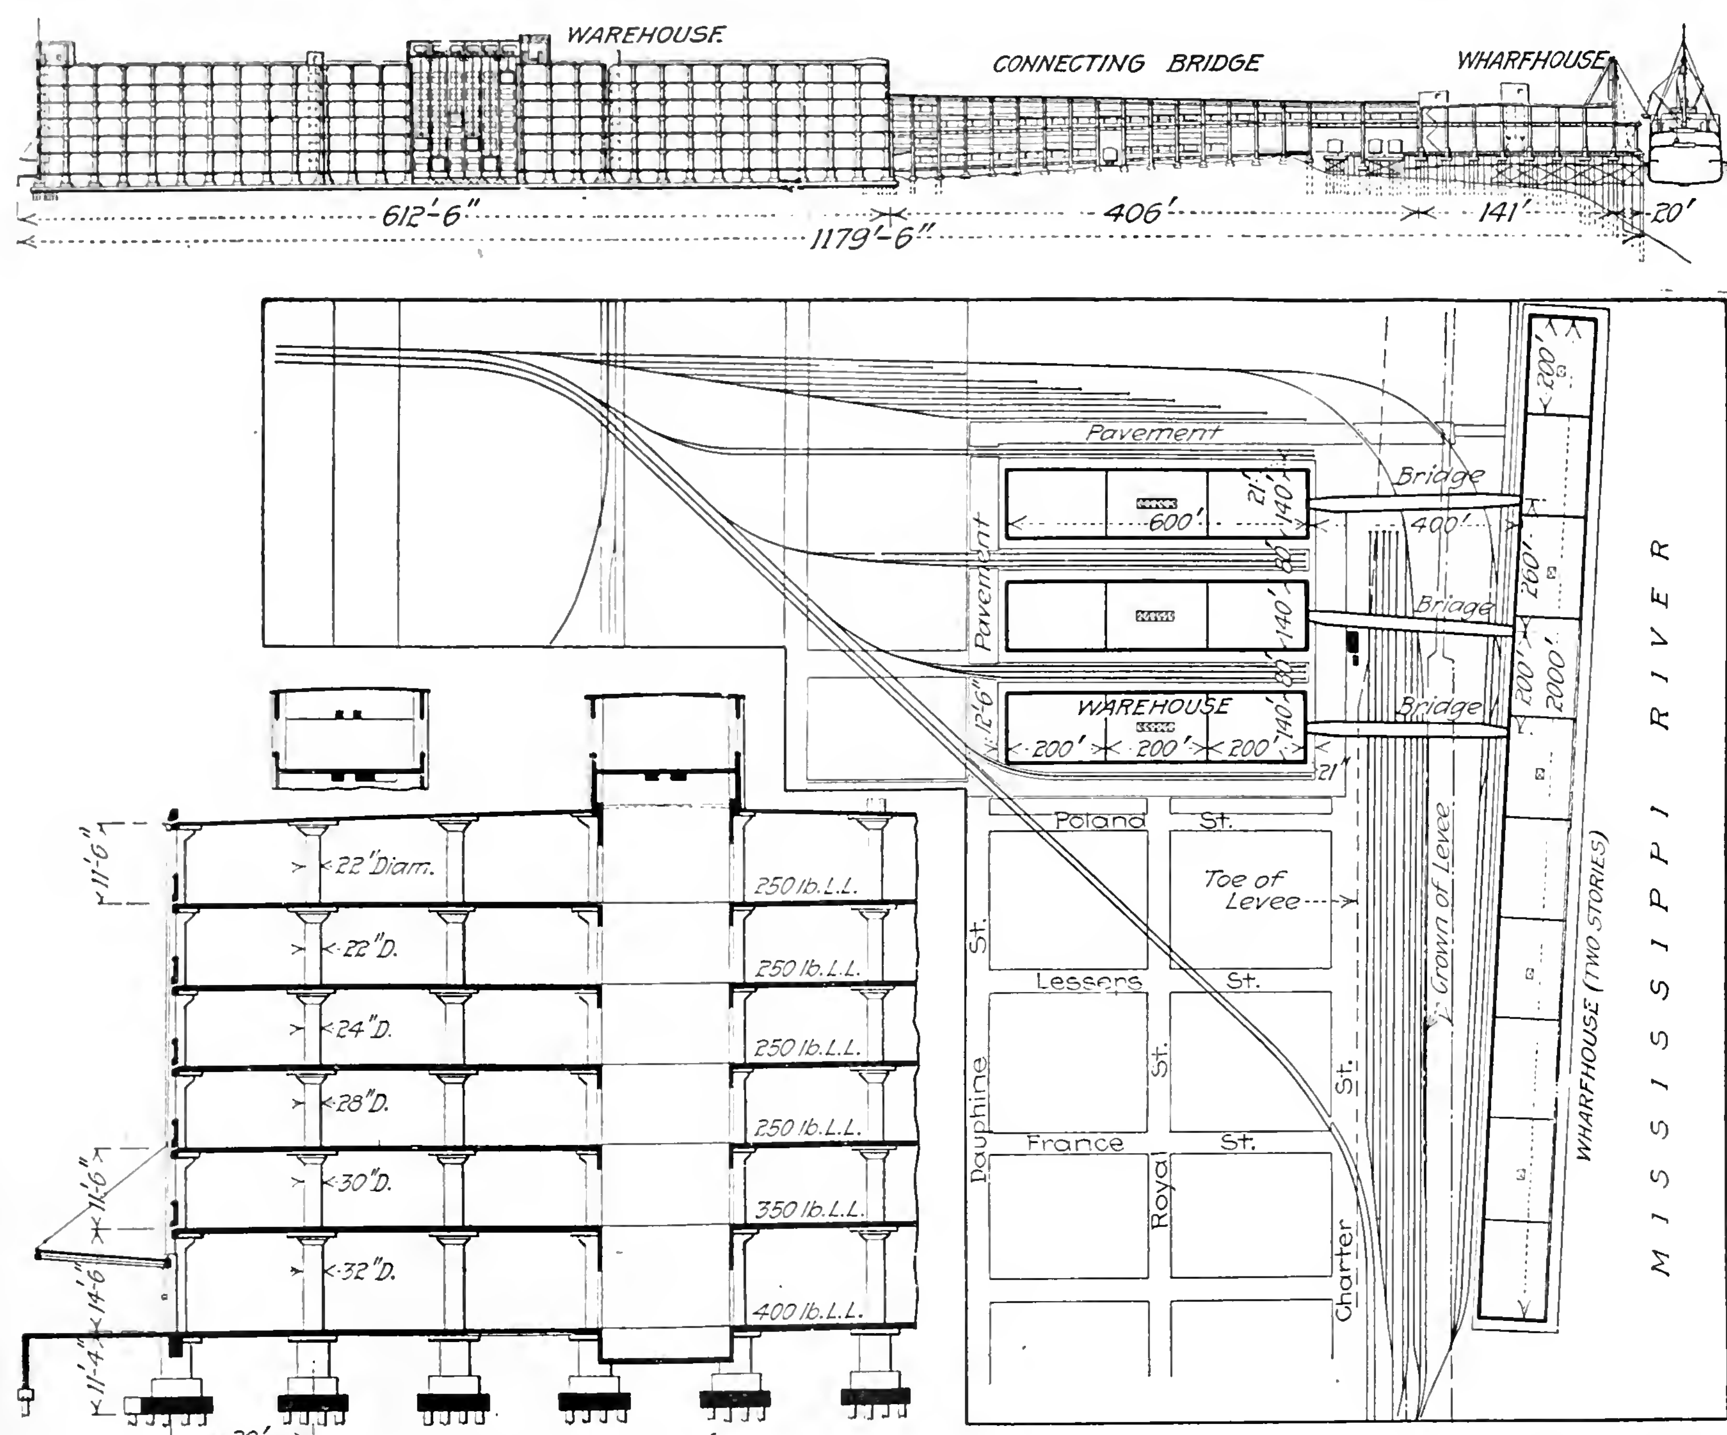
Three Concrete Warehouses Tied to 2000-Foot Wharfhouse on River by Bridges Permitting Access to All Floors — Rail and Water Connections and Storage Facilities Make Peace-Time Use Important

By George H. Davis
Ford, Bacon & Davis, Supervising Engineers

ARMY supply bases for the storage and transshipment of overseas freight to the Expeditionary Forces were located, rather late in the war, at Boston, Brooklyn, Norfolk, Philadelphia, Charleston and New Orleans. Of these the projects at Boston, Brooklyn and New Orleans are for permanent structures designed primarily for the war use but so located and arranged as to make them valuable additions to the peace-time operations of the port. The Boston and Brooklyn bases have already been described in *Engineering News-Record*. The New Orleans base, still under construction, is the subject of this article.

As shown on the accompanying plans, the plant covers an area of more than 48 acres, including various structures and yards, and is composed of three reinforced-concrete warehouse units of the same design, each 600 ft. long, 140 ft. wide and six stories in height, with two-story steel and pile wharf and wharfhouse 2000 ft. long and 140 ft. wide with connecting bridges joining the wharfhouse with the warehouse units. The connecting bridges are of structural steel of the inclosed multiple-deck type, spanning Chartres St. and the intervening railroad yards. There are approximately nine miles of single-track railroad serving the plant. The yards accommodate 520 cars, the warehouse units 135 cars and the wharf 88 cars, a total of 743. The total floor space of the three warehouse units is 35 acres, and of the two-story wharfhouse 13 acres, a total storage area of 48 acres. It will be noted that the floor area is the same as the ground area of the site. If all of the floor area of the structures were loaded to capacity the plant would contain more than 178,500 tons of freight for shipping, equivalent to more than 10 days' average movement over all the wharves, private and state, in the port of New Orleans.

The wharf is of sufficient length to accommodate at



Part Cross-Section through One Warehouse

PLAN AND ELEVATIONS OF THE ARMY SUPPLY BASE ON THE MISSISSIPPI AT NEW ORLEANS

first-off anchorage five to eight oceangoing ships simultaneously, and similarly the trackage immediately adjacent to the warehouse platforms, as previously stated, will conveniently accommodate more than 135 standard box cars.

Comparative Cost—The plant, including the yards, warehouse units, wharf and wharfhouse with complete equipment, will cost approximately $15,000,000. This is 1.2 times the cost of all the state and municipal port improvements on the river front made to recent dates, including the grain elevator plant and wharf, the cotton warehouses and wharf, the Public Belt R.R. and yards, and all the miscellaneous state-owned wharves.

The advantages to the City of New Orleans of this great expenditure by the Federal Government are self-evident. It goes further than any previous expenditure toward the fixing at this port of the center of gravity of concentration, storage and distribution of commodities for Western nations, especially South America.

The plant includes such features of design as are in use in the world's greatest ports, namely:

(a) Extensive storage capacity at ship side;

(b) Maximum loading and unloading capacity in a ship's length due to:

1. Double-deck wharfhouse;
2. Multiple-story warehouse units, and
3. Multiple-deck connecting bridges between wharfhouse and warehouses.

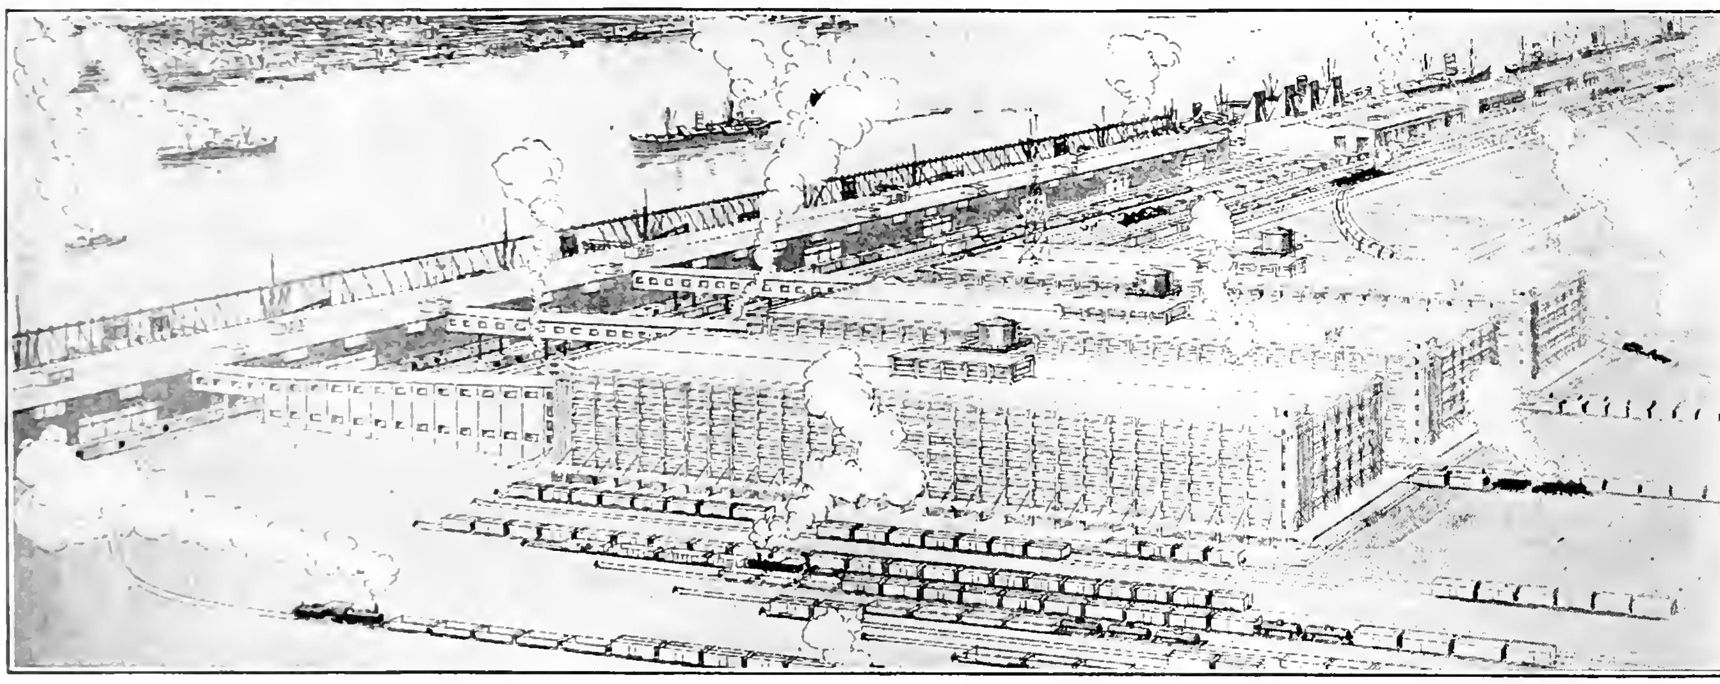
(c) Loading, unloading and transportation appliances as described.

Commercial Advantages—These are:

1. Increased speed in freight movement, thus reducing the ship's time in port by approximately 40% over the time required at the ordinary single-story unequipped wharfhouse;
2. Reduced handling cost per ton of freight;
3. Reduced storage cost per unit of capacity;
4. Reduced insurance costs on account of compartment design and fireproof construction;
5. A probable further classification of harbor facilities placing commodities such as steel and iron products, petroleum, coal, coffee, tobacco, sisal, grain, sugar and cotton at definite locations.

This warehousing, handling and shipping plant is of standard design and completely adapted to (a) the storage, transfer and loading of miscellaneous and standard package commodities; (b) both import and export transfer and storage, and (c) use as manufacturing lofts and factory machinery housing. The warehouses and wharfhouse have a column spacing of 20-ft. centers and an external glass area of 33% and 11%, respectively, being completely lighted for all the purposes noted before.

As stated, the warehouses are built for war or peace requirements of the Army as well as both public and private warehousing. Coffee merchants of Kansas City, Chicago or Denver can have their consigned coffee transferred from ships to these warehouses and from the warehouses to their customers in Memphis, Birmingham or Dallas, without handling the coffee beyond the port-of-entry storage. This is equally true of virtually all commodities. Tobacco can be shipped from Kentucky and held in storage for curing at the warehouses at New Orleans while sales are being made in Europe or elsewhere.



ARCHITECT'S PERSPECTIVE SHOWS NEW ORLEANS ARMY BASE AS IT WILL LOOK WHEN COMPLETED

The use of the warehouses can be extended so as to supplement the private storage capacity of all wholesale businesses.

The capacity of the plant is 178,500 tons, as stated, and in standard packages of principal imports and exports its capacity is:

	Warehouses	Wharfhouse	Total
Coffee (bags)	2,400,000	1,000,000	3,400,000
Sisal (bales)	350,000	150,000	500,000
Cotton (bales)	400,000	200,000	600,000
Tobacco (hogsheads)	100,000	50,000	150,000

Features of Design—As will be noted from the attached drawings, the design of the plant and its individual units is such as best to adapt it to use in a river harbor necessitating longitudinal wharf frontage.

The buildings are relatively narrow, the width being approximately one-quarter of the length. This feature allows a maximum length of railroad platforms and an arrangement of yard and loading trackage perpendicular to the wharf. The clear-story height of all the warehouse units is 10 ft. 8 in., except the first story in each building, which is 13 ft. 7 in. The minimum clear-story height in the wharfhouse is 17 ft. 6 in. for the first deck and 11 ft. for the second deck. The multiple-deck

structural steel bridges correspond in clear-story height with the joined buildings. The loading capacity on the various floors of the warehouse units is:

First	floor	400 lb. per square foot
Second	floor	350 lb. per square foot
Third	floor	250 lb. per square foot
Fourth	floor	250 lb. per square foot
Fifth	floor	250 lb. per square foot
Sixth	floor	250 lb. per square foot
Roof		25 lb. per square foot

The pile foundations of units No. 1 and No. 3 are designed for the total dead load and 85% of the live load, using a dead load of 12 tons per pile.

Under unit No. 2, to avoid the great difficulties and consequent delays of excavation, the standard piles in units No. 1 and No. 3 were replaced by composite piles, the lower section, approximately 48 ft., being of untreated timber, the upper section, approximately 8 ft., being of concrete installed in accordance with the design and under the supervision of the Raymond Concrete Pile Co. These piles are designed to sustain 16 tons.

The columns are designed for full dead loads and the following percentages of live loads:

Roof	100%
Sixth floor	85%
Fifth floor	80%
Fourth floor	75%
Third floor	70%
Second floor	65%
First floor	60%

The warehouse units are of reinforced concrete throughout. The structural design of the buildings is in accordance with the Chicago Building Ordinance, with exceptions as follows:

A. Flat-Slab Design:
1. The positive moments in bands perpendicular to the wall in the wall panels are 20% greater than for interior panels.
2. The negative reinforcement perpendicular to the walls and wall panels for the bands at columns is the same in amount as the negative reinforcement over the interior columns.
3. All negative reinforcing steel perpendicular to the walls is hooked 6 inches.

B. Beams:
1. Continuous beams are designed for the clear span.
2. The spandrel walls are self-supporting.
3. Lintels supporting the flat-slab floors are designed to carry the full dead and live load of one-fifth of the panel width tributary to same, considered as a uniform load.
4. Negative reinforcing bars in end spans are hooked 6 inches.

C. Spiral Columns:
1. The Considère formula is used in computing spiral columns.
2. The average core stress does not exceed 1200 lb. per square inch.
3. The concrete stress is 700 lb. per square inch for 1:2:4 concrete.
4. The amount of spiral reinforcement is not less than ½% of the core area nor greater than 1½ per cent.
5. The amount of vertical reinforcement is not less than 1% of the core area and not more than 4 per cent.

D. Laced Columns:
1. The concrete stress is 500 lb. per square inch for 1:2:4 concrete.
2. Lacings are not less than ¼ in. in diameter and they are spaced not more than 12-in. centers.
3. The amount of vertical reinforcement is not less than 1% of the effective area of the column nor greater than 4 per cent.

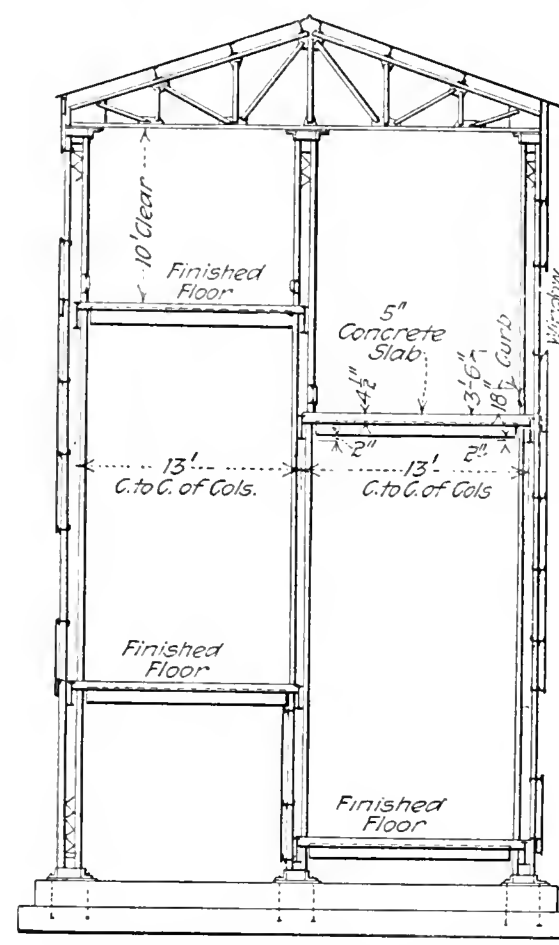
E. Concrete Stresses:
1. The extreme fiber stress for concrete in slabs and beams is not greater than 700 lb. per square inch for 1:2:4 concrete.

F. Steel Stresses:
1. Steel stress for tensile reinforcement for beams and slabs does not exceed 16,000 lb. per square inch.
2. Steel stress for tension in beam stirrups does not exceed 12,000 lb. per square inch.

G. Temperature Reinforcement:
The amount of temperature reinforcement is not less than ¼ per cent.

All other features of construction are in general accordance with standard specifications.

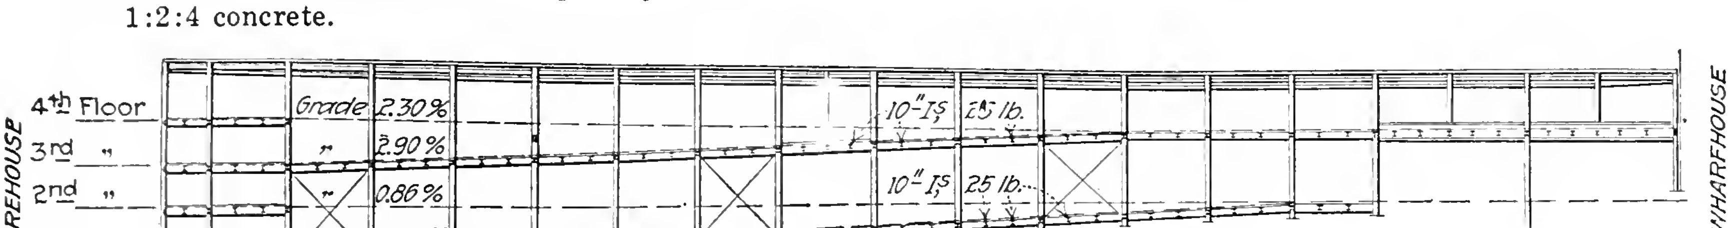
Piling is of round yellow pine and of various lengths for various parts of the plant. Under the warehouse units the points of the piles rest in a sand stratum at approximately —28 (Cairo Datum) giving a total penetration of approximately 51 ft. The piles are driven for the entire length through Mississippi River alluvial deposit until they bring up at the sand stratum before mentioned. Under the wharfhouse all piles and all exposed timbers are treated with 16 lb. of creosote oil per cubic foot. These piles range in length from 50 to 120 ft. In general, piles longer than 100 ft. are spliced, the lower portion being of plain timber and the upper of treated timber.



CROSS-SECTION THROUGH ONE OF THE CONNECTING BRIDGES

The cement is of standard brands of American portland cement. The fine aggregate is obtained locally and is limited in size to ¼ in. in diameter. The coarse aggregate consists of river gravel obtained from various sources, of sizes between ¼ and 1½ in. Concrete mix, except in special locations, is of 1:2:4 proportions.

The wharf is of treated and untreated timber, upon which is superimposed the wharfhouse of structural steel, inclosed by corrugated steel and rolling doors.



BRIDGE BETWEEN WAREHOUSE AND WHARFHOUSE HAS RAMPS TYING TOGETHER ALL FLOORS IN EACH

The plant is completely equipped for fire protection with sprinkler system and auxiliary appliances. It is lighted by electricity and heated by steam. The sewerage and drainage systems are in accordance with standard ordinances of the municipality.

As shown in the perspective a multiple-story bridge connects warehouse No. 1 with the wharfhouse. This structure has four ramps—that is, the first and second floors of the warehouse are connected to the first floor of the wharfhouse, and the third and fourth floors of the warehouse are connected to the second floor of the wharfhouse. The bridges connecting warehouses No. 2 and No. 3 each with the wharfhouse will be of two levels, extending from the third and fourth floors only of each warehouse to the second floor of the wharfhouse. Small bascule bridges close the railroad track openings in connecting bridge No. 1. Each consists of two leaves hinged at the outer end and electrically operated by a cable attached to a drum driven by a 10-hp. motor. Signals and brakes insure safe operation.

Handling Apparatus—Elevators for freight and passenger service are as follows:

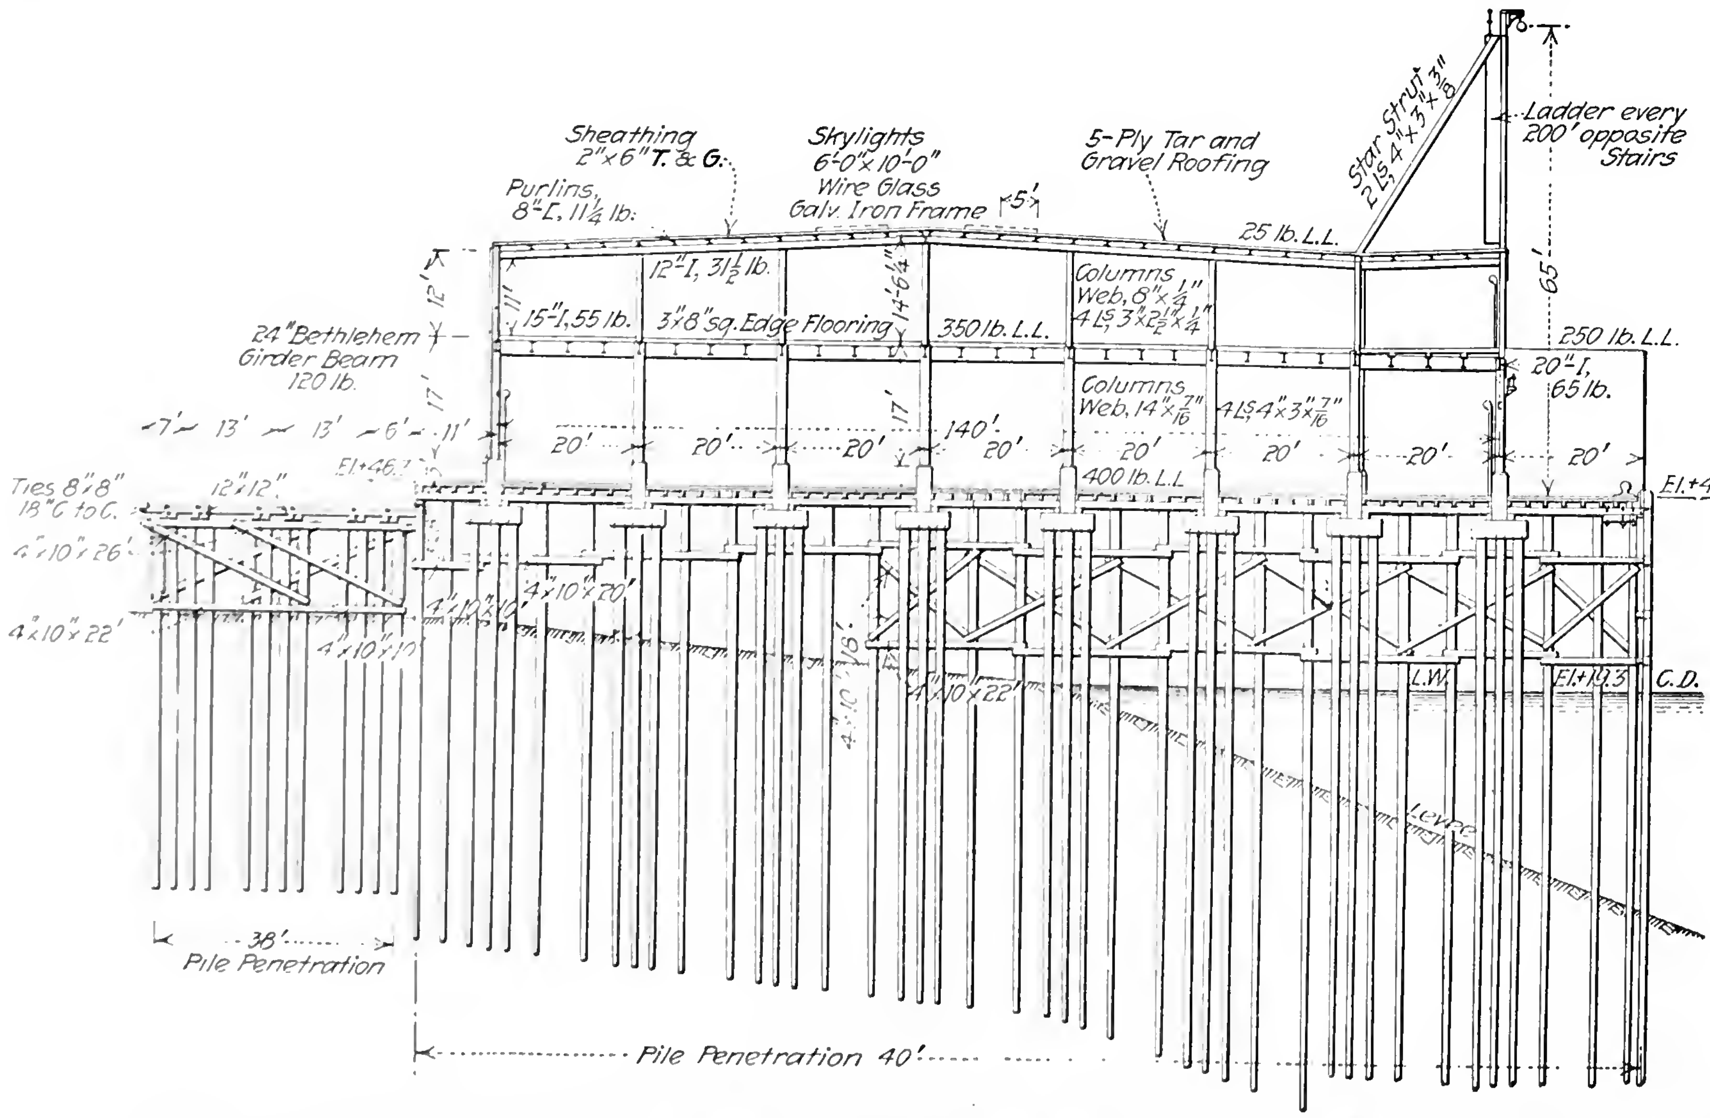
	Wharfhouse	Warehouses
Number	5 freight	15 freight 3 passenger
Location	1 every 400 ft.	5 freight 1 passenger in center of each building
Capacity	10,000 lb.	10,000 lb.
Speed	100 ft. per minute (freight)	150 ft. per minute (freight) 250 ft. per minute (passenger)
Floor area	785 sq.ft.	2295 sq.ft. (freight) 126 sq.ft. (passenger)

Space has been arranged for one additional freight and one passenger elevator in each warehouse. Provision has been made for spiral chutes for the discharge of commodities. The transfer of freight longitudinally is by means of electric tractors and trailers and the use of hand trucks. Bridges are so designed that a minimum use of the elevator system will be required, on account of the three bridges connecting the wharfhouse and the warehouses.

Quantities of some of the more important items required for this plant are as follows:

Warehouses	
Number of piles	31,700
Cu.yd. of sand,	48,000
Cu.yd. of gravel,	93,000
Bbl. of cement,	162,000
Cu.yd. of concrete	108,000
Tons of reinforcing steel	7,500
Ft.b.m. form lumber	9,000,000
Sq.ft. steel sash	113,000
Sq.ft. of roofing	252,000
Wharf and Wharfhouse	
Number of creosoted piles	21,000
Feet, b. m., creosoted timber	5,000,000
Feet, b. m., untreated timber	2,000,000
Lb. structural steel	9,000,000
Sq.ft. corrugated steel siding	96,000
Sq.yd. creosoted wood-block flooring	37,000
Sq.ft. roofing	280,000
Sq.ft. steel sash	16,000

The construction of the New Orleans Army supply base is under the general supervision of Brig. Gen. R. C. Marshall, Jr., U. S. A., chief of the Construction Division of the Army, and in direct charge of Maj. A. Pearson Hoover, constructing quartermaster, who went direct from the Boston Army supply base. Ford, Bacon & Davis are supervising engineers of the base. This firm is represented by George H. Davis, member of the firm; Charles J. Hardy, New Orleans resident engineer, and Frank J. Trelease, engineer-in-charge. The George A. Fuller Co. is general contractor for the entire work and is represented by Walter T. Smith, vice-president of the company. The wharf and wharfhouse construction was sublet by the general contractor to Holbrook, Cabot and Rollins, of Boston.



DETAILS OF WHARFHOUSE BUILT ON MISSISSIPPI AT THE NEW ORLEANS ARMY BASE TERMINAL

How Educational Reconstruction Should Develop

Modern American Engineering Education Must Become More Effectively Concrete in Application of Theory to Practice

By L. W. W. Morrow

Assistant Professor of Electrical Engineering, Sheffield Scientific School, Yale University, New Haven, Conn.

RECONSTRUCTION problems are the most important subjects now being considered by the thinkers and workers of America. One of the greatest of these is the problem of educational reconstruction. The educational system of this country has been subjected to war conditions, and has experienced an almost revolutionary experiment. Educators are considering the past with the view of building for the future, hence a proposal for revolutionary changes in methods of engineering education is timely.

Modern American education was largely based on German educational systems and ideals. German schools and German educational methods were the patterns for the American system. Germany was the Mecca for graduate students. The past four years have shown a fruition of German educational ideals. The war has proved them utterly false and materialistic, however efficient. The German goal was materialism, and the foundations of the national idea, "Might makes right," were embedded in the educational system.

Not only has the war exploded the German educational bomb, but also it has subjected the educators of this country to an experience that rocked them on their foundations of academic seclusion and caused them to study critically pre-war educational methods.

The war first depleted the schools of students through the voluntary enlistment and then, before many schools were in financial straits, refilled the schools with soldiers to be trained for Army needs. The material for vocational training was largely obtained by selection from drafted men. The vocational and special training division of the Army existed sufficiently long to demonstrate its success. It accomplished its purpose and produced startling results in training men for Army needs under war conditions.

Problem Confronting Educators

The problem now confronting the schools may be divided as follows:

1. How to apply to civilian training the good elements of military training and the educational methods learned through war training.

2. How to remove German educational ideas and ideals from our schools and yet retain true educational efficiency.

3. How to educate future generations so as to maintain the present awakened civic conscience; to secure the spiritual element necessary for true culture and ideal civilization, and at the same time secure and maintain industrial and material preëminence.

4. How to coördinate and revise educational methods to secure a product better suited to the changed world conditions, and how to coördinate the educational system with civic and industrial life, in order that both may be vitalized.

What features of war training can be profitably incorporated in civilian training? Was the vocational training a success because of its methods, or because of the sense of duty and patriotism inculcated by the war spirit?

Concrete Application of Theory in Vocational Training

Vocational training has a definite goal. Every endeavor is to reach the goal in the shortest time. No time is given to extraneous subjects. Concentration and discipline are the keynotes of the work. The cornerstone of the educational method is the physical and concrete application of theory at the time when theory is studied. The student is taught to use his hands and his brain at the same time.

Green men carefully selected, fairly matured, capable, physically fit and mentally alert, with only high-school preparation, in 13 weeks have become well versed in radio-telegraphy from the theoretical and practical standpoint. This necessitated teaching them electricity and magnetism, direct currents, alternating currents, trigonometry and radio principles. After one month's work these men passed technical examinations equivalent to those given electrical engineering students at the end of their junior year. They obtained their knowledge through concentrated study and experimentation, under rigid military discipline.

Army training teaches that selection of material, discipline, concentration and the concrete are efficient aids to education.

The discipline is not that due to a uniform or to the manual of arms, but is the discipline that means self-control, promptness, thoroughness, self-reliance and a sense of responsibility and accountability.

Concentration means the intensive study of one thing at a time and mastering it before another subject is introduced. It means having a definite goal and bending every effort to reach that goal in the quickest time.

The concrete means studying a subject from the physical and applied standpoint. It means that theory follows experimentation, and that only that theory is used which has utilitarian applications. It means using experimentation and physical presentations to obtain knowledge.

How can we obtain true discipline in civilian training? Shall we introduce military training, and trust that discipline will result? Past experience has taught that a few hours' drill each week in no sense of the word inculcates true discipline. A more vital application must be made. There is a question whether military training is essential to proper discipline. Discipline can as readily be obtained through a tightening of our educational requirements. There was too much leniency and laxness in our pre-war educational system. For the proper development of the students, too much freedom from control is as bad as too rigid repression.

Educators can require promptness in students; they can hold students more rigidly to requirements; they can instill a nobler and broader idea of education in their students, and can by word and example exemplify and introduce true discipline.

The great difference between civilian training and Army training lies in the fact that the former has no

concrete goal, no fixed target at which to aim, as contrasted with the latter.

The object of an engineering school is to develop a product that will benefit society materially and socially, the material benefit being gained through the incorporation into industrial pursuits of workers well grounded in the natural sciences and capable of increasing their industrial applications, the social benefit being gained through the addition of men to the world's citizenship who are culturally developed and equipped with perspective, vision, and civic ideals such that a better civilization and citizenship will result.

In order to produce such a product the engineering school must afford the following facilities: (1) Instruction in the fundamental sciences underlying industrial applications; (2) an atmosphere and environment conducive to social idealism, cultural, and general development and true ideas of service and worth.

The student enters an engineering school with a development of codified knowledge and personality that is very meager. It is the function of the school to develop the personality of the student to its full extent through proper environment and educational supervision; to develop the codified knowledge of the student in every direction not only as regards engineering knowledge, but as regards the humanities, and in addition to accentuate his codified knowledge of engineering and of the special branch he elects.

The larger schools of this country have developed artificial divisions called departments. These divisions, too frequently, are independent entities and give their courses without any reference to the other departments also concerned with the education of the student. The mathematics, physics and chemistry departments have their own ideas as to the proper method of presenting their subjects, and the student is taught each subject as though it stood alone and were not coördinated with the other fundamental sciences. Too often each department tries to develop a specialist in the one science rather than to coördinate all the sciences in the mind of the student.

Such conditions make for inefficiency. The departments must be coördinated and must be subordinated to the fundamental idea of turning out a product with a sound and correlated knowledge of the fundamentals of engineering.

Eliminate Abstract Teaching

The concrete method of presentation is difficult to adopt in our educational systems. Tradition and precedent are overwhelmingly in favor of teaching fundamental science as an abstract rather than a concrete thing. Theory comes before practice. This is entirely artificial, and is due to taking the easiest way.

Engineering fundamentals should be taught in the applied manner, which involves the utter elimination of the abstract subjects called physics, chemistry, mathematics, etc., as such; the entire elimination of the abstract and the general in favor of the concrete and the applied; the introduction of experimentation as the direct road to knowledge; the giving of practice before theory rather than the converse; and the use of logic, psychology, and common sense in teaching.

All science is experimental and can best be taught from the experimental standpoint. The keynote of the applied method of teaching is to use the concrete to find out the *how* of things and follow with the *why* of things and thus conform to nature's educational method —first *see* what happens and then determine *why* it happens and *how much* it happens. This means that the abstract subjects, physics, mathematics, chemistry, etc., would be applied to a given experiment or piece of apparatus sufficiently to explain *why* and *how much* it happens and would coincidently bring into the instruction English and economics as applied to expressing and appraising the experiment and its results.

This necessitates a careful planning of experiments such that in an engineering course the student will have to apply all the abstract fundamentals of physics, chemistry, mathematics, mechanics, etc., before he has finished the experimental work of the four years. This involves a revolutionary change in educational methods and in the qualifications of engineering educators, for the experiments must not only bring out the fundamentals but must be interesting, practical and of an engineering nature.

In addition, this method implies a selection of the students for the engineering schools and the classification of these students into divisions of similar mental and engineering qualifications. A few simple psychological tests are more valuable for determining whether the prospective student is of engineering caliber than any stereotyped entrance examination—the latter requires only memorization, the former requires thinking and an attitude of mind essential to engineering success.

Administrative Remodeling Required

An education scheme of this nature would use all the equipment and teachers now available in our engineering schools, but would require an administrative remodeling of departments and a coördinated type of education rather difficult to administer.

The first requirement is a carefully planned series of experiments on concrete subjects in conformity with the subdivided engineering student classifications to insure an appropriate fundamental content. The second step would be the allotment of selected instructors to handle the classes in accordance with the engineering and personality classifications of the students. The third step would be the allotment of the classes to the different engineering and scientific laboratories.

The mathematics, economics, physics and mechanics departments would cease to exist as such and the chemistry department would be changed to chemical engineering, but the instructors, laboratories and equipment of these former departments would be utilized where needed for experimental or instructional purposes. *Abstract courses would be entirely eliminated, the student would take only one course classified by the engineering department elected, and his time would be allotted by coördinated faculty agreement.*

Every experience of life and industry teaches that real knowledge is best gained by using the hands and the brain at the same time. Any efficiency engineer handling labor will bear out the foregoing statement. Mathematics, physics, chemistry and mechanics must be taught as experimental, concrete and applied subjects, if real educational efficiency is to be attained.

Probably the greatest task in educational reconstruction is to maintain the present spiritual and idealistic attitude in the nation. The war has proved that efficiency solely in materialism means destruction. Ger-

many concentrated on the materialistic; industrial supremacy, martial supremacy and financial supremacy were her civic ideals, with no leavening of truth and idealism. The world needs no greater example of the falsity of such ideals. No civilization can exist that has not humanistic ideals as well as materialistic. The war has taught that future education can only be successful if it inculcates in the students a realizing sense of the importance of idealism and true culture, as well as giving them sound training for preëminence in material pursuits. The humanities are as essential as the sciences in any true educational system.

The word "humanities," as generally accepted, means history, literature, art, etc. It is not necessary to teach Greek, Latin, art or literature to instill the true humanitarian spirit in students. As has recently been stated, "Greece was the only uneducated nation; yet every other nation has been educated by Greece"—meaning that Greece had no traditional history, literature or art to study, but developed her own culture. Greece cultivated her own humanities and culture, and they have been accepted by later nations as standards for emulation. Our humanities need not be those of Greece. Our education should develop the humanitarian spirit through developing in the nation conditions such as existed in Greece whereby spontaneous cultural development will occur.

Coöperation Needed

The day of the academic attitude in education has passed. Education must be reconstructed on the basis of the utmost coöperation between the schools and industry. The product of the schools supplies the demands of industry. Educators are needed in industry, not only on material grounds, but also because inherently they are the leaders in idealistic thought. Industrial men are needed in the schools, on the other hand, to train students properly and efficiently for industrial work.

Both the educators and the industrial men gained breadth and vision through their war experiences. The views and needs of industry became widely disseminated among educators, and, on the other hand, industrial men gained a truer knowledge of American educators and educational methods. Industry had need of pure scientific knowledge and gained it from the educators. Much of the pre-war antagonism and narrowness of view has disappeared. Every indication points to a more intense educational and industrial coöperation. Industry will establish research scholarships; will use educators as consultants on labor and other industrial problems; will furnish competent men to help educate students for the needs of the industrial era—if properly encouraged to do so by American educators.

In addition to school-room work, the educational institution must furnish the facilities and environment for intellectual and moral growth. The teachers should be men who are respected and emulated by the students, they must be approachable and must be interested in the students. They must coöperate in student activities to the utmost and encourage all social and other nonscholastic activities that make for proper student development. Teaching should be a profession and not a side issue with research or commercial engineering the main issue. Teachers should be selected for their teaching ability rather than for their research and mathematical ability.

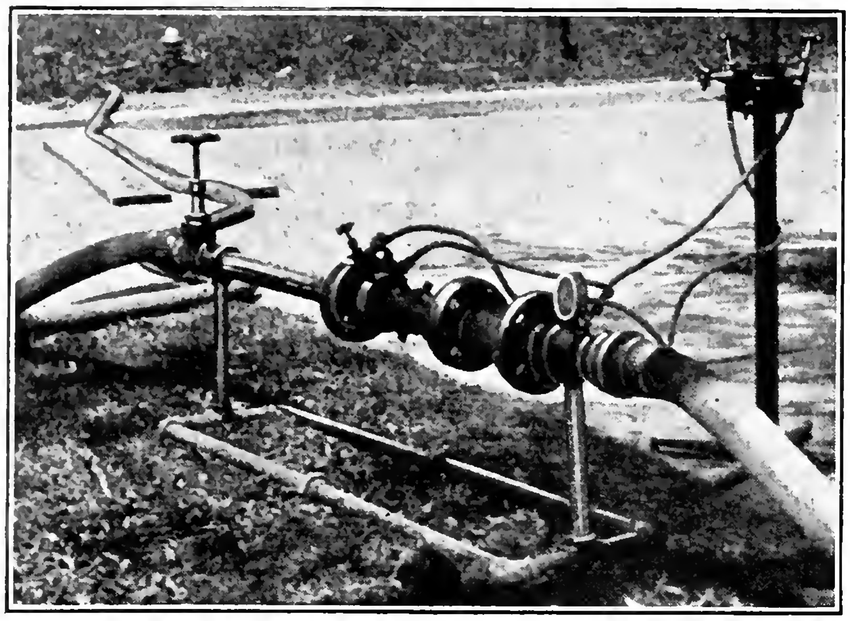
A proper application of the foregoing principles will increase the efficiency and value of engineering education, but no compromise plan will attain the results desired. The plan is difficult to carry out, but far from impossible. The war has revolutionized industry—reconstruction is the key-word of today. Nothing needs reconstruction more than engineering education.

Devices for Water-Waste Surveys at Oak Park, Illinois

Portable Venturi Meter to Test Pipe Districts—Pitometer Inserted in House Service Makes Leakage Charts

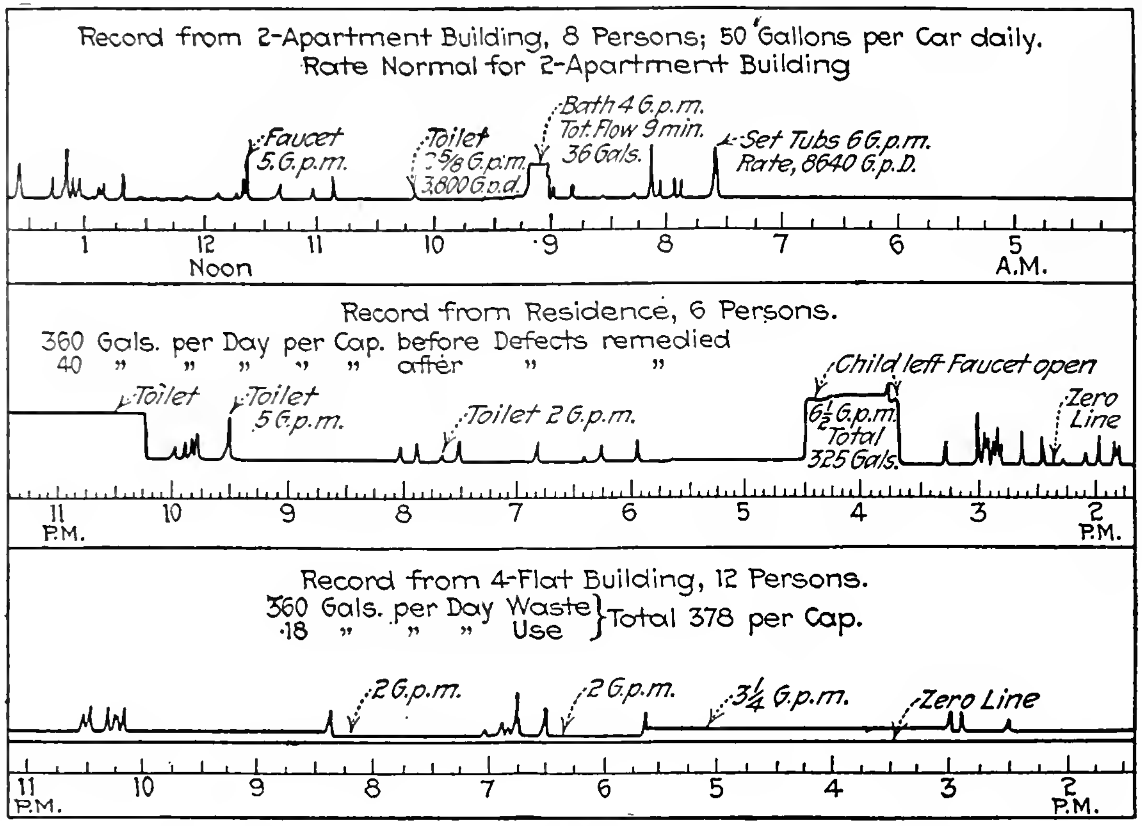
PRELIMINARY to a water-waste survey, it is advisable to make a rough pitometer test of the entire city, according to a paper read before the Western Society of Engineers by Herbert P. Matte, chief sanitary engineer of the Illinois State Department of Public Health. This is done by isolating certain districts by closing gate valves and then measuring the supply through one main left open. On small systems it is possible to make this test by shutting down those districts entirely for a few minutes, especially in the residential sections, and noting the drop in the rate of consumption as indicated by the recording chart at the master meter, providing it is on the distributing system.

In districts which are completely metered the velocity of the smallest feed main may be so low that it is impossible to obtain an accurate record of the consumption if there are no large leaks. It is then necessary to bypass the flow through a small pipe (2-in. or less) in order to increase the velocity. The most practical way of doing this is to feed from a fire hydrant outside the district through a fire hose to a hydrant within the district. A regular displacement meter may be used and the rate obtained by noting its readings at regular intervals, but this method is not very useful owing to the fact that several drafts may occur during the test. Two methods used at Oak Park, Ill., are described by Mr. Matte. One consists of a 2-in. venturi meter with a ⅝-in. throat which can accurately record rates from 3 to 50 gal. a minute. This is shown in the accompanying



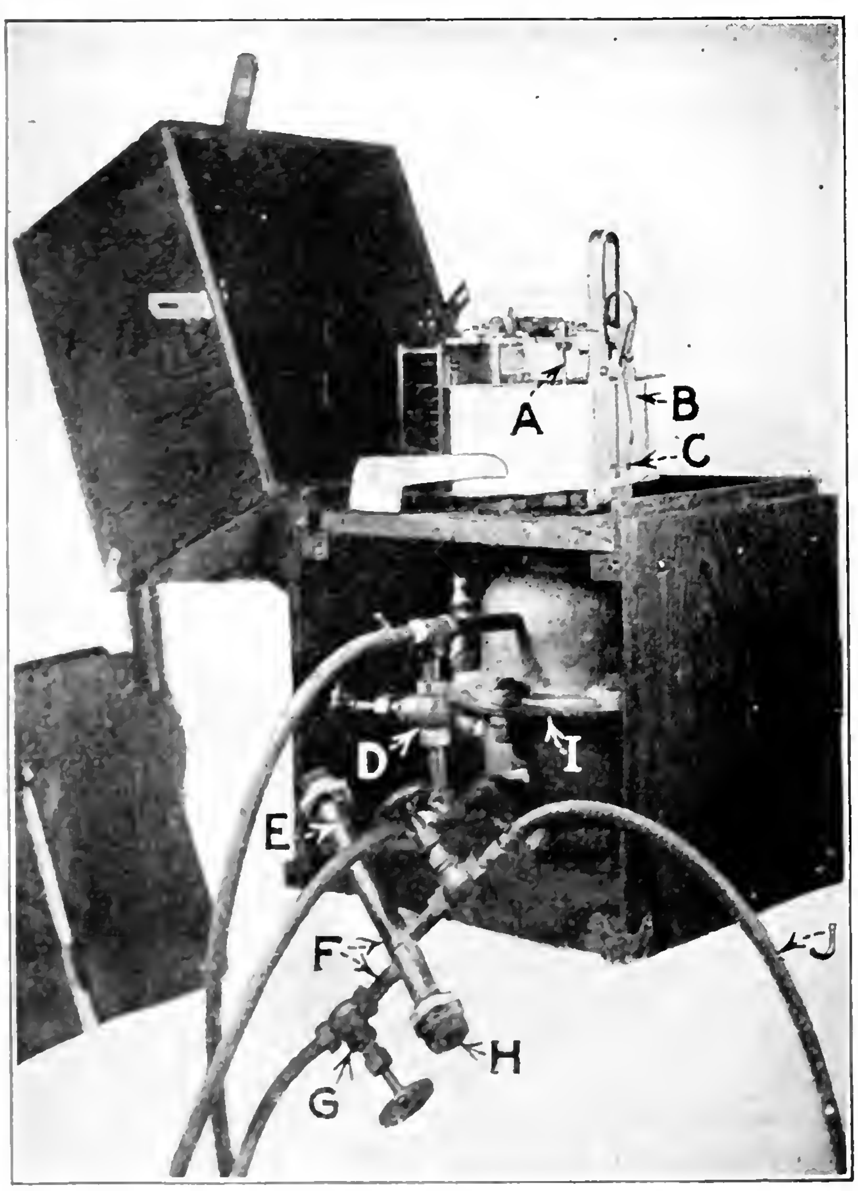
PORTABLE VENTURI METER WITH BAROMETRIC MERCURY MANOMETER FOR WATER-WASTE TESTS

view. The other is by using pitometers inserted into short pieces of pipe, 2-in. or smaller. This permits the measurement of as low as $\frac{1}{4}$ gal. per minute. Contrary to the usual method, all the Oak Park tests were made during the day, after determining the hours in which the flow was somewhat steady. The districts varied between one-quarter of a mile and two miles in length. As the rate of consumption could be watched, it was rarely found necessary to be on the job for more than half an hour at a time in order to determine the minimum rate of consumption. The population of the district was obtained from the school census, and the average daily consumption through the domestic meters was obtained from the water accounts. Thus, an estimate of the legitimate rate exclusive of the underground leakage was determined. Where there was not much leakage the normal pressure was maintained through 600 ft. of fire hose. Where the flow was abnormal, the valve on the meter was throttled, in order to bring the reading within the limits of the manometer.



SAMPLE OF CHARTS FROM WATER-WASTE DETECTOR

A rate of 60,000 gal. per day at 10-lb. pressure in a pipe only half a mile long was observed in one case, the normal pressure in the mains being 45 lb. Tests by the aquaphone disclosed six service leaks which wasted 200,000 gal. a day. This meant a leakage rate of 305 gal. per capita per day, while the service meters indicated only a total per capita consumption of 45 gal. After repairs were made the leakage rate dropped to 10 gal. a day.



DETECTOR FOR DOMESTIC WATER WASTE

A, rod to diaphragm; B, paper $2\frac{1}{2}$ in. wide; C, pen; D, bypass; E, $\frac{5}{8}$-inch brass meter nipple; F, pitot tubes; G, $\frac{1}{4}$-inch needle valves; H, threads for $\frac{5}{8}$-inch meter couplings; I, diaphragm; J, pressure tube

To determine the cause of high water bills where there was no leakage and the consumer was sure he was not wasting water, the water department at Oak Park designed a recording detector or pitometer, which, when substituted for the meter, gives a graphic record of the consumption for 24 hours or a week. This device consists of a piece of $\frac{1}{2}$- or $\frac{3}{4}$-in. brass pipe 7 in. long, into which are inserted two $\frac{1}{16}$-in. brass pitot tubes, one pointed upstream and the other perpendicular to the axis of the pipe. For convenience, these tubes are soldered into $\frac{1}{8}$-in. brass nipples. Two needle valves and strong rubber tubing complete the detector, which is inserted into the house service either in place of or tandem with the meter.

A special type of recorder with a rapidly revolving chart, so that drafts lasting only $\frac{1}{2}$ min. could be detected, indicated at what time and how long faucets were left open for baths, for washing dishes or clothes, or for lawn sprinkling; how often toilets were flushed, etc., together with a record of all leakage of $1\frac{1}{2}$ gal. a minute or more. Part of a sample chart is shown in one of the illustrations.

In the first experiments the pitot tubes were connected to a mercury U-tube, by means of which rates ranging from less than $\frac{1}{2}$ gal. per minute to 30 gal. per minute were measured by using the $\frac{1}{2}$-in. and $\frac{3}{4}$-in. nipples. A camera provided with a 3-in. revolving sheet of bromide paper was adjusted so that the lens magnified the deflections through a slot about 0.008 in. wide. A pocket flashlight supplied the illumination, through a condenser, and the power was furnished by a single cell storage battery constructed for the purpose. The only drawback was that the high deflections were beyond the range of the slot, although small leakage was detected which the disk meter failed to record.

After fruitless attempts to alter the quantitative measuring device of the displacement meter so that

it would register in gallons per minute, the next step was to design a recorder which could take care of all flows. This new recorder, shown in one of the illustrations, will detect rates as low as 1½ gal. per minute, and there is no limit to the maximum recording capacity if larger meter tubes with lower center velocities are used. The diaphragm is constructed of ⅛-in. mechanical rubber, and Mr. Matte states that it was surprising to note the power transmitted through the stuffing box. The recovery after a short draft is rapid, even at maximum velocities, as indicated by the accompanying drawing of actual records. The recorder is not extremely accurate, but frequent rating by means of the regular meter-testing outfit indicates that it is amply dependable. It has been used successfully, in connection with a 2-in. venturi meter, in making waste surveys by means of the hydrant and hose method described above, and gives much assistance in determining the varying consumption in the district tested so that the leakage can be ascertained.

Comparison of Long and Short Highway Contracts

Opportunity for Both—Outgrown Methods Should Be Discarded—Long Contracts Cheaper and Desirable to Attract Large Construction Organizations

By H. Eltinge Breed
First Deputy Commissioner of Highways, New York State

Evidences indicate that highway work offers the biggest immediate opportunity to all kinds of contractors, both large and small. For the present needs there is a scarcity of experienced highway builders, and the attraction of large construction organizations experienced in other fields will depend largely on the sizes of the contracts available. Comparison of the relative cost of letting a long stretch of road by one contract, or by several contracts, shows a large saving for the former procedure, if proper precautions are taken in organization and in the selection of the plant. More economical distribution of materials and plant, without disturbing the work of other contractors on an adjoining site, is also to be expected. While many lines of private enterprise still falter in uncertainty, there is urgent need for highway work and the means to satisfy this need are at hand. So great is the opportunity that there is danger lest is be wasted by trying to hold the future to the routine of the past. Now is the time to shape larger means to greater ends, and to advance fearlessly beyond outgrown practice.

Large amounts of money are available for highway work, and public opinion is favorable to such expenditures. Two hundred millions—and more to follow—have been appropriated by the Federal Government; $50,000,000 and $60,000,000 bond issues have been passed in Pennsylvania and Illinois, respectively, and large appropriations have been made by many other states. Public sentiment, roused by the transportation experiences of the past two years, is solidly behind road construction, and is being intensified through nationwide propaganda conducted by good roads and automobile organizations, chambers of commerce, and material and motor-car interests, while labor of all kinds demands productive employment that will hasten the readjustment of conditions.

Future Progress Threatened

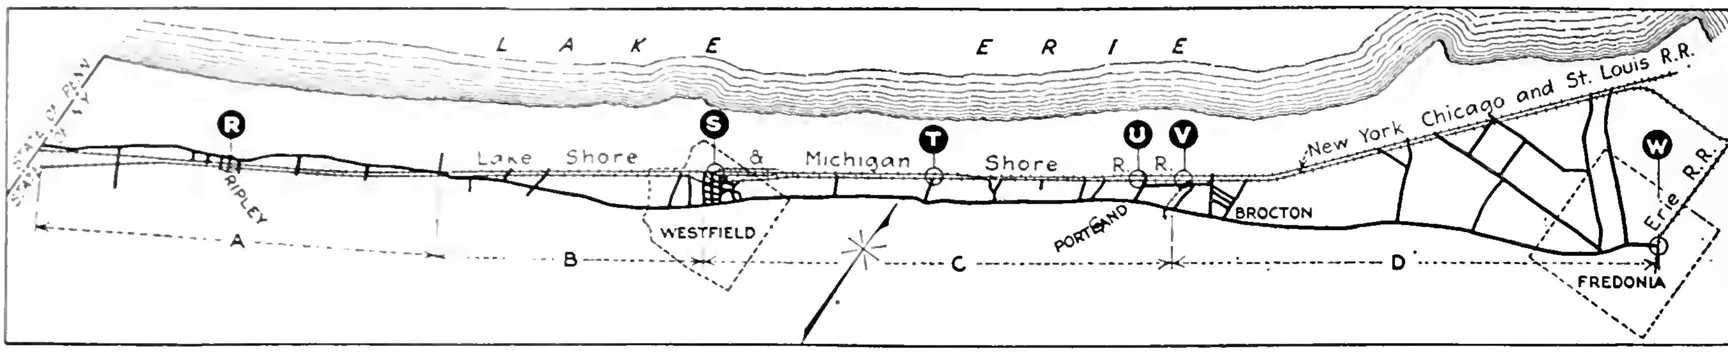
Nothing threatens our progress in the future more gravely than the practice of letting all contracts in lengths averaging one to five miles. This has encouraged the man with small capital and a one- or two-unit plant to enter the field, and to his initiative and courage our roads today owe much. But it has practically excluded large organizations which, figuring other contracts in terms of millions, could not afford a shift to such small game as the highways have offered. The reasons for the short contract are obvious: Tradition, from the days when highway contract work was trifling and uncertain; red tape, which has tied up with legal restrictions getting work done; fear felt by the small man lest he be crowded out by a more powerful competitor; and the reluctance hitherto of large concerns to enter highway work because they were not sure that it offered sufficient opportunity for a large capital investment in plant.

Scarcity of Contractors

As the matter now stands there are not enough contractors available for work advertised on the short-contract basis. In New York State there are 600 miles of abandoned and new contracts ready for letting, which require, for plant and backing, a contracting capital of about $2,000,000. Of the 554 formerly listed, there are now only about 100 going contractors in the state equipped for highway work, with an estimated total capital of $1,000,000. Not even all of these are available for new work, as some already have all they can handle. And this in the state where the extension of highway work has attracted most men into the business. We must have more men for the actual construction work. The length of our contracts will determine to a large extent whether these men shall all be comparatively small beginners in contracting or whether large and experienced organizations shall be included.

One thing is certain—long stretches of work will be let at one time. We now see our highways in terms of national systems instead of as convenient spurs to the barns of local politicians. We plan highways that shall traverse the country, north and south, east and west. A route shall cross one state and connect with the corresponding route in an adjacent state. A very few of these routes are already completed, of others only short gaps are to be built, but the majority, in stretches from 20 to 80 miles, still exist only in blueprint plans. Shall such stretches be broken up into sections or advertised for one bid?

Let us consider an actual, concrete case. Route No. 18 of the New York State highway system, shown in the accompanying sketch, runs from the Pennsylvania State line northeasterly along the New York Central & Hudson River R.R. to Fredonia. The distance is 25.76



HAULING DIAGRAM FOR ROUTE NO. 18 FROM THE PENNSYLVANIA STATE LINE TO FREDONIA, N. Y.
R, S, T, U, V and W show railroad sidings

miles. The engineer's estimate for a concrete pavement 16 ft. wide and an average depth of 6 in., at present prices, would be $800,000.

Consider this divided, according to the old practice into four contracts as follows:

State line to Forsythe	6.74 miles,	Contract A
Forsythe to Westfield	4.02 miles,	Contract B
Westfield to Brockton West Corporation line	7.65 miles,	Contract C
Brockton West Corporation line to Fredonia	7.35 miles,	Contract D

Then consider the whole distance from the state line to Fredonia in one contract lettered A-D.

For close comparison let us plant the one large contract and the four short ones with the same kind of equipment. Plant has been figured on the basis of completing the road in one season.

The total cost of a plant, new, for Contract A-D is $139,100, with $6300 additional for supplementary plant.

Contract A requires $44,600 worth of new plant with $3300 for supplementary plant; Contract B requires $35,100 worth of new plant; Contract C requires $41,100 worth of new plant and $6300 for supplementary plant; Contract D requires $53,600 worth of new plant and $6300 for supplementary plant. Total cost of new plant for the four contracts, $174,400; total cost of supplementary plant $15,900—an increase in cost over plant for a single contract of $44,900. The season's additional cost of plant for the four contracts over the one contract is $13,414 plus $2112 for the supplementary plant. These totals were arrived at by figuring the interest charge at 6% on the basis of actual cost, plus 12% for repairs on regular plant and 6% for repairs on the supplementary plant, allowing 20% for depreciation on new plant, with an allowance of only 10% for depreciation on supplementary plant because it is used less.

We must also figure the approximate freight on this plant and the on-and-off charge of loading and unloading, as well as the moving charge for the four contracts, which amounts roughly to about $2000 more than that for the single contract. Thus, on the one item of plant alone we have saved through the one long contract $17,526.

Supplementary plant is necessary to insure the completion of the longer sections in the one working season. It would, of course, have been possible to have figured other kinds of plant, but the character of the plant used—concrete mixers, unloaders, rollers and motor trucks—is such as would show smallest depreciation and greatest salvage value.

The necessary motor equipment was figured on the basis of the actual quantities involved for the exact average haul. The planting of the job and the work was figured on the basis of three organizations for the large contract, with a possible supplementary organization to piece out any section running behind, while the small work was figured on the basis of four organizations, with the possible use of two supplementary organizations.

Without doubt, the organization and overhead charges for doing the work would be less in the long contract than in the four units that comprise it. Obviously, we cannot estimate here in exact figures, because these costs always depend upon the individual contractor and the individual organization. There are, however, certain advantages and disadvantages that would apply generally.

Interference of Short Contracts with Each Other

Suppose the long stretch of road cannot be as advantageously broken up as the one shown in our map. In order that his supplies may come freely to each contractor, a cross-road must traverse his contract, either near the middle or else at both ends. Should this be lacking he must either build one himself at consuming expense, or he must petition the adjacent contractor for permission to haul over his part of the road. This may or may not be granted for all or part of the time, and John Jones may get on his job some morning to find that the crushed stone for which all his force waits is held up for a week because his neighbor has just put in green concrete.

Three efficient contractors finish their jobs on schedule time; one weak brother gets his all torn up and has to leave it impassable till the next season. The one undone makes useless the three done. The public is incensed. Having learned the value of coördination, it begins to question the wisdom of four different concerns all doing the same job, of paying four overhead costs where one might suffice, of holding four persons instead of one responsible for completion and success.

The demand thus arises that long stretches of road, from 15 to 30 miles, be let in one contract, except in unusual cases where specialized construction work is involved. Suppose this is done with Route No. 18 to Fredonia. The contract is advertised and awarded to the Mammoth Construction Co. The bids have indicated one gain over the old plan; the work can be done at less cost to the public and probably with more profit to the contractor. Here are some other items of saving besides what we have already detailed in respect to plant:

1. The contract is limited to one season, as it could scarcely be with the four concerns. The public thus has the route completed in one year. The cash saving is from $500 to $1000 a mile—the extra charge which every good contractor adds to work carried over the winter season. Engineering charges also are always lessened, according to the rapidity with which work is completed.

2. The overhead cost of a large organization doing

a big piece of work decreases in proportion to the amount of work done. Men of higher grade can be employed to conduct the work. The broader scope will attract them, as well as the larger salaries justified by their increased responsibilities. Plant can be more economically employed. The large organization carries enough plant, so it is less likely that it will have to buy special equipment for any one job. This lowers its bid. All the plant is kept more continuously busy, so that a smaller amount need be charged off against that depreciating in idleness. There is less shifting of plant from place to place, because the same units will be kept on the long job throughout the season.

3. The greater power of a large organization makes for efficiency and economy. Materials bought in quantities cost less, and better service is obtained in their delivery. Labor is often more available for large organizations, because of their wider prestige. Financial strength means the ability to tackle the hard and often less remunerative part of the work at the beginning, without playing out of time for the "velvet."

4. Equipment for efficiency is justified in the large undertaking, even at great expense. It pays to build railroad sidings and spurs for freight haulage to a 25-mile contract, whereas for a short contract the hauling and unloading would have to be done by more costly methods.

Requirements of Large Contractors on Highway Work

If the large companies entering highway work already possess ordinary equipment, such as hand tools, plows, scrapers, wagons, drills, boilers and engines, pipe line and small pump, etc., they will have to buy such new machinery as the particular job requires. For water-bound imported-stone roads, this machinery will consist of an unloader, a roller, wagons or trucks, and a road machine; where local stone is used, a crusher and bin also, but not the unloader; for roads of bituminous macadam, penetration method, imported stone, the pipe line and small pump may be omitted and a bituminous-material distributor provided; for concrete roads, a concrete mixer, and, in addition, the same plant as for water-bound macadam. Additional wheelbarrows, finishing tools, forms, etc., are required also. Brick pavements require in addition a small roller and grout machine. For bituminous macadam mixed method, a hot mixer and an asphalt roller, and if on concrete foundation, the same equipment as for concrete pavement is required. It must always be remembered that the unloading and hauling equipment will depend upon the quantities involved and the length of the haul.

There are several dangers peculiar to the large organization. If it has had experience in railroad work, it is well prepared to run its organization extensively as well as intensively, but if its operations have been confined to limited areas such as are involved in structural buildings, dams, foundations, etc., it will have to learn that a road unrolls its length like a ribbon, and that the man at one end of it can see the other end only through the eye of his mind. This quality of imagination that visualizes the unseen is prerequisite in every highway engineer and contractor, and in every assistant in charge of work. Placed himself in one spot, he must be able to tell at any given moment exactly what is happening at every other spot in his domain. He must be able so to plan that every bit of work beyond his ken as well as within it dovetails neatly into the whole, without waste of energy or loss of time. Such organizing ability is essential to the success of any highway contract. Furthermore, because it is always moving on, road work requires a flexible organization and men with power of quick adaptation. The routine foreman who has succeeded in house building would probably be out of his element in highway work.

Experienced men well trained in highway work are scarce; they should and can command good salaries. Construction companies entering the field must scan their payrolls to see that the importance of a man's particular work is commensurate with the skill and the salary of the man who is doing it. Otherwise, they cheat themselves and also some other contractor who probably needs the man's services.

At every turn is the temptation to overplant the large contract simply because it is large, on the assumption that more work will be done. It won't. Instead, machine power will lie dormant and the human power involved will be wasted. On average highway work of excavating, grading, filling, subsurfacing and surfacing, there is needed one full unit of plant for about every five miles. More than that clutters.

Any successful construction company knows the necessity of keeping down the overhead expense. Nowhere does this show more tendency to soar than in highway work, just because of that extensiveness of which we have already spoken. The large companies will find it helpful to gather exact engineering cost data and to figure in advance all the details of every phase of their work. They will then be able to correlate expenses so as to keep within bounds.

One Argument Against Long Contracts

There is one argument against the letting of long contracts—that it will exclude the smaller men from competition. This objection may be met in several ways. We have seen that there is at present more highway work to be done than there are contractors to do it, and that it will be public gain and economy to attract large construction organizations to highway work by letting contracts for long distances. As the editorial in *Engineering News-Record* of Mar. 13, 1919, p. 503, on this subject suggested, there will be enough short stretches of road, one to ten miles long, to engage all reliable contractors with small units—connecting links, short spurs to newly developing centers of traffic, resurfacing for maintenance, etc. To secure the widest competition, however, contracts could be advertised for alternate bids. The Fredonia road, for example, could be advertised in one contract for large concerns, and it could be broken up and advertised in four contracts for the smaller competitors. If the total of their low bids for the work were lower than the lowest single bid for the whole piece, then the work would be let in four contracts. I think that would be improbable, if the big concerns were making reasonable bids.

Where it would be very probable is in spurs to be built radiating like spokes from any large center as a hub. Suppose Fredonia to be such a center, with roads of permanent type leading from it five to ten miles in ten different directions. All of these could be included in one contract, and also each one could be advertised in a separate contract. It would be an interesting experiment in organization for the big con-

cern to try such a contract, with one central force in the city directing all its activities along the ten spurs. I believe it would be tremendously successful. But the smaller contractors would stand a good chance of winning their separate contracts and proceeding just as they do today. Another element would thus be added to the contracting game, played by men who are born lovers of hazard—or they wouldn't be contractors.

The alternative brings with it an opportunity for the smaller men. Their logical progression now is from one to two to three and four or more contracts. These may be scattered all over the state, so that the contractor loses all sense of coherence and spends much valuable time going from one job to another. His success will bring greater rewards, when, instead of bringing more jobs, it will add simply more miles to the one job, and leave him still with a definite center of gravity. He too will bless the long contract.

Society Service

A Section Dealing with the Results of Teamwork by Technical Men

Philadelphia Club Maintains Membership by Broad Policies

The Philadelphia Engineers' Club some years ago, through a vigorous campaign, built up a large membership. Despite the war, that membership has been well maintained and the club has continued to prosper, both financially and as a social and intellectual center for the engineers of Philadelphia. Much of the success is due to the very broad policies adopted with reference to affiliated members and to the vigor and resourcefulness of the house and entertainment committees.

At present there are 1800 active members and 600 juniors and associates, giving a total membership of 2400. In addition, there are about 1000 affiliates. These affiliates are members of local sections of national engineering societies which have the privilege of holding their meetings at the clubhouse. For these privileges the sections pay to the club $1.50 a year for each of their members, and those not holding club membership are thereby constituted affiliates and get the club's monthly journal, a vigorous, well printed, well conducted organ. It costs more than $1.50 a year to send the journal to the affiliates, but the club regards its loss in this direction as the cost of advertising, as it conveys monthly to these affiliates the news as to the activities of the club, and thus serves to bring the desirable men into active membership.

As an indication of the vigor of the entertainment committee may be cited the means employed for obtaining a large daily use of the luncheon facilities of the club. An average of 65 engineers is found there every noon-time. When it was discovered that Tuesday was a small day, the entertainment committee made arrangements for Tuesday luncheon talks. Thursday, for some reason, was found to be a low day also, and therefore a special menu is always arranged for Thursday, while music is provided on Saturdays. There is a ladies' dining-room, for the wives, sisters and daughters of the members, and this dining-room is used to full capacity every noon.

Every second week there is a smoker with a paper or a "movie" on some more or less popular topic. The technical activities are provided by the local sections of national engineering societies, and there are so many of these that there are technical meetings every week. Saturday afternoon trips are arranged, during good weather, at least every other Saturday and sometimes every week.

The club supports a very well arranged clubhouse with an ample meeting room and library. The dues of active members are $25 a year, while the initiation fee also is $25.

Letters to the Editor

Comment on Matters of Interest to Engineers and Contractors Will Be Welcome

Professional Engineers and Union Labor

Sir—It is evident that the secretary of the American Association of Engineers has handled without gloves the subject of trade unions in his letter in your issue of Feb. 20, 1919, p. 394. And the public often chastises labor organizations when they hesitate to submit disagreements to arbitration! If his statement that "the outstanding characteristic of union labor is selfishness" can be taken as any criterion of the opinion of the engineers of this country, the solution of the misunderstandings and antagonism between capital and labor is further away more years than I care to count.

Altruism can hardly be said to be the attribute of any particular class, educated or otherwise. Is it fair to put the unqualified brand of "selfish" on union labor? The setting up of class distinction is a step backward. We have just fought a war against political autocracy in order to establish democracy, and the world must progress in this direction. When labor is thus chastised unjustly a tendency to lessen the production costs or increase the output is hardly to be expected. In this connection the words of Shylock come to mind:

> "Fair sir, you spit on me on Wednesday last.
> You spurned me such a day; another time
> You called me dog; and for these courtesies
> I'll lend you thus much moneys."

Ah, no—you can demand a day's work from men, but without justice you better have the paymaster get some cash to pay off the men who want their time. With such an attitude on the part of the engineer there is not likely to be any very close bond of fellowship or mutual understanding between labor and the professional engineer. The attitude of the engineering profession toward labor has been that of aggressive haughtiness and superiority. Labor has had to buck capital for increased wages. In the process the engineer has seen fit to act as go-between. For the most part the engineer has considered capital his client and has tended to show a preference for the point of view of capital in contradistinction to the contentions of labor where disagreements arose concerning working conditions. In the shuffle the remuneration of the engineer has not improved perceptibly.

The first task of the engineering profession is to define what is meant by the term "engineer." Until

such time as this is clearly understood, all argument is futile and it is impossible to arrive at what is a fair wage. You have men calling themselves engineers who can run a level or a transit, but they have no technical education. It is true that a high-school boy can go into an engineering office and in a short time handle a level or transit; a little geometry, trigonometry and logarithms added to his outside work gives him the basic knowledge to handle a considerable variety of work. As a matter of fact, I know any number of bricklayers and carpenters who can handle either a level or a transit and they also have some knowledge of mathematics. The draftsman is closely allied with engineering, but is in the same category as the others mentioned above. Are they engineers? Tell me now, are men of this type qualified to receive as much or more than mechanics? What do you mean when you say "engineer"?

Aside from the technique of the profession, the engineer of the future, to be broadly successful, must be a master of what is called human engineering; he must have a knowledge of men and an appreciation of these conditions, sociological and economic, that have a bearing on the increased production and output of labor. It goes without saying that the cirricula of the colleges must be regulated accordingly.

Springfield, Mass. THOMAS P. MORRISSEY.

Draftsman's and Shoemaker's Salaries

Sir—As another instance of the comparative value of the highly trained technical man and uneducated skilled labor, I quote below advertisements from the official bulletin of examinations published by the State Civil Service Commission of Ohio, for examinations to be held Apr. 9, 1919:

"Architectural Draftsman—the Ohio Board of Administration; Professional and Scientific Service. Architectural group; Grade III. Salary $1500 per annum (fee $1).

"Duties—Incumbent of this position, the duties of which require the exercise of independent judgment, designs items of secondary importance under supervision of architect, develops the more important designs from rough sketches made by the architect, and exercises partial supervision over the work of a tracing clerk.

"Qualifications—(1) Such training as is evidenced by a degree of bachelor of architecture from a technical school of recognized standing, and (2) at least two years of practical experience in architectural work; or (3) at least three years of practical experience in architectural work of similar character will be accepted in lieu of a course in a technical school."

The second advertisement is as follows:

"Shoemaker—Ohio State Reformatory, the Ohio Board of Administration: Skilled Labor Service, Shoemaker Group; Grade I. Salary $1200-$1400 per annum (fee $1).

"Duties—The incumbent of this position, under supervision of the superintendent of shoe shop, assists in supervising inmates employed in the shoe factory; makes patterns for new styles, instructs inmates in the use of various machines, and keeps machines in repair.

"Qualifications—Not less than three years of practical experience in employment affording opportunity to become thoroughly familiar with modern methods and machinery used in manufacture of shoes."

C. H. MCGARRY,
Senior Civil Engineer, Bureau of Valuation, Interstate Commerce Commission.
Chattanooga, Tenn.

Why Not Higher Wages For Other Navy Engineers?

Sir—I have read with interest the letter of William F. Fox, the editor's comment, and the reply of the Secretary of the Navy in regard to readjustment of pay for Navy Department employees, in your issue of Mar. 27, p. 634. The scale of pay for draftsmen may be adjusted to their satisfaction, but for technical employees, who in my opinion are just as valuable as these draftsmen—and more valuable, in some cases—nothing has been done so far as these employees know.

Early in February, or perhaps in January, the Navy Department convened boards at all navy yards to revise the scale for technical employees, and the recommendations of these boards have been in the Secretary's office for weeks, while these employees are struggling along at rates of pay in many cases far below that paid to second-rate mechanics. The former receive the same scales that existed before the war.

The inspectors, to which class the writer belongs, are required to perform difficult and exacting survey work, often in marsh and water, engineering work that pertains to dredging, sea-wall and dock construction, besides supervising millions of dollars' worth of construction, making estimates and valuation, in most instances performing their own clerical work.

Is it fair that this class of trained men, many of whom have spent the best part of their lives in the service of the Government, should be treated this way?

J. M. LUSHBAUGH,
Paris Island, S. C. Inspector, United States Navy.

What Is Correct Interpretation of Overhaul Specification?

Sir—The following overhaul specification has been the subject of considerable contention between the engineer and contractor on a large highway project:

"The free haul on all materials incorporated into the work as a permanent part thereof shall be one mile from the points or locations designated by the engineer, from which such material may be obtained by the contractor for delivery and use upon the work. For each mile or fraction thereof in excess of the said one-mile free haul that the contractor shall be compelled to haul materials to the site at which they are to be used in the work, he shall be paid at the rate per ton-mile bid by him for such overhaul (the short ton of 2000 lb. shall be used). Payment for overhaul as above defined shall be the product of the actual number of tons of material incorporated in the completed structure by its distance in miles and fractions thereof less one mile, of its center of mass from the points of locations, designated by the engineer, as above defined."

Applying this to road-surfacing material, the contractor bids 25c. per ton-mile, and claims payment at that rate for each ton of material incorporated in every mile of work beyond the free haul. The engineer takes

the position that the above clause is merely a technical way of expressing "average haul," and that the contractor is not entitled to 25c. per ton-mile until the material has been actually hauled one mile.

Thus, in the first overhaul mile, for instance, assuming that 100 tons of material are incorporated therein, the contractor asserts there is due him, at the bid price mentioned, the sum of $25, while the engineer asserts that all the material has actually been hauled one-half mile, and the contractor is entitled to payment in the sum of $12.50.

Can readers of *Engineering News-Record* give us a frank interpretation of the above specification?

Forrest City, Ark. R. G. WILLIAMS.

Consistency Test for Concrete Used in Laboratory Practice

Sir—The article by H. A. Davis of the Emergency Fleet Corporation in your issue of Mar. 27, 1919, p. 603, calls attention to a distinct advance in field practice with reference to the control of the consistency of concrete. It may be of interest to note that this method has been in use for several years by a number of testing laboratories. The following quotation is from a set of recommendations prepared under date of November, 1914, by Subcommittee II of Committee C 9 on Concrete of the American Society for Testing Materials, of which the writer is chairman:

> There is no well-recognized standard for the consistency of concrete for use in test specimens. The following method for determining the proper consistency of concrete for laboratory tests will be found to give fairly reliable results: Mix a small batch of concrete sufficient to fill a 6 x 12-in. or 8 x 16-in. cylindrical form. Place in the form in the manner described below. As soon as the specimen is completed, remove the form entirely from the fresh concrete by a steady upward pull. Use care not to disturb the fresh concrete. The correct amount of water has been used when the specimen of fresh concrete shortens about ¼ in. for the 6 x 12-in., and ½ in. for the 8 x 16-in. cylinder upon removing the form.

This set of recommendations was drawn up in conference with Prof. M. O. Withey of the University of Wisconsin for the guidance of testing laboratories which were then coöperating with the committee in carrying out investigations of concrete. Certain revisions were subsequently made in these recommendations by the committee without making any essential change in the method for determining "normal" consistency of concrete.

It is the writer's belief that this method of consistency control was suggested as early as 1912, by Sanford E. Thompson, chairman of Committee C 9.

This "slump" test was described by the writer in the course of a discussion at the Conference on Concrete Road Building held in Chicago, February, 1916. (See *Proceedings*, p. 145.)

In our research work at Lewis Institute we now consider a "slump" of ½ to 1 in. in a 6 x 12-in. cylinder as normal consistency. This gives a more workable concrete than the smaller slump originally recommended, and is more representative of consistencies which can be used in placing concrete. It is found convenient to express other consistencies as percentages of the normal determined by the slump test.

The "slump" test can be made with entire satisfaction by placing a pair of handles or a bail on the metal cylinder form and lifting the form by a steady upward pull with the hands. This is the method contemplated in the original recommendations of Committee C 9.

This test is being incorporated in the revised specification for concrete-road construction by several of the midwestern state highway departments. The requirement is that the concrete shall show a slump of not more than, say, 2 in. for machine-tamped and finished roads, and not more than, say, 5 in. for hand-finished work.

In view of the predominant influence of the quantity of water on the strength and other properties of concrete, the control of the consistency of the mix becomes of prime importance in all work. It is a controlling factor which is generally neglected in tests of concrete carried out in the laboratory with a view to studying the relative merits of different materials, or varying the proportions or methods of concrete making.

D. A. ABRAMS,

Professor in Charge, Structural Materials Research Laboratory, Lewis Institute.

Chicago, Ill.

International Language for Modern Engineers

Sir—I, too, have read with interest the discussion upon "International Language for Modern Engineers," in your issues of Feb. 27, 1919, p. 442 and Mar. 27, 1919, p. 635. Why not adopt English as the international language? It is as expressive as any other and is used by more people than either Esperanto or French.

While French was the diplomatic language of the world, I understand that English has recently supplanted it in a large measure. H. S. MCKIBBEN.

Warren, Ohio.

Peculiar Railroad Section Identified

Sir—The rail section shown on p. 684 of your issue of Apr. 3, 1919, is a relic of about 1860, and is one of the never ending and never successful endeavors to eliminate the low joint and the consequent discomfort to the riders, and the high cost of rolling-stock maintenance.

A considerable amount of this rail was laid by the New York Central R.R. in the neighborhood of Rochester, N. Y., and possibly in other localities. It was not bolted together but riveted, the joint of one side being midway of the length of the other side. The interior ribs were to prevent the webs being drawn in by the riveting. It was smooth-riding, but its life was short.

Haddonfield, N. J. ALONZO G. COLLINS.

High Liability Insurance Rates

Based on total payroll, liability insurance rates in Wisconsin range from 3.9% to 8.95%, depending upon the character of the operation. On bridge construction of no unusual hazard as high as 10% has been charged. The losses in highway construction are very small. It is stated, for example, that on state road work from 1915 to 1917 aggregating several million dollars in cost, the total losses by accident were slightly over $5000. An excessive burden of cost for accident protection, it is considered, is thus being placed upon road construction, and the Wisconsin Highway Commission is to seek relief through legislation, to reduce the cost of liability insurance and surety bonds.

Hints for the Contractor

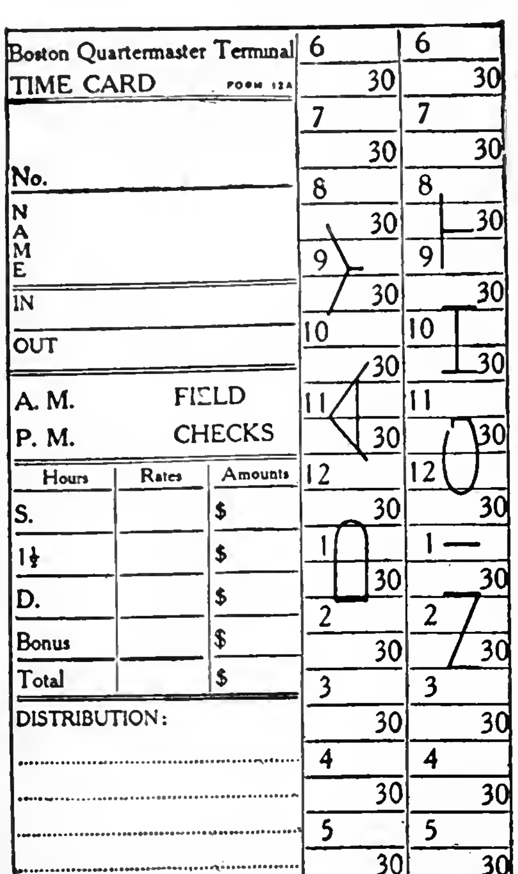
DETAILS WHICH SAVE TIME AND LABOR ON CONSTRUCTION WORK

Time Card As Complete Check On Workmen

COMPLETE daily records of the hundreds of workmen engaged in constructing the $28,000,000 Army supply base at Boston, Mass. (see *Engineering News-Record* of Sept. 19, 1918, p. 522), were kept by time cards. Each card when turned in at night carried records of time when received, time when work started, forenoon at-work check, afternoon at-work check, time when work stopped, and time when returned. By the number of the punch mark it was shown for which foremen the card holder worked and, therefore, the kind of work performed. Cards of six colors were employed, a different color for each working day of the week. The illustration represents the face of one of the cards; on the back are printed in English and Italian brief instructions to the workman.

Other Articles in This Issue of Interest to Contractors:

An exact routine was followed in recording time. After being hired the man was conducted to the Government button booth, where a serial number was assigned to him and a badge was given him. He was then conducted by a messenger to the time booth, where he received a time card and also a brass check bearing the same number as his badge. This brass check was used for getting tools. He was then conducted by the messenger to the foreman to whom he had been assigned.



TIME CARD CHECK FOR LOCATION OF WORKMAN SEVERAL TIMES DAILY

(Original size 3 x 5 in.)

Each morning the workman went to the time booth and received a time card, which was stamped by an electric time stamp, connected with the master clock. After receiving the card he went to the foreman to whom he had been assigned, and the foreman punched the time card at the time of starting work. Each foreman had a numbered punch, and should a man go to another foreman than the one to whom he had been assigned, the error was detected at once. The foreman kept the card until the man stopped work for the day, when he punched the time of stopping work. Should men be shifted to a new foreman or to a different section of the work, the time cards went with them to the new foreman. Each foreman punched the cards when the men left and when getting new men.

A time checker was assigned to a certain number of foremen and was responsible for all field work in connection with the time of these men. Once in the forenoon and once in the afternoon he located each workman by his badge and checked him on a time checker's report. He then went to the foreman and punched the card of each workman he had located. Each time checker had a different lettered punch. Should the foreman have cards of men whom the checker could not find the foreman was required to tell where they were working, and if the time checker found them he returned to the foreman and punched the cards. If he could not, the men received no time. On the afternoon check the timechecker inspected the foreman's reports, saw that every man carried by that foreman appeared on the foreman's report with the proper rate, hours and labor distribution, and, if necessary, he made the report out for the foreman.

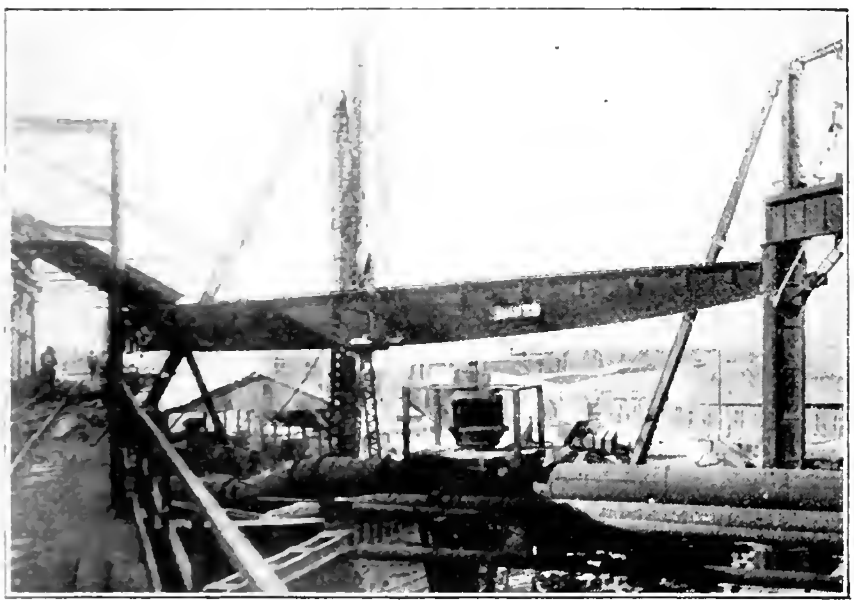
When finished working for the day, after the foreman had punched his card, the workman took his time card to the same booth from which he received it in the morning. The card was then put through the time stamp. Time was then computed, and the rate checked against the time checker's report and the foreman's daily report, and if all agreed the time was entered on the time checker's summary sheet. The cards were then turned over to the payroll department and entered on the roll. This timekeeping system was worked out by Maj. Charles R. Gow, constructing quartermaster. The W. F. Kearns Co., Boston, Mass., was the general contractor.

Derricks Tilt and Swing Long Girders Between Obstructions

FOUR 94-ft. girders were successfully passed over occupied tracks and threaded through intervening obstacles to a position 53 ft. above the ground in a converter building, by means of a crane and a derrick which repeatedly swung and tilted their load to find a clear way for hoisting. The girders weighed 37 tons each and were for bridge cranes. They had to be hoisted and set with their ends on the crane runways

of the building, which was erected over several tracks on which traffic must continue and over portions of a building which the new building was to replace. A straight hoist was nowhere possible, clearances were small, and sulphur from converters bothered the workmen. The procedure was as follows:

Each girder was received mounted in the usual manner on three flat-cars. When the time arrived for the erection of the girder it was blocked up and balanced on the middle car, and the end cars were switched aside. The girder was then run in through the first bay of the building as far as possible, while the operating tracks were still kept clear. Then a 25-ton locomotive crane, whose boom had been lengthened to 69 ft. by a 20-ft. extension, was headed up to the broadside of the



LOCOMOTIVE CRANE AND DERRICK PLACE BRIDGE CRANE GIRDERS

girder and a hitch taken so as to "telegraph" or swing the girder forward endwise until within reach of a derrick set inside the building. The derrick took a hitch well along the girder, as shown by the view, so as to support about two-thirds of its weight. The crane was then shifted to inside the building and hitched to the extreme end of the girder. Hoisting was then begun. The girder was raised horizontally by the derrick and crane until projecting parts of the old building were encountered, when it was necessary to boom right and left three times to clear the obstacles. Finally, to pass the 94-ft. girder between the runways, which were only 90 ft. apart, the derrick-supported end had to be tilted sharply upward. Good speed was made. In eight hours two girders were placed and a third girder was made ready for moving into the building.

The work was done for the Consolidated Kansas City Smelting and Refining Co. by the El Paso Bridge and Iron Co., El Paso, Tex., Henry E. Robertson, engineer of construction, acting as superintendent.

Blasting Mats Under Building Foundations

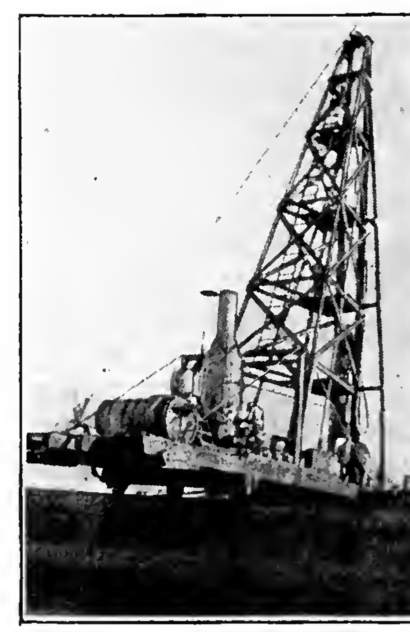
IN BUILDING the section of the Broad St. subway under the Philadelphia City Hall, one step in the work requires the use of temporary concrete mats which serve as mud sills for one end of needle beams. When the underpinning is completed, so that the needling may be removed, the first step after removal of the earth is to take out these mats. For a time they were removed with cold chisels and air hammers, but progress was so slow that the practice was adopted of putting in a half stick of dynamite and blowing them down. It is found that the effect of the charge extends a good deal beyond its immediate location, serving to loosen the mat over a large area, so that with slight hammering it can then be brought down with ease.

Part of the equipment for breaking up the mat after the charge has been fired is an air-driven cutting hammer, the barrel of which is so long that it can reach deep into confined spaces. It is a single-stroke machine, made by the Rivet Cutting Gun Co., of Cinncinati, Ohio.

The work at the Philadelphia City Hall is being done by the Keystone State Construction Co., with which is associated the Underpinning and Foundation Co., of New York City.

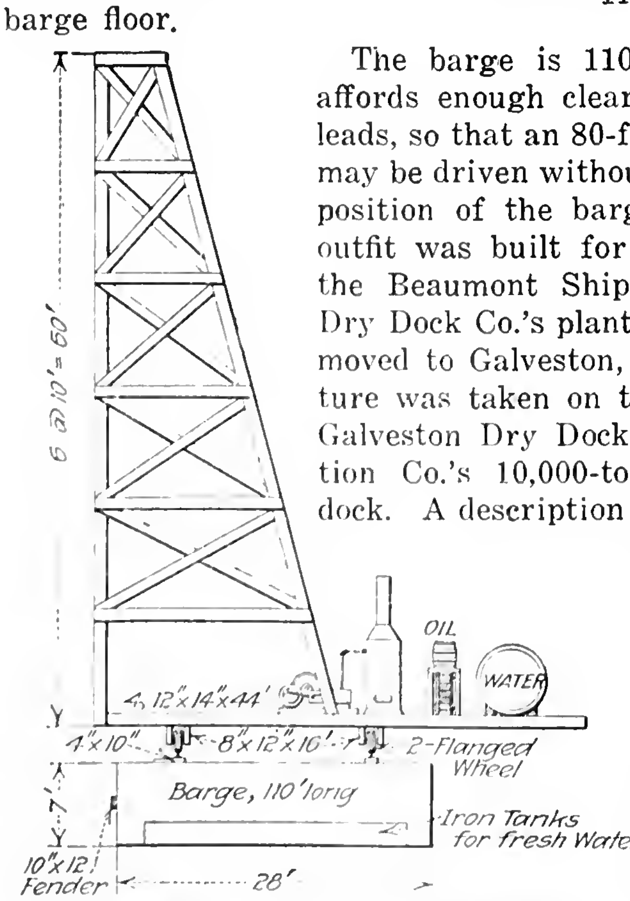
Wheels on Driver Save Many Moves of the Driver Barge

MAXIMUM speed in moving from pile to pile is gained in Capt. John Jacobson's driver-barge outfit by mounting the leads on a truck and placing the truck on a track which runs the length of the barge. A 9 x 10-in. two-drum double engine mounted on the truck is used as piledriver engine, as well as for the movement of the leads and of the barge. The boiler is also mounted on the truck. It burns fuel oil. According to Captain Jacobson, ample steam is produced with a single burner. A barrel behind the boiler and a tank at one end of the barge hold the fuel-oil supply. Steel tanks for a 10-day supply of fresh water for steam production are placed below the barge floor.



LEADS, ENGINE AND BOILER MOUNTED ON MOVEABLE TRUCK

The barge is 110 ft. long, and affords enough clear track for the leads, so that an 80-ft. row of piling may be driven without changing the position of the barge itself. The outfit was built for rush work on the Beaumont Ship Building and Dry Dock Co.'s plant, and was later moved to Galveston, where the picture was taken on the slip for the Galveston Dry Dock and Construction Co.'s 10,000-ton floating dry dock. A description of the building of this dry dock was published in *Engineering News-Record* of Mar. 20, 1919, p. 552, where many other details were described.



PILEDRIVER MOVES ON WHEELS

NEWS OF THE WEEK

New York, April 24, 1919

Predicts European Demand for Young Engineers

According to a letter recently received by A. D. Creer, consulting engineer of Vancouver, B. C., from a young engineer who had consulted the secretary of the Institution of Civil Engineers, Dr. J. H. T. Tudsbery, the latter is advising young men that within a year there will be a greater demand in Europe for engineers than ever before. This advice is considered significant, in view of Dr. Tudsbery's reputation for conservative statement.

No Labor Union for Roadmasters

The Roadmasters' and Maintenance of Way Association of America has issued a notice to railway maintenance engineers, roadmasters and supervisors of track, denying certain rumors that the association had affiliated with a labor union. The statement quotes a resolution adopted by the executive committee last November to the effect that the association cannot be identified with any labor organization without departing from the purposes for which it has stood for 36 years, and which are set forth in the charter of the association as follows: To meet and discuss matters pertaining to track and to raise the standard of work committed to the charge of its members.

Reconstruction Information Available

The United States Council of National Defense has announced that it has a great quantity of material on hand relating to the various problems which come under the general head of reconstruction, and that it will be glad to coöperate with business men who have problems along this line to solve. The reconstruction and research division of the council, 18th and D Sts., Washington, D. C., should be addressed for information.

Self-Propelled Steel Canal Barges To Be Built

The Division of Inland Waterways, United States Railroad Administration, has just let contracts for the construction of 20 self-propelled steel cargo barges for the New York State Barge Canal. Twelve of these barges are to be built by Terry & Tench, of New York City, at a price of $87,000 each. Four barges will be built by the Dravo Contracting Co., of Pittsburgh, at $87,000 each, and four by Starr & Bennett, of Newbern, N. C., at $83,500 each. The barges will carry 450 tons of cargo and will be capable of towing three 600-ton barges besides.

Employment

For the convenience of engineers returning from military life, and others, there are listed below agencies which may be helpful to those who are seeking employment:

Engineering Societies Employment Bureau; secretary, 29 West 39th St., New York City.

American Association of Engineers, 29 So. La Salle St., Chicago. Service to members only, but Army or Navy engineers in uniform who are eligible to certified membership may join without payment of entrance fees or dues while in uniform and for six months after discharge.

Engineers' Service Bureau, maintained by the Joint Council of Engineering Societies of San Francisco, Engineers' Club, 57 Post St., San Francisco. Only applications by mail or wire will be considered.

The Federal director of the United States Employment Service in New York State announces the receipt of a letter from J. P. Morgan & Co., in which $100,000 is offered for the purpose of continuing the work of the service up to July 1 of this year. The Professional and Special Section in New York will therefore be continued, but will be located at the main office, 469 Fifth Ave., New York City.

Bids in for Cantonments

Bids submitted by various firms for the 13 Army cantonments offered for sale, as mentioned in *Engineering News-Record* of Mar. 27, 1919, p. 639, have been received by the War Department. The bids, in tabulated form, are given on p. 235 of the Construction News section of this issue.

W. B. Parsons Returning With Engineer Unit

Cable advices have been received from Col. William Barclay Parsons, Engineers, U. S. A., that Companies B and C, seven officers and 266 men, including Lieutenant Colonel Hudson, sailed for this country on the "Santa Theresa," and that the remaining companies, 49 officers and 696 men (including Colonel Parsons) sailed Apr. 15 on the transport "Chicago."

Iowa Water-Works Men Hold Spring Meeting

Depleted Well Supplies, Pollution of Them, Iron Removal, Hardness Limits, Uppermost Topics

Postponed from 1918 on account of the war, the annual meeting of the Iowa Section of the American Water-Works Association was held Apr. 16-17 in Iowa City. So interested in the state problems were the thirty participants that they intend to meet again in October. Serious shortages and growing pollution of the well supply, forcing cities to surface sources, problems arising from extreme hardness and iron, treatment, distribution, costs and the financial outlook, all taken up from the local standpoint, gave ample evidence of the value of the formation of the section.

As heavier drafts have been made on many well supplies of the cities of the state the ground water has receded to an alarming extent. This is particularly true in the southwestern section. Lafayette Higgins' paper on "Future Public Supplies" gave valuable information on this point, on the excessive cost of deep-well pumping and treatment—that is, if treatment can be effected at all. Many supplies have a mineral content, near or about 1100 ppm., which he considered the upper limit beyond which it is unfit for use even after treatment. He divided the state into three general areas. In the inland portion, drill or tubular wells are the only possible future source. Cities located on the streams must eventually use them, for few of the valleys contain gravel beds sufficiently free from silt to collect the water by wells or galleries. Impounded water will be the only logical course for many cities, and luckily they are located in that area of the state having the greatest rainfall and at least a 50% run-off.

Discussing pollution, Miss Zelma Zentmire, water analyst for the State Board of Health, indicated that for the 18-month period beginning July, 1917, more than 50% of the public shallow wells examined are unsafe and that only 75% of deep wells are acceptable. Of the private wells 75% of the shallow wells examined are bad, as are 33% of the deep wells. On the other hand 95% of the treated supplies examined are good.

An iron-removal plant at the Iowa State College consisting of a dripping aërator, sedimentation and rapid filter reduces the iron content from shallow wells in a creek bed from 8 to 0.07

(*Concluded on page 842*)

Greater Winnipeg Water-Supply in Service

Concrete Aqueduct 96.3 Miles Long Will Carry Soft Water to District of 92 Square Miles Area

Despite the war, the new gravity water-supply for the Winnipeg Water District, work on which was begun in 1913, became available between Mar. 28 and Apr. 5. It was doubly welcome, writes W. G. Chace, chief engineer of the district, because the previous artesian supply, obtained by pumping, had a hardness of nearly 500 ppm., compared with about 40 for the new supply. The source is Indian Bay, on Shoal Lake, an arm of the Lake of the Woods. Except for a few Indians, the drainage area is uninhabited.

The aqueduct is 96.3 miles long and has a total fall of 294 ft. For the easterly or upper 84.62 miles it has a daily capacity of 120,000,000 U. S. gal. At this point there will ultimately be built a reservoir with a capacity of 300,000,000 U. S. gal. From here 11.7 miles of pressure conduit, with a daily capacity of 75,000,000 U. S. gal., have been built and will be duplicated in the future.

Of the entire length of aqueduct, 77.5 miles are of open-flow section and 18.8 miles are of reinforced-concrete under pressure, with heads up to 90 ft. Beneath the Red River there is a tunnel 1800 ft. long, lined with 60-in. cast-iron pipe.

The Greater Winnipeg Water District includes the Cities of Winnipeg and St. Boniface, the town of Transcona and parts of St. Vital, Fort Garry, Assiniboia, East and West Kildonan, and has an area of about 92 square miles. The water debt is a lien on the works and the lands in the district. The capital charges are paid by taxes on the lands alone. Operating and maintenance charges are to be met by the municipalities supplied.

The water-supply project was based on a report made by Rudolph Hering, Frederic P. Stearns and James H. Fuertes. The latter has been consulting engineer for the district throughout. W. G. Chace is chief engineer. M. V. Sauer was originally chief of design. He was succeeded by James Hyslop.

Most of the work was done by local contractors. The largest contract, for the easterly 47.4 miles, was held by the Winnipeg Aqueduct Co., composed of Messrs. Carter, Halls and Aldinger, and the Northern Construction Co., and having William Smail as superintendent. This contractor, jointly with the Canada Lock Joint Co., also built 9.3 miles of 5½-ft. reinforced-concrete pipe. J. C. Mitchell was superintendent of the pipe company.

For a British Ministry of Health

Provision is made for a British Ministry of Health in a bill now before Parliament. It would include the present Local Government Board, with a new name and additional powers. Later some of the powers of the ministry would be transferred, including such matters as public libraries, the regulation of whistles, heavy locomotives and motor cars on highways, old-age pensions, and local elections.

Americanization Conference Program

The program for the conference of Americanization specialists and workers to be held in Washington, May 12-15, inclusive, under the auspices of the Interior Department, has been divided into four sections, each day having a special topic, as announced by the Americanization division of the Bureau of Education. Monday will be educational day, Tuesday will be given over to a consideration of Americanization in the industries, Wednesday to addresses on racial relationships and Thursday to the social aspects of the Americanization movement. Franklin K. Lane, secretary of the interior, will speak at a banquet to be held Wednesday evening.

War Material Is Available for Highway Work

The Bureau of Public Roads of the Department of Agriculture has received from the War Department an inventory of available tractors and a tentative inventory of trucks, as the first step in carrying out the law, enacted at the last session of Congress, authorizing the Secretary of War "to transfer to the Secretary of Agriculture all available war material, equipment and supplies not needed for the purposes of the War Department, but suitable for use in the improvement of highways." There is every indication that the War Department will coöperate with the Department of Agriculture in the disposal of surplus stocks, and it is expected that inventories of all materials will be completed within the next two weeks and submitted to the Secretary of Agriculture, so that he may decide what use to make of them in the construction of highways.

Some of the materials and equipment which could be used to advantage in road building has been enumerated as follows:

Machine Tools, Engineering and Construction Equipment—All metal and wood-working tools; steam shovels; hand tools; forging equipment; iron and structural workers' power tools and machinery; contractors' equipment, such as dredges, ditchers, concrete mixers; industrial railways, etc.

Trucks and Motor Equipment—Trucks; trailers; animal- and hand-drawn vehicles; passenger automobiles.

General Supplies—Tentage, paulins, harness, saddlery, saddlers' supplies; shelf and heavy hardware; tools, handles, tool chests, containers; mess, camp and kitchen equipment; hemp and jute products; brooms and brushes.

Remount—Horses and mules.

Raw and Scrap Materials—Explosives.

Ordnance and Ordnance Stores—Tractors and trailers, caterpillars.

New York State Highway Department Is Reorganized

Under the new highway commissioner, Frederick Stuart Greene, whose appointment was noted in *Engineering News-Record* of Apr. 17, 1919, p. 792, the main office force of the New York State Highway Department has been reorganized. The following changes have been made in personnel:

As first deputy commissioner, Paul Schultze, of Albany, succeeds H. Eltinge Breed, resigned; as second deputy commissioner, Irving V. A. Huie, of New York City, succeeds F. W. Sarr, resigned; as third deputy commissioner, Charles Van Amburgh, of Broome County, succeeds Benjamin Rice, resigned, and as secretary of the commission, Royal K. Fuller succeeds Irving J. Morris, resigned.

Mr. Schultze, the new first deputy, has had extensive experience in highway construction. He was second deputy commissioner from 1913 to 1915. Upon graduation from the Rensselaer Polytechnic Institute in 1891, he entered the New York State Engineer's department as assistant engineer in charge of bridges and roads, remaining until 1900. From 1900 to 1908 he was city engineer and superintendent of public works in the City of Utica, N. Y.; from 1908 to 1912, county superintendent of highways of Oneida County; from 1912 to 1913, city engineer of Troy, N. Y. Since 1915 he has been a consulting highway engineer and contractor in Albany, N. Y., and during the war was superintendent of roads at the Jacksonville Powder Works in Tennessee, and built the roads at the du Pont Powder Works at Carney's Point and Deepwater, N. J. As first deputy he will have charge of all new highway construction work of the department.

Mr. Huie, who will be second deputy in charge of maintenance, is a graduate in civil engineering at New York University, 1911. Upon graduation he entered the office of F. A. Molitor, consulting engineer, New York City, where he remained until 1916, becoming principal assistant engineer to Mr. Molitor on railway location and valuation work, both in this country and Brazil. Early in the war he was commissioned first lieutenant in Company B of the 1st Regiment of Engineers, and during the war he was advanced to the rank of major of engineers.

Mr. Van Amburgh, the third deputy, who will have supervision of all work on town highways, has been county engineer of Broome County. The new secretary, Mr. Fuller, has served several terms as secretary.

Ontario Highways Act Passed

The Ontario legislature has passed the highways act introduced by the Government, appropriating $5,000,000 for highway construction and maintenance. The Hon. F. G. MacDiarmid, minister of public works, stated that the Government highway program includes the building of a provincial highway

from Toronto to Windsor, of which probably 200 miles will be of concrete, 175 miles of macadam, and the remainder of gravel. The work will take several years. In addition, the appropriation includes about $1,800,000, to be paid to the counties for the improvement of county road systems. There are 37 counties under this scheme, the average expenditure of each being $100,000 annually. The province will provide 40% of this outlay.

Recommend Large Pier at Portland, Me.

In the report of the State Harbor Commission of the State of Maine for the calendar year 1918, there is a report prepared by the firm of Fay, Spofford & Thorndike, of Boston, on the advisability of building a public pier at Portland, Me. As a result of the investigation the commission recommends to the legislature that the state construct a pier in tidewater at Portland at the site selected and recommended by the engineers, the pier, freight sheds and railroad connections to be built, controlled and operated by a harbor board, which should be appointed by the Governor and council.

Furthermore, it recommends that the state legislature authorize the issue of $1,150,000 bonds to take care of the improvements. The engineers' report points out the strategical position of Portland as a port and the present lack of modern pier facilities there. The engineers do not specify the pier design in detail, but indicate enough of its general construction to show what the layout will be. It is expected that the legislature will provide for the structure.

Dwelling-House Plans of Housing Corporation Available

Plans for dwellings, prepared by the United States Housing Corporation for building homes in congested industrial centers during the war, are to be made available for general public use. The Department of Labor announced that types of homes would be given to "own-your-own-home" committees, promoting building activities in cities.

In the department's effort to expand the home-ownership campaign, letters were sent to municipal officials, labor leaders and club organizations in many cities, urging local campaigns.

Working Conditions Service

To assist industrial establishments in securing and maintaining the health, safety and good government of their workers, the United States Department of Labor has formed a Working Conditions Service, in three divisions: (1) Industrial hygiene and medicine, with personnel detailed from the United States Public Health Service; (2) labor administration; (3) safety engineering. Details are given in a pamphlet obtainable from Grant Hamilton, director general of the United States Department of Labor, Working Conditions Service, Washington, D. C.

British Government Plans Department of Transportation

The British Government has for some time been planning to establish a separate Government department to deal with all matters of transportation, and a bill for that purpose is now pending in Parliament. The new department is to be called the Ministry of Ways and Communications and is to take over the powers of supervision over railways and other transportation utilities, which have long been exercised by the Board of Trade. So long as the railways continue under direct Government management, as has been the case since Great Britain entered the war, this authority also is vested in the Minister of Ways and Communications. Besides the railways, the minister receives authority over the street railways, canals and other inland waterways, docks, piers, roads, bridges, ferries and the supply of electricity. The bill empowers the minister to fix all rates and charges and the wages of labor on all utilities under his charge. While there has been no official decision as to whether the Government will take over permanently the railway lines of the country, the bill in Parliament gives the minister authority to purchase any utility under his charge outright at a price fixed by agreement or by condemnation proceedings.

Great economies have been effected in the operation of British railways since the establishment of Government control, through the consolidation of facilities and the cutting down of train service. Notwithstanding these economies, the increases in wages to railway employees have so increased the operating expenses that the estimates submitted to Parliament indicate a probable deficit of some $300,000,000 on this year's operations.

It is said that the first head of the new Government department will be Sir Eric Geddes. Sir Eric spent his early business life in the United States, where he was engaged in the lumber business in the South. Later he was connected with the Baltimore & Ohio R.R. and then became manager of the Northeastern Ry. of England, and in 1916-17 was director general of military railways and inspector general of transportation.

Iowa Engineers Must Register

Engineers and land surveyors in Iowa must be examined and registered by a State Board of Engineering Examiners, according to a bill which has passed both houses of the General Assembly. The bill provides for the appointment by the Governor of an examining board of five members, who will conduct examinations and issue certificates to persons qualified to practice professional engineering or land surveying. The expenses of this board are to be paid from the examination and registration fees. Severe penalties are provided for illegal practice, and the board has authority to revoke a certificate for fraud or incompetency. All plans, specifications and reports must be stamped with the official seal of a registered engineer

Engineers and surveyors who have practiced for two years or more in Iowa may be registered without examination at any time within six months after the act takes effect. The act does not apply to full-time employees of a corporation doing work solely for that corporation; or to existing contracts; or to United States Government employees; or to assistants to registered engineers and surveyors; or to the operation of mechanical plants; or to the construction of works of a strictly private nature, such as farm drainage; or to the subdivision of land where no controversy is involved.

Pearl Harbor Dry Dock Finally Completed

The United States naval dry dock at Pearl Harbor, near Honolulu, was unwatered for the first time Apr. 11, and found free from leaks. It is expected that the dock will be ready for service by July 1. It is designed for the largest vessels, being 1040 ft. long by 148 ft. wide.

The first attempt to build this dry dock failed and the plans were abandoned, as a result of foundation failure that occurred as the site was being unwatered for the first time. Under the revised plans, according to which the dock has been built, the concrete structure was cast in 16 sections, which were floated to place, as described in *Engineering News-Record* of July 25, 1918, p. 173.

Weights and Measures Convention

A conference of weights and measures officials is to be held at the Bureau of Standards, Washington, May 21-24. The last such conference occurred in 1916, and many questions are pending which the coming conference is to consider. In the 14 years since the movement was initiated, much progress has been made in bringing about uniformity in state legislation concerning weights and measures, and in improving the methods of inspection. S. W. Stratton, director of the Bureau of Standards, is president of the annual conference, and L. A. Fischer of the bureau is secretary.

Plan Reunion of "Eighty-Niners"

Plans have been made for a reunion dinner to be held in New York City about May 27, at which it is hoped that all the survivors of a party of American engineers, belonging to the four national engineering societies, who sailed for Europe 30 years ago to visit England and the Paris Exposition of 1889, may be present, with members of their families.

It is requested that anyone who was of that party communicate with the secretary of the committee, Jesse M. Smith, Engineers' Club, 32 W. 40th St., New York City.

Iowa Water-Works Association Holds Spring Meeting

(*Concluded from page 839*)

ppm. C. S. Nichols described the installation and operating experiences, indicating that no difficulties with crenothrix had arisen and that the operating cost was $6.10 per million gallons.

The latest improvements to the Des Moines galleries in the way of an irrigation and ponding system were described by A. T. Luce, the newly appointed chief engineer of the Des Moines Water Company.

An example of the high cost of deep-well pumping was given in detail for Grinnell by Dean W. G. Raymond, a member of the State Board of Conciliation, to which the Iowa Light, Heat and Power Co. has appealed for adjudication of the water-pumping costs to which the city objected as being too high. The charge was 22c. per 1000 gal. and 15.2c. was found, on expert examination, to be the actual total cost with all interest and depreciation percentages added. Settlement was made on this basis.

Waterloo Kept Water-Main Construction Costs Low

Water-main construction costs in Waterloo for the past four years were given by W. A. Judd, the 1918 pipe-laying figure being kept consistently low by retaining the former dependable emergency gang.

C. R. Henderson, manager of the Davenport Water Co., is opposed to laying mains in alleys. His paper on the subject was in effect an argument by which he converted the city officials to his viewpoint. No room, impaired service due to alleys not being continuous, and none at all in one direction, were his chief points.

Thomas Healey, also of the Davenport Water Co., described experiences, all favorable, with metalium as a substitute for lead as a pipe-jointing material. Other uses, such as packing behind bands on cracked pipe and as a substitute for grouting under engine foundations, were noted by H. V. Knouse, of the Metropolitan Water District, Omaha.

He also described the monolithic reinforced-concrete lining of several reservoirs in Omaha since 1914. The fact that every operation in the construction was carried on with labor under direct control of the designer seemed to be a large factor in the success with which the work was prosecuted. The service has been entirely up to the expectations of the designers.

Advocates Formula for Loss of Head in Clean Pipes

S. L. Etnyre, superintendent of the Council Bluffs water-works, is of the opinion that the parent association should adopt a single basic formula for the less of head in clean pipes. In his paper were noted experiments on long stretches of new pipe 6, 8, 10 and 16 in. in diameter. Only one of the 10 formulas generally available checked with his results.

The officers elected for 1919 are as follows: Chairman, W. A. Judd; vice-chairman, G. E. Shoemaker; directors, H. V. Knouse and W. A. Hostetler. J. H. Dunlap is the acting secretary during the absence of Lieut. J. J. Hinman in France.

Civil Service Examinations

New York.—Junior assistant engineer, State Engineer and Highway Department, $1200-$1440 per year, May 24. Apply to State Civil Service Commission, Albany, N. Y. File applications before May 24.

New York.—Bridge designer, Public Service Commission, First District, $1501 to $2100 per year. Apply to State Civil Service Commission, Albany, N. Y. File applications before May 24.

Philippines.—Wireless engineer, Bureau of Posts, Philippine Government, $3000 per year, June 10. Apply for form B. I. A. 2, to be filed before June 10, filled in by medical officer in the service of the United States.

Tennessee.—Assistant highway engineer, $1800 to $2100 per year, May 7, at Nashville. File applications as soon as possible.

For United States Civil Service examinations listed below, apply to United States Civil Service Commission, Washington, D. C., or to any local office of the commission, for form 1312.

United States.—Expert patent investigator, $1800 to $2400 per year, and technical patent expert, $2400 to $3600 per year, May 20.

United States.—Highway bridge engineer, $1800 to $2100 per year, junior highway bridge engineer, $1200 to $1600 per year, Bureau of Public Roads and Rural Engineering, May 21. File applications in time to arrange for examination at place selected by applicant.

United States.—Engineer in forest products, $1860-$3000 per year; assistant engineer in forest products, $1200-$1800 per year, Forest Products Laboratory, Madison, Wis., May 27. File applications before May 27.

United States.—Chief of road survey party, $1800 to $2100 per year, transitman for road surveys, $1200 to $1800 per year, highway draftsman, $1200 to $1800 per year, Bureau of Public Roads and Rural Engineering, May 29. File applications before May 29.

United States.—Scientific assistant in public health work, Public Health Service, $1500-$2500 per year, June 3. Apply for form 2118, to be filed before June 3.

United States.—Senior engineer and senior architect, Interstate Commerce Commission, $1800-$2700 per year, June 10. File applications before June 10.

United States.—Assistant material engineer, Bureau of Construction and Repair, from $4.48 to $6.40 and upwards per diem. No date specified. Applications should be filed without delay.

United States.—Junior recreational engineer, Forest Service, Denver, Colo., $1800 to $2400 per year, May 6. Apply for Form 2118.

United States.—Statistician, Department of Interior, $1800 per year, May 13. Apply for Form 2118.

Engineering Societies

Calendar

Annual Meetings

NATIONAL FIRE PROTECTION ASSOCIATION; 87 Milk St., Boston, Mass.; May 6-8, Ottawa, Can.

AMERICAN ASSOCIATION OF ENGINEERS, 29 S. LaSalle St., Chicago; May 13-14, Chicago.

NATIONAL CONFERENCE ON CITY PLANNING; 19 Congress St., Boston; May 26-28, Niagara Falls and Buffalo.

AMERICAN WATER-WORKS ASSOCIATION; 47 State St., Troy, N. Y.; June 9-13, Buffalo, N. Y.

AMERICAN SOCIETY OF CIVIL ENGINEERS; 29 W. 39th St., New York; June 17-20, St. Paul-Minneapolis.

AMERICAN SOCIETY FOR TESTING MATERIALS; University of Pennsylvania, Philadelphia; June 24-27, Atlantic City, N. J.

AMERICAN CONCRETE INSTITUTE; 6 Beacon St., Boston; June 27-28, Atlantic City, N. J.

The Engineering Society of Western Massachusetts was formed at a meeting held in Springfield Apr. 16. The meeting was addressed by William Spencer Murray, consulting engineer, New York City, Dr. George Otis Smith, director of the United States Geological Survey, and Prof. L. P. Brackenridge, of Yale University.

The Cincinnati Chapter of the American Association of Engineers recently elected the following officers: President, E. K. Ruth; vice-president, G. E. Halstead; secretary, L. P. Kimball; treasurer, Charles S. Carroll. The matter of proposed license laws for engineers was discussed, and a committee was appointed to make a report at the next meeting, to be held Apr. 30. The chapter will be formally installed May. 24.

The Southern California Association of Members of the American Society of Civil Engineers was addressed by Robert A. Cummings, consulting engineer of Pittsburgh, and member of the Committee on Development, at a meeting held Apr. 9. Frederick C. Noble, consulting engineer, New York City, also a member of the Committee on Devel-

opment, spoke on the work of the committee. The meeting was also addressed by Dr. Ford A. Carpenter, United States meteorologist, who spoke on "Precipitation in Southern California," and by F. C. Ebert, hydrographer, United States Geological Survey, on "Flood Run-Off." The committee on reconstruction and development presented its report to the meeting.

The Portland (Ore.) Chapter of the American Association of Engineers, in process of formation, has elected the following officers: W. H. Marsh, president; R. W. Barnes, principal assistant engineer, Southern Pacific Co., secretary-treasurer.

The Engineers' and Architects' Club of Louisville, Ky., held a meeting Apr. 15, which was addressed by Alfred Pirtle, who spoke on "Railroad Reminiscences," including a review of the history of local railroads, beginning in 1843. Several reels of motion pictures, furnished to the club by the War Department, illustrating engineering work in the Army, were shown.

The Scranton (Penn.) Engineers' Club held a meeting Apr. 17, at which Maj. L. S. Doten, U. S. A., spoke on sewage-disposal plants in the United States Army cantonments.

The Topeka (Kans.) Engineers' Club made a trip of inspection to the city water-works, Apr. 5, as the guests of Wilbur Stanfield, newly elected water commissioner, and Jesse Shaw, superintendent of the plant.

The Albany Society of Civil Engineers was addressed Apr. 22 by J. Loewenstein, assistant engineer, American Bridge Co., who read a paper, illustrated with motion pictures and lantern slides, on "The Hell Gate Bridge."

The Louisiana Engineering Society was addressed Apr. 14 by Maj. W. B. Gregory, U. S. A., on "Pumping Machinery Used by the American Army in France."

Personal Notes

MAJ. MAX C. TYLER, Corps of Engineers, U. S. A., has been assigned to duty in charge of the District of Columbia water-supply system, the reclamation of the Anacostia River and the improvement of the Potomac River, succeeding Col. W. L. Fisk, U. S. A., retired. Major Tyler had been in command of the 212th Engineers, which was reorganized at Camp Devens, Massachusetts, with the rank of colonel for the period of the war.

LIEUT. THORNDIKE SAVILLE, U. S. A., who was stationed at Langley Field, Hampton, Va., in charge of the installation of the water-works and sewage-disposal plants, has received his discharge from the service and has become associate professor of sanitary engineering, University of North Carolina.

LIEUT. PATRICK J. SLATTERY, Air Service, American Expeditionary Forces, has just received his discharge from the service and has become associated with RAYMOND J. VAN WAGNER and ANTHONY J. DAINO, both formerly assistant engineers on subway construction, New York City, under the firm name of the Slattery Engineering & Construction Co., Inc., engineers and contractors E. 42nd St., New York City.

H. A. DIXON, division engineer, Canadian Northern Railway System, Vancouver, B. C., has been appointed chief engineer, Canadian National Railway System, Western Lines, succeeding Allen T. Fraser, whose death was noted in *Engineering News-Record* of Apr. 10, 1919, p. 747.

LOUIS JALOVEC, electrical engineer and designer of X-ray apparatus, Chicago, has been appointed assistant to the United States Foreign Trade Commissioner to Czechoslovakia. He will be stationed in Prague, Bohemia, and will furnish particularly information in regard to markets, although inquiries for data of any kind about the country will receive attention.

CAPT. ROLAND TONER, Construction Division, U. S. A., who recently received his discharge from the service, has been placed in charge of the construction of buildings in Eastern Canada for the Allen Theatre Enterprises of Toronto, Ont.

ROSS J. BUCK, contracting engineer, has been appointed assistant engineer for the Board of Sanitary Commissioners, Indianapolis Sanitary District. From 1907 to 1914 Mr. Buck served in Government engineering work in the Philippines, and after his return to this country entered the general contracting business.

WILLIAM E. PETTY, who was chief draftsman for Division No. 3, New York State Highway Department, until he entered the Federal Government service several months ago to build the roads in Camp Eustis, Virginia, has been appointed confidential agent for the highway department, with office at Albany, N. Y.

CAPT. E. J. BURKE, Engineers, U. S. A., and, after his discharge examiner for the United States Employment Service, has been selected as manager of the Chicago Chapter of the American Association of Engineers. After leaving the University of Illinois in 1913 he was assistant engineer on track-elevation work for the Chicago, Rock Island & Pacific Ry., and later was employed on drainage work in Tennessee.

CAPT. B. C. BRENNAN, U. S. A., who recently received his discharge from the service, has resumed his position as city engineer of Kenosha, Wis., succeeding P. J. HURTGEN, who acted as city engineer in his absence, and who now becomes commissioner of public works.

SIDNEY B. BOWNE has received his discharge as assistant sanitary engineer, United States Public Health Service, and has resumed his position as secretary-treasurer of the W. E. Sexton Co., Inc., engineering contractors, Mineola, N. Y. He has been appointed village engineer of Mineola for the coming year.

LEWIS R. ASH, whose resignation as city manager of Wichita, Kans., was noted in *Engineering News-Record* of Apr. 3, 1919, p. 693, has again been retained as city manager of Wichita. He is a member of the firm of Harrington, Howard & Ash, consulting engineers, Kansas City. For several years he was city engineer of Kansas City.

CAPT. FRANK L. BOLTON, Engineers, U. S. A., has received his discharge from the service and has returned to the firm of Gannett, Seelye & Fleming, consulting engineers, Harrisburg, Penn., as resident engineer in charge of the Mill Creek flood-control project, as well as the work of the firm in western New York, western Pennsylvania and Ohio.

P. F. STARY, highway engineer, Pine County, Minnesota, has resigned to become county highway engineer at Fargo, N. D., succeeding Eric Martinson, who resigned to engage in highway contracting.

MAJ. WALTER B. ELCOCK, U. S. A., has received his discharge from the service and has returned to his former work as district engineer in charge of the Atlanta, Ga., office of the Portland Cement Association.

JOHN A. WALLACE, who has been associated with the New York State Highway Department since 1907, and was recently stationed at Jamestown, has been appointed highway engineer for the Federal Bureau of Public Roads, with headquarters at Montgomery, Ala.

CAPT. HOWARD H. GEORGE, Engineers, American Expeditionary Forces, who recently returned from France and received his discharge from the service, has resumed his former work as assistant engineer, Public Service Railway Co., Newark, N. J. Captain George served as engineer-officer

in charge of building construction of the storage depot at Montierchaume and was afterward transferred for duty with the base section engineer at Havre.

CAPT. T. E. SEELYE, of the firm of Gannett, Seelye & Fleming, who has been overseas with the 105th Engineers, has been assigned for special duty in France as instructor in advanced hydraulics at the American University, France.

CAPT. W. WATTERS PAGON, Construction Division, U. S. A., who recently received his discharge from the service, has opened offices as a consulting engineer in the Lexington Building, Baltimore.

LOUIS J. SNYDER and J. L. LANGTHORN have become associated under the firm name of the Langthorn Co., Inc., to conduct a general engineering and contracting business, with offices at 2 W. 45th St., New York City.

S. H. LEA, who formerly was engaged in construction work for the Government at the Langley Aviation Field, has been appointed road engineer for Mineral County, West Virginia, with headquarters at Keyser.

ALLEN H. STUBBS, formerly of the civil engineering department of the University of Nebraska, has been appointed manager of the Kansas City office of Hedrick & Hedrick, bridge engineers.

J. C. ALLISON and PAUL M. ENTENMANN have become associated under the firm name of Allison & Entenmann, consulting engineers, with offices in Los Angeles and Calexico, Calif.

ROY THOMAS, previously engineer of Gila County, Arizona, has been appointed city engineer of Miami, Ariz., and will have special charge of flood-control work which has just been undertaken.

W. HOWARD CORDDRY, who recently returned from overseas, has received his discharge from the service and has returned to his work with the firm of Gannett, Seelye & Fleming, consulting engineers, Harrisburg, Penn.

VIRGIL P. KNOTT, associate professor of civil engineering, Arkansas State University, has been elected state highway engineer, succeeding Hugh Carter, resigned.

CAPT D. A. TOMLINSON, instructor in the Coast Artillery at Fort Monroe before his discharge from the Army, has been made assistant secretary of the American Association of Engineers. He has charge of the railroad work, and will aid in the service clearing house department. He was until recently manager of the central zone of the United States Employment Service. Captain Tomlinson saw service on the Mexican border in 1916, previous to that having been valuation engineer on the Chicago & Western Indiana Railroad.

ALAN CORSON has been appointed superintendent of Fairmount Park, Philadelphia, succeeding Jesse T. Vogdes, whose death was noted in *Engineering News-Record* of Mar. 27, 1919, p. 644.

ROGER W. HARMAN, 204th Engineers, U. S. A., who recently received his discharge from the service, has returned to his former position with Gannett, Seelye & Fleming, consulting engineers, Harrisburg, Penn.

HALE D. JUDSON has resigned as city engineer of St. Joseph, Mo., to enter the State Highway Engineering Department.

H. MARCUS, who served with the Bureau of Yards and Docks during the war, has returned to his duties with the Marcus Contracting Co., New York City.

R. W. WATERMAN, hydraulic and irrigation engineer of Los Angeles and Blythe, Calif., has removed to Fresno.

F. A. TROSKEL has been appointed city engineer of Marquette, Mich.

OBITUARY

JOHN T. DICKERSON, general manager of the Strauss Bascule Bridge Co., Chicago, died in that city Apr. 14. He was born in 1878 and was a graduate in civil engineering of Rose Polytechnic Institute in the class of 1902. For the past seven years he was identified with the Strauss Bascule Bridge Co. Prior to that time he was assistant engineer and general sales engineer with the Scherzer Rolling Lift Bridge Co., of Chicago, and before that he was in the bridge departments of the Chicago, Burlington & Quincy and the Chicago, Rock Island & Pacific R.R. companies and the American Bridge Company.

CHARLES BRINKERHOFF RICHARDS, scientist and inventor of the Richards steam engine indicator, and for 25 years Higgins professor of mechanical engineering at Yale, died in New Haven, Apr. 20, in his 86th year. During the Civil War he was consulting engineer and assistant superintendent at the Colt's Arms factory at Hartford. Later he served as superintendent of the Southward Foundry & Machine Co., of Philadelphia, before he was called to the Sheffield Scientific School. In recognition of his invention of the steam engine indicator, he was decorated with the Legion of Honor of France. He was consulting engineer for the state capitol at Hartford and other large buildings.

GEORGE FERDINAND BECKER, geologist and mining engineer, who had been connected with the United States Geological Survey since 1879, died in Washington, D. C., Apr. 20, at the age of 72. He was a graduate of Harvard University, received the degree of doctor of philosophy from Heidelberg University, and in 1871 was graduated from the Royal School of Mines in Berlin. For four years he served as instructor in mining and metallurgy in the University of California, from which he went to the United States Geological Survey. At the time of the Spanish-American War Dr. Becker was detailed to serve as geologist on the staff of General Bell with the Army in the Philippines.

CHARLES E. CHENEY, former county surveyor of Marion County, Indiana, died in Indianapolis Apr. 14. He was 45 years old. He was a graduate of Purdue University in the class of 1897, and soon after his graduation was appointed city engineer of Frankfort, Ind.

J. A. STAMPS, chief engineer of the Atlanta water-works, died in that city Apr. 5. He had been connected with the water-works department for 36 years.

JOSEPH E. JOHNSON, JR., consulting engineer, New York City, whose death on Apr. 4, 1919, was noted in *Engineering News-Record* of Apr. 10, 1919, p. 747, was born in 1870 and was graduated from Haverford College in 1888, receiving the degree of mechanical engineer in 1891. He entered engineering work as a draftsman in the Baldwin locomotive works, Philadelphia, and was afterwards engaged with the Straight Line Engine Co. and the Cranberry Iron & Steel Co. He later entered the service of the Carnegie Steel Co., in the blast-furnace department, and afterward became general manager of the Princess Furnace Co. In 1909 and 1910 he was general superintendent for the Republic Iron & Steel Co., operating three blast furnaces and 900 coke ovens. From 1901 to 1913 he was manager of the Ashland plant of the Lake Superior Iron & Chemical Co., Ashland, Wis. In 1913 he opened an office as a consulting engineer in New York City to engage in private practice. Besides being a generous contributor to the technical press, he was the author of treatises on "Blast-Furnace Construction in America," followed by "The Principles, Operation and Products of the Blast Furnace." Outstanding features of his work were his theory of the constitution of cast iron and his theory of the critical temperature of the blast furnace.

Portable Pumping Plant for General Municipal Use

A portable pumping plant and catch-basin cleaner that can be used for a great variety of municipal uses has been put on the market by the Springfield Engineering Co., of Springfield, Ohio. It consists in the main of a pumping outfit and a 6-cu.yd. tank, the whole mounted on a standard Kelly-Springfield five-ton chassis. It may be used for cleaning out catch-basins, spraying trees and shrubbery, spraying paint, and for garbage removal.

The pumping unit consists of a centrifugal pump running at 1900 revolutions per minute, driven by a silent chain direct from the drive shaft of the truck. Catch-basin cleaning is accomplished through the injector principle; that is, the material removed from the catch-basin does not pass through the pump, but the necessary lift is created by means of an injector. The vacuum thus produced is about 26 in. When the apparatus is used in this way, the procedure is to fill the tank half full of clear water, the pump then using the tank as a suction well. The tank itself is fitted with a ¼-in. screen behind which the water carrying the solids is deposited. The screen is cleaned by a jet under pressure, through a bypass from the pump. So successfully have the cleaning device and the general arrangement of the discharge pipe in the tank worked that it is possible to get from 4 to 4½ cu.yd. of solids in the tank on the completion of the operation. The lid of the tank can be screwed down tight, so there is no slopping of liquid into the street. When the tank is filled the truck can run to the dumping ground, and the body is then tilted by means of a hydraulic hoist, the tail of the tank being hinged so that no shoveling is necessary. The tail end is fitted with a gasket so that there is no leakage during pumping operations.

For spraying purposes the spray material or paint is put in the tank, and passes directly through the pump,

PORTABLLE PUMPING PLANT CLEANING CATCH-BASINS

the pressure at the jets under these conditions being from 100 to 105 lb. per square inch.

By removing the screen in the tank the body can be used for garbage or ash removal.

The machine described above is listed as the G-1. The G-2 machine is the same, except that there is in addition a pressure tank on top of the pump, and the truck is fitted with four flushing and two sprinkler heads, so that the machine can be used for street flushing and sprinkling.

Federal Trade Commission Loses Its Chief Counsel

Announcement is made by the Federal Trade Commission that its chief counsel, John Walsh of Wisconsin, has resigned to resume the private practice of law in Washington. His resignation was accepted, to take effect Apr. 15.

Business News

The Chicago Pneumatic Tool Co. has moved its Milwaukee office from room 1315 to 1418 Majestic building, to obtain larger quarters.

J. E. Mason, Western advertising representative of *Engineering News-Record*, has resigned to enter the sales department of the Blaw-Knox Co., at Pittsburgh. Mr. Mason is succeeded by Fred G. Hudson, formerly Western manager of *Chemical & Metallurgical Engineering*, McGraw-Hill Co., Incorporated.

The Neptune Meter Co., of New York City, has acquired a building from the Russell Motor Car Co. of Toronto, Canada, for the manufacture of Trident water meters for Canadian trade, under the name of Neptune Meter Co., Ltd. The manager-director for the Canadian branch is William H. Randall, formerly superintendent of the maintenance and distribution department of the Toronto Water Works.

The appointment of E. E. Maher, formerly Western manager of the Lea-Courtenay Co., and more recently district manager for the Terry Steam Turbine Co., is announced by the Dayton-Dawd Co., Quincy, Ill., manufacturer of centrifugal and underwriters' fire pumps. He will be manager of the Chicago branch, with offices at 30 North Michigan Boulevard.

The American Steam Conveyor Corporation, of Chicago, announces the appointment of Charles H. Florandin, formerly of the National Electric and Welding Co., of New York, as general manager of Eastern territory.

The A. P. Green Fire Brick Co. of Mexico, Mo., has opened an Eastern district sales office at 30 Church St., New York City. Howard C. Thayer, formerly field mechanical engineer for the J. G. White Engineering Corporation at the United States Nitrate Plant No. 2, is in charge.

Trade Publications

A new booklet on path-digging, self-feeding, self-propelling wagon loaders has just been issued by the George Haiss Mfg. Co., Inc., 142nd St. and Rider Ave., New York City.

"Tile Drainage" is the subject of a new book written by James A. King, of the King Farms Co., Otranto Station, Iowa. The publishers and owners of the copyright are the Mason City Brick & Tile Co., of Mason City, Iowa. The booklet deals with various phases of farm drainage.

The Western Wheeled Scraper Co., of Aurora, Ill., has just issued an 8-p., 9 x 11-in. pamphlet showing a number of new machines and devices for handling road work on large contracts.

The Guarantee Trust Co. of New York has just issued an illustrated booklet, entitled "Shipping's Share in Foreign Trade—Fundamentals of Ocean Transportation." The book is one of a series dealing with export trade, and is written to meet the needs of beginners in the field, and to be a handy reference for the experienced trader. It contains information for fixing rates, computing the capacity of vessels, the customary commercial terms used in quoting prices to foreign buyers, etc.

"Pile Hammers" is the title of bulletin No. 25, issued by the McKiernan-Terry Drill Co., Park Row Building, New York City. The pamphlet is 6 x 9 in. and has 43 pages. It describes the method of using the various sizes of double-acting steam hammers in the driving of both heavy and light sections of wood and steel sheeting and concrete piles.

The Austin Manufacturing Co., of Chicago, has just issued a 9 x 12-in. pamphlet of 4 pp., dealing with road rollers of both the steam and gasoline-driven type.

"Lidgerwood Coal-Handling Cableways" is the title of bulletin No. 34 issued by the Lidgerwood Manufacturing Co., 96 Liberty St., New York City. The possibilities of cableways for storing coal are set forth, and diagrams of the various layouts for utilizing them are outlined.

Foresight as a Dividend-Paying Asset

AN investment of a hundred million in ships before the war, said Homer L. Ferguson before the Foreign Trade convention in Chicago last week, would have saved a billion dollars during the war. In other words, a stitch in time would have saved nine, a fact which the nation until recently declined to recognize in the matter of merchant marine and naval auxiliaries. Mr. Ferguson's remark goes beyond ships, however. Foresight is needed in all activities, and nowhere more than in technical industry. During the past two years those producers who had improved their plant and equipment for high efficiency and were ready for the highest demands as to capacity and speed of production formed the backbone of the home army, and incidentally earned the dividends of success. Similarly, the men who today are preparing for the future will constitute our industrial strength in the new era.

Opposing Reports on New York Garbage Disposal

THE muddled garbage-disposal situation in New York City would not be cleared a bit if equal value were to be given to the directly opposing recommendations of the Merchants' Association, which advises incineration, and the Brooklyn Chamber of Commerce, which pronounces for reduction. But the two reports are not of equal value. The Merchants' Association report reads as if written before the war, in accordance with preconceived notions that "cremation" is the only sanitary means of garbage disposal. Cost data are purposely avoided. The Chamber of Commerce report takes into account the importance of waste conservation by grease and fertilizer recovery, and presents cost estimates for both systems of disposal. Both reports—but very differently—show the need for a thoroughgoing engineering study of the whole problem of garbage collection and disposal for the five boroughs of New York City. As we have previously urged, here is work for the engineering societies. They may not be called upon to make the needed studies, but they should never rest until they have used every reasonable effort to see that the studies are made.

What Is a Building Material?

STATISTICS are dangerous things. Once they are established their source is forgotten, and the user may do with them what he wills. Offhand, it looks as though some such end may come to the figures on building-material prices collected by the United States Department of Labor and published in the pamphlet entitled "A Comparison of Prices During the Civil War and Present War." Every day quotations from this investigation bob up in unexpected places, proving many and various things. Whether the theories so expounded are valid or not, those who study them should know that the "building materials" on which this exhaustive study were based are eighteen, and their names are alphabetically arranged: Brick, cement, chestnut lumber, flaxseed, furniture, hemlock, lime, linseed oil, oxide of zinc, pine boards, pine in log, putty, spruce, tar, turpentine, tubs, window glass, wooden pails. The necessity for finding materials with available prices during two widely separated wars may have restricted the investigators, but why masquerade such a collection under the heading "Building Materials"?

An Achievement in Bridge Raising

AN achievement which probably represents the solution of a greater number of field problems than ever before confronted an erection engineer is the raising of the Pennsylvania R.R. bridge over the Allegheny River a maximum distance of 13 ft., described on another page of this issue. This operation involved the jacking up of the double-deck main spans, designed for six railroad tracks, the heaviest for their length in the country, without interference with the dense traffic in and out of the Pennsylvania station, and was carried out under a strict time limit in less than five months for the actual raising of the main spans. The great number and special arrangement of jacks necessary—the four lines of trusses were raised on the intermediate piers without shifting the jacks—and the difficulties in obtaining a sufficient number of adequate capacity; the necessity for working on these intermediate piers in restricted space limits, requiring the design of jacking girders to support the ends of two trusses in each line without encroaching on train-clearance lines, the design of grillage units which could be easily handled and installed from the hanging platforms below the main trusses; the application of a well-known hydraulic principle in a simple device for indicating the relative level of the ends of the trusses being raised on a given intermediate pier, kept at the same level to prevent twisting of portal bracing and end floor-beam connections; the design of spliced extensions for the columns in the approach viaduct, and the scheme for placing precast concrete blocks in building up the piers of these approaches—all introduced complications and difficulties which required unusual ingenuity in their solution. That the whole series of operations should have been carried out so successfully within the one-year time limit allowed by the Government is a real tribute to the engineers in charge.

Training Operators of Construction Machinery

HOW to obtain competent operators of construction machinery will be a burning question when the prospective construction program is started, for the supply of such men is always limited. It is not uncommon for a contractor to find himself faced with a shutdown because he lacks a man able to handle a road roller, concrete mixer, trenching machine or piledriver. His only recourse is to select some promising man from among the laborers and assign him to the task, with the foreman to give him such instruction as opportunity permits. This means likelihood of delaying or even spoiling a part of the work and of causing excessive maintenance and repair expense on the machinery while the man is acquiring proficiency. How can this condition be remedied and the supply of machine operators increased? The short courses in highway construction held by many Western state universities, during the winter, appear to offer a logical means for training such men. It is generally easy to get a few competent operators as instructors at that time, before the construction season opens. A method which has been tried at the Nebraska State University, in view of the shortage of men to operate construction machinery on road work, consisted in organizing a special short course very similar to that already established for the instruction of tractor operators for agricultural machinery. A three-week course of lectures and demonstrations should suffice to turn out men able to handle machinery efficiently and economically. Men thus trained are not to be classed as common laborers, and probably many of them would develop into foremen or superintendents.

Full Facts on the Engineering Standards Movement

OPEN discussion of plans and purposes is a first essential in a matter that concerns future engineering and industrial development so intimately as the Engineering Standards movement. The thought of every engineer on the subject is needed. But hitherto there has been no possibility of such thought and discussion, because those in charge of the planning failed to take the engineering public into their confidence. Dr. E. B. Rosa's elaborate statement of the case in this issue supplies a substratum of fact on which the reader may build his thought. Obviously, discussion must be based on information concerning such matters as form of organization, intersociety relations, field to be occupied, control and financing.

Relying on broad support for its ultimate success, the Engineering Standards movement is in its very nature one that peculiarly demands widest publicity; even more so at the present point of proposed reorganization on surprisingly broad lines. The statement which we publish is founded on this very thought, that the soundest results will follow if all engineers will consider the subject with close attention, on the basis of the facts.

Were any proof needed of the desirability of an open statement of the situation, it might be found in the fact that some of the men most closely concerned with the movement, men responsible for the direction of large societies in connection with it, are misinformed as to essential phases of the committee activities. Without breach of confidence it may be said that comments on the editorial discussions of the standards movement printed in these columns Apr. 10 and 17 have made this quite evident. Therefore, if misconception prevails in circles that should be fully informed, it is idle to expect that engineers the country over can form useful opinions concerning the movement.

We bespeak for Dr. Rosa's statement close and interested study. It describes the plan which is now before the directing boards of the societies—though the divisional feature of the organization is for the present only Dr. Rosa's personal idea of what should develop. The Engineering Standards movement concerns all engineers and all who are engaged in industrial technology. Few developments of such broad importance have come before the profession in years.

The central feature of the reorganization soon to be decided upon is the inclusion of safety-code work with work on standards of shape and quality of materials. But accompanying this very important change is that of improvement in organization. The aim now is to make the Engineering Standards Committee a broadly representative institution, which in its present make-up it is not and could not be. If the movement as a whole is to be constituted by the free and enthusiastic coöperation of numerous societies, only a broadly democratic constitution can bring success.

There are many phases of the remarkable organization and system set forth that invite comment; and there is not a little that might be questioned or traversed. The data of the psychological problem with which the noted physicist deals in this instance seem to call for scrutiny. Perhaps the method of deduction also may be worth examination. But it is precisely these elements of the statement that must be considered in full by the court of engineering opinion. In harmony with Dr. Rosa's clearly expressed thought, the widest range of study and reflection upon the subject will best promote the right outcome.

With respect to one point, however, the author's statement needs to be put in clearer light at once, for the point is fundamental to many considerations of the subject. Dr. Rosa disclaims all technical action or judgment on the part of the Engineering Standards Committee. He says that the committee "will approve a standard . . . not because the committee has itself examined it and passed an independent judgment upon it, which that committee will not attempt to do." This goes to the heart of the question of how conflicting interests in the formulation of a standard are to be harmonized. What will develop in those cases where duplication, or conflict of authority, or unharmonized difference of technical opinion, occurs? It is held by many advocates of the standards organization that duplication and conflict now occur to a harmful degree, and that they would be eliminated by the proposed system. And these same men, like Dr. Rosa, hold that the committee will accomplish this object without entering into technical questions.

Such views need to be tested by the proof of actual fact. They should be applied, for example, to the question of possible protests against the A. S. M. E. boiler-code work, to the controversy over motor-car axles, to the conflict in the field of specifications for cast-iron water pipe, to the situation in which steel-rail specifications are involved, and to the difficulties of some years ago in the matter of the cement specifications. In

such cases as these—as also in others that may readily arise; for example, if a standardization of I-beam sections should be undertaken—there are unavoidable technical differences which no mere overhead pacificatory direction could level. They include differences between societies, differences between producer and user, and differences between producers, or between users, but technical differences in all cases. Only technical methods can successfully settle such differences, and for this reason reassuring advance disclaimer of all technical action by the Standards Committee is likely to be belied by subsequent developments.

A Clarion Call to the Profession

LAST week's meeting in Chicago, at which delegates from 74 societies gathered to consider the advisability of pushing the formation of a Federal Department of Public Works, marked a distinct step forward in engineering-society activity in this country. What is more, it sounded a clarion call to the profession: Can engineers, architects, chemists and their co-workers in construction activities get together with an effectiveness equal to the task of carrying through a great national project?

If the spirit of last week's conference is consulted, the answer is clearly and emphatically, Yes. Could there be a more competent body to give that answer? Here were representatives of every type of society, the great nationals, the locals from coast to coast, and architects', chemists' and contractors' organizations. There was such unanimity, such confidence, that repeatedly Philip N. Moore, sitting as chairman at the really pivotal session, pleaded that if anyone saw insuperable obstacles to the movement or lacked faith in it that he come forward and express himself. But there were no objectors.

That the task is not an easy one was fully realized. The delegates went home fully appreciative of that to which the conference had set its hand, but confident not merely that the result would be accomplished but that through the doing of the task the profession would be bound together as never before. The inevitableness of that secondary result is obvious. An effective organization alone can win in this project—and that organization can be made permanent, the agency for doing thereafter the many things that have long awaited the hand of a national organization of engineers.

Fortunately, the project is one on which it is easy to unite. No selfish, no local, no partisan interest is served. The public good alone is the issue—and it recommends itself no less to other patriotic citizens than to engineers, architects, chemists and their allied workers. Therein, in fact, lies the solid reason for its success—that the public at large can be won to its support.

The project is now in hand. There is no turning back. Success alone can be the end of the endeavor.

Mr. Channing, chairman of Engineering Council, said at the dinner that nothing had given him such hope for ultimate professional unity as the proceedings of the conference. In so saying he echoed, we are sure, the views of everyone present. We take it that Mr. Channing's hopes were founded chiefly on the unanimous opinion regarding the need for a centralizing agency and on the very evident spirit of give and take that prevailed. But there were other hopeful indications—a grasp of political problems (which surely will stimulate united action), an understanding of methods of promotion and organization, and a determination that engineers shall no longer be hesitant in promoting their group interests. The agitation of the five years just passed is bringing results. Crystallization is apparent. The day of professional unity is not far off.

What form the organization that will unite the profession eventually will take cannot now be foretold. Certain it is that the first step will be federation. Repeatedly, plans have been proposed for a single engineering society, all-embracing, extending its scope to civic activities as well as to technical and scientific development. Those proposals have had but small response. Eventually we may find the mechanism for such a development, but the time is not now. At the conference the sentiment plainly was in favor of federation—and federation under Engineering Council.

As to Engineering Council, its opportunity to become the medium of unifying the profession has been immensely advanced through this conference. In fact, if we read the sentiment aright, it was that the council was the logical agent of unity. The attitude of its members was so broadminded, their appreciation of the problems of all classes of engineers so evident, that the council won friends for itself even among those most critical of it in the past and most doubtful of its ability, because of its genesis and constitution, to represent the profession broadly. The last objection seemed to be removed when Mr. Channing told of the pending amendment to the rules which would permit the admission of local societies.

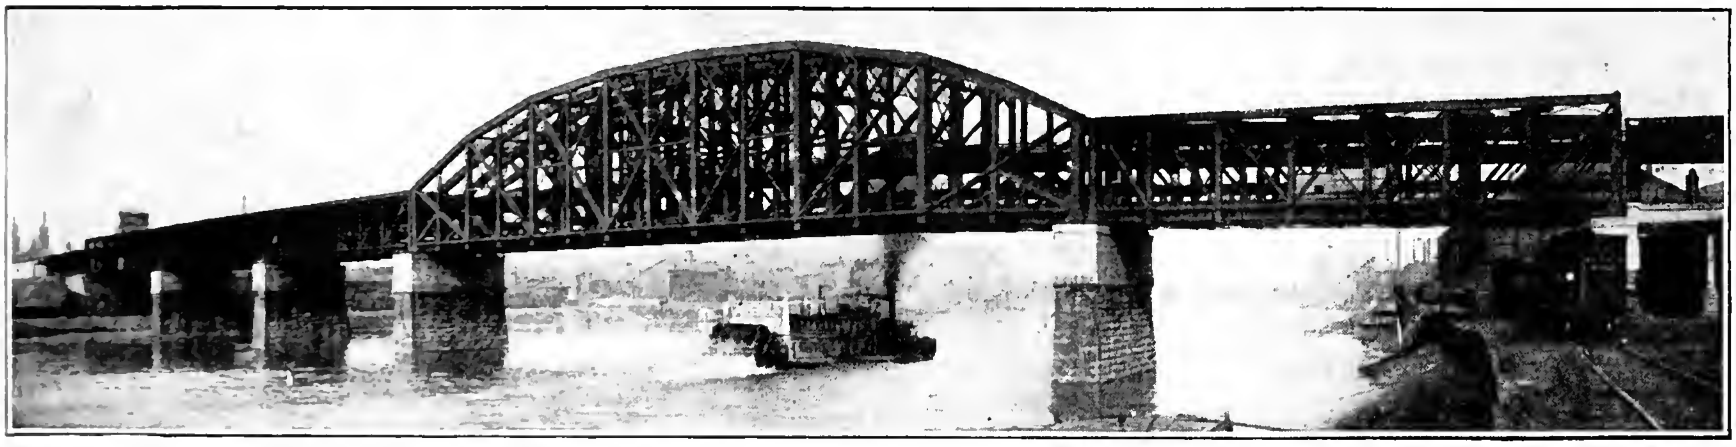
Not a little of the favorable impression made by the council was due to its broadminded handling of the conference. It called the conference, made it possible, but of its own volition elected to have no part therein. In other words, where it might easily have dominated, it freely stepped aside, declaring its object to be merely that of affording a forum where the societies could reach their own decisions. Upon the announcement by Mr. Channing that council members as such would have no voice in the proceedings, the conference at once accorded to them and to the members of the National Service Committee the privilege of the floor.

Finally, a word should be said as to the effectiveness of the arrangements for and the machinery of the conference. They were a tribute to the organizing ability of those in charge. The tentative program, adopted quickly by the conference, showed full appreciation of the probably necessary steps of the procedure, but was unhesitatingly changed in detail to suit the needs as the conference developed. The conduct of the chair was effective and tended to expedition. The Western Society of Engineers supplied not only the meeting place but plentiful stenographic and clerical assistance. The technical societies of Chicago, through their General Committee, took care of the housing of the delegates and gave a dinner to the entire conference.

It was a big piece of work effectively handled. It will linger long in the pleasant recollections of those who attended, and will go down in the annals of the profession as one of its most important meetings.

Raising Allegheny River Bridge 13 Feet By Jacking

Without Interruption of Traffic Underclearance of Four-Track Two-Level Steel Structure at Pittsburgh Is Increased 12.6 Feet



DOUBLE-DECK STEEL SPANS LIFTED BODILY TO INCREASE CLEARANCE BY 12.6 FEET—PROGRESS PHOTOGRAPH AND FINAL APPEARANCE

ONE of the most original engineering accomplishments ever carried to successful completion is the lifting of about 7800 tons of steel bridge truss spans and 7150 tons of approach viaducts a maximum distance of 13½ ft. with absolutely no interruption of the heaviest railroad traffic. On Mar. 23, 1917, the War Department ordered that the Pittsburgh, Fort Wayne & Chicago Railroad bridge over the Allegheny River at Pittsburgh, Penn., consisting of five main river spans of four-truss, double-deck type and their approaches, be raised from a clearance line at El. 738 to a revised line at El. 750.6, and fixed the time limit for completion at one year from date. It was required that the lifting operation should be carried out between trains and proceed consecutively from pier to pier to prevent excessive grades. All the truss spans on any one pier were raised simultaneously by the use of hydraulic jacks of 100-, 200- or 500-ton capacity. The actual operations of lifting these spans, which were designed for six tracks and are the heaviest for their length in the country, were carried out in less than five months.

Restricted space and side-clearance limitations complicated the problem of placing new steel grillages on the main piers and providing support for the jacking girders. Furthermore, the approach girder spans and steel bents also had to be raised and the piers supporting these bents rebuilt by the addition of precast concrete blocks. In the Pittsburgh approach where the side clearances were limited, spliced column extensions were added to the base of the steel column to give the necessary height. A simple device was installed to indicate whether the various spans at one pier were being kept at the same level during the raising operation.

After the completion of the raising, Mar. 15, 1918, much other work had to be done on the bridge, such as the replacing of corroded angles in the upper level struts of the bracing and the placing of cast-iron protection plates above the lower-level tracks, and the introduction of diagonal longitudinal bracing in the approach viaducts on both ends of the bridge.

This bridge was erected in 1902, and a general description of the structure will be found in *Engineering News* of Nov. 20, 1902, p. 417.

General Requirements—The Government order required a clear height 12.6 ft. greater than that furnished by the original structure. This involved the raising of the grade of the lower-level tracks at the ends of the longest span a distance of 12.47 ft. and 13.44 ft., respectively, the latter being the maximum lift required in the structure. The various lifts at the end and intermediate piers are given in the accompanying table, which also indicates the jacking loads at the piers, the length of spans and the dead weight of the spans.

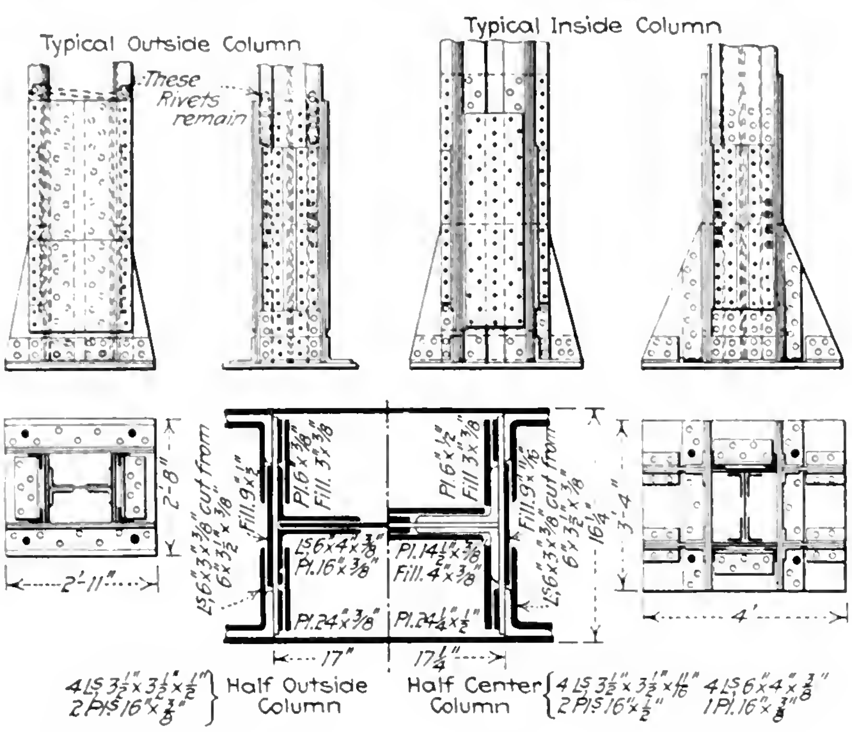
The total length raised was 3283 ft., which was divided into five operations, as follows: (1) Five main river spans supported by six piers, total length 987 ft.; each span is composed of four trusses of double-deck of pin-connected type on a skew, designed for three tracks

MAIN TRUSS SPANS AND WEIGHTS—DISTANCES RAISED

Pier or Span No.	Span Center to Center of Piers, Feet	Dead Weight of Span, Tons	Total Jacking Load at Pier, Tons	Distance Raised, Feet
1	165.5	1199	602	10.47
2	337.5	3459	2331	12.47
3	160.9	1057	2258	13.44
4	160.9	1048	1048	13.19
5	160.5	1052	1048	12.53
6	.....	....	528	11.26
Total		7815	7815	

on each deck, although only two tracks on each deck have been placed; (2) Pittsburgh approach viaduct of 25 half-through plate-girder spans supported on steel column bents, the total length being 823 ft., weight 4000 tons; (3) The Duquesne Way viaduct, 24 spans of which were raised, covering a total length of 1230 ft., weight 2350 tons. This is a double-track-deck plate-girder viaduct supported on steel columns; (4) Allegheny approach viaduct, composed of five half-through plate-girder spans, double track, on steel columns, length 177 ft., weight 800 tons; and (5) Penn Avenue bridge, which is a three-span half-through plate-girder bridge 60 ft. long, with steel columns at intermediate points.

In planning the operation noninterference with traffic was the most important point to be considered, so that all lifting equipment had to be designed to insure the most rapid lifting operations possible. No attempt was made to lift any part of the superstructure under live load. All of the superstructure resting upon any given pier had to be lifted at the same time and kept level during the operation, the distance lifted being limited by the

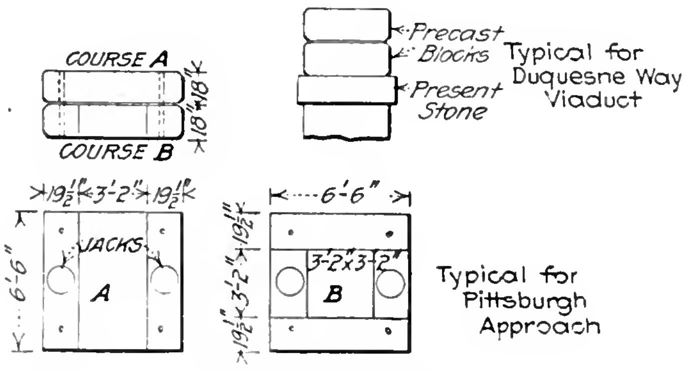


TWO TYPES OF DETAILS OF TYPICAL SPLICES FOR COLUMN EXTENSIONS

fact that no grade exceeding 1% was to be permitted during the progress of the work. In order to prevent undue strain of the riveted connections in the viaduct approaches, it was planned to raise the girders in consecutive sections of three spans, each lift to be limited to two or three inches.

As the interval between trains was seldom more than 15 min., a complete telephone system connecting the train dispatcher's office with those points in the field where the work was being carried on was installed. An elaborate chart was prepared to show when the track was required, how long, and when it would be released. During the work it was found necessary to allow 1.5% grade at various stages, and the final maximum grade is 1.28% on the Pittsburgh approach. The grade of the upper-level tracks was modified so that they were not lifted the same amount as the lower-level tracks, the difference being made up in depth of ties, some ties as deep as 20 in. being required.

History of the Operations—The work was let on a percentage basis, and as many new requirements were discovered the added work extended the time of the final completion of the contract nearly one year longer than that required to raise the bridge to its new level. Preliminary work on the approaches was started June 7, 1917, and all extra work on the main spans and approaches was completed Mar. 15, 1919. The lifting of the main spans and the Allegheny approaches began



PRECAST BLOCKS IN APPROACH PIERS

Oct. 30, 1917, and the last lift was completed Mar. 15, 1918, the contract date limit being Mar. 23. The average lift on the main piers was 3 in. at first, increasing to about 6 in. per day, the maximum, accomplished Feb. 25, 1919, being one foot three inches.

Work on the Pittsburgh approach began Aug. 11, 1917, and was finished Mar. 11, 1918, the work being carried on simultaneously throughout the structure with a force that averaged about 75 men. The addition of splice material and reinforcement for corroded struts and floor-beams, the installation of new longitudinal bracing, and other additional work, kept the contractor on the work for another year.

Approach Columns Raised—The first work was the enlargement of the concrete piers supporting the columns of the approach bents to give sufficient width to support the jacks. As seen in one of the photographs, built-up steel brackets were bolted on two sides of the columns to support the dead weight. Beneath these the jacks were placed, the capacity of these jacks varying from 40 to 80 tons. For the heavier brackets eight 1¼-in. bolts were used at the lower end to take the tension, and wood blocks were inserted between the column angles at the top to take the compression.

The first operation was the placing of wood blocks for supporting the jacks, or, in case the precast blocks were finished, outside units were used under the jacks, as indicated by one of the drawings. The jacking up proceeded in 2-in. increments, using timber blocking under the column bases until the structure had been raised about 2 ft., when the center precast block under the column base was inserted. The second tier of these blocks consisted of five units, as indicated on the drawing, the outside oblong blocks running in the opposite direction to those of the first tier. In placing this second tier, the first units placed were those under the jacks, the latter then being used to raise the column by means of brackets in 3-in. lifts, using timber blocking until the column was high enough for the insertion of the center section under the column base. The outside sections could then be placed and the work proceed in similar order tier by tier.

On account of insufficient lateral clearance for trains on the track under the viaduct, the concrete blocks on the Pittsburgh approach were brought up only to the level of the new ground line. The additional height necessary was provided by steel column extensions spliced to the old columns, as indicated on one of the drawings herewith showing the two general types—the inside column with central diaphragm, and an outside column of four angles and two web plates only,

using new center diaphragms at the splices. In placing the new column extension, the dead and the live loads were supported by timber struts from the ground to the girders, one on each side of the column, each composed of three 12 x 12-in. timbers resting on timber cribbing drift-bolted to fit. After thus supporting the superstructure, the old column bases were removed by

PRECAST CONCRETE BLOCKS FOR PIERS AND ABUTMENTS AT PENN AVENUE

cutting out the rivets, new holes were drilled, the column extensions were inserted, and the splice material was added.

As the original structure was constructed with a level grade, the introduction of the grades on the approaches made it necessary to add new longitudinal bracing between columns in certain bays. On the Pittsburgh approach this bracing was introduced in five bays at various parts of the structure, always being placed in a fixed span. Double diagonals were used in all cases except in the end bay, where a special detail was necessary to connect to the abutment because of the presence of an electric-wire conduit running along the abutment. Details of this concrete-covered steel-beam construction to span the conduit and connect to the abutment are indicated in one of the accompanying drawings. In the other approaches, single diagonals with a subdiagonal and vertical at the center to shorten the unsupported length of the strut were used, thus decreasing the number of points of connection between the new diagonals and the columns.

Jacking Up Main Trusses—The eight truss bearings at each intermediate pier were lifted at the same time, keeping all trusses at the same elevation in order to prevent undue strain on the rigidly connected floor-beams and portal bracing. The scheme finally adopted to allow rapid and continuous jacking operations is indicated by the diagram herewith. The problem was to design the jacking girders and steel grillage units to avoid interference and to keep outside of the train-clearance line. New steel brackets were bolted to the vertical end posts of the main trusses, below which the 500-ton hydraulic jacks could be placed upon jacking girders. These girders were carried by jacking columns built up of I-beams and placed in openings left in the grillage units.

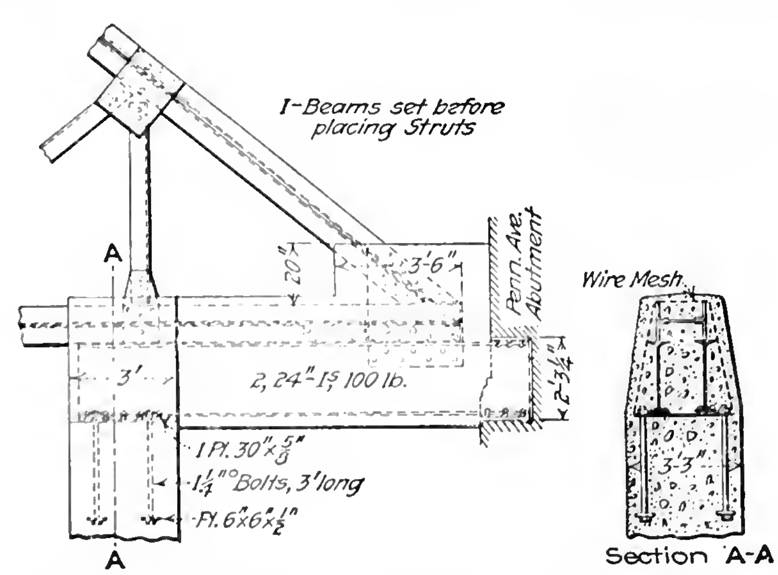
It was first necessary to raise the railroad track 8 in. to increase the clearance. The ends of the old I-beam grillages were burned off in order to allow the outside units of I-beams filled with concrete to be placed. These outside units, which had to carry the complete dead load on the jacks, were built up of I-beams bolted together before the concrete filling was placed.

The posts and jacking girders were then erected and the old truss grillages were bolted to the shoes, and jacking proceeded, using 3-in. timber blocking under the old grillages until the trusses were high enough for the insertion of the central unit of the first tier of new grillage. As the 500-ton jacks only had an 8-in. stroke, the clearance between the jacking girders and the truss shoes only permitted an 8-in. raise, and it was necessary to raise these jacking girders every time the bridge was raised 8 in. The dead load of the jacks, jacking girders and supports was about six tons, hence a set of auxiliary jacks was installed to raise the jacking girders by brackets, as indicated on the sketch, to allow rail grillages to be slipped under the jacking columns. These rail grillages were later replaced by I-beam stools. All of these operations, of course, had to be carried on simultaneously at each of the four truss points on a given pier. After the operations had become familiar, it was possible to carry through one complete cycle for a 4-in. raise and place the 3-in. plank in four minutes.

Special Device Insured the Constant Level—A simple hydraulic device was designed, on the principle of water seeking its own level, to indicate when the truss bearings were not at the same relative elevation during the operation of lifting. A ¾-in. pipe was placed below the floor of the span, and risers with glass indicator tubes were placed at each truss. Water with coloring matter was inserted, and the level indicated by placing a rubber band around the glass tube at the beginning of the lift.

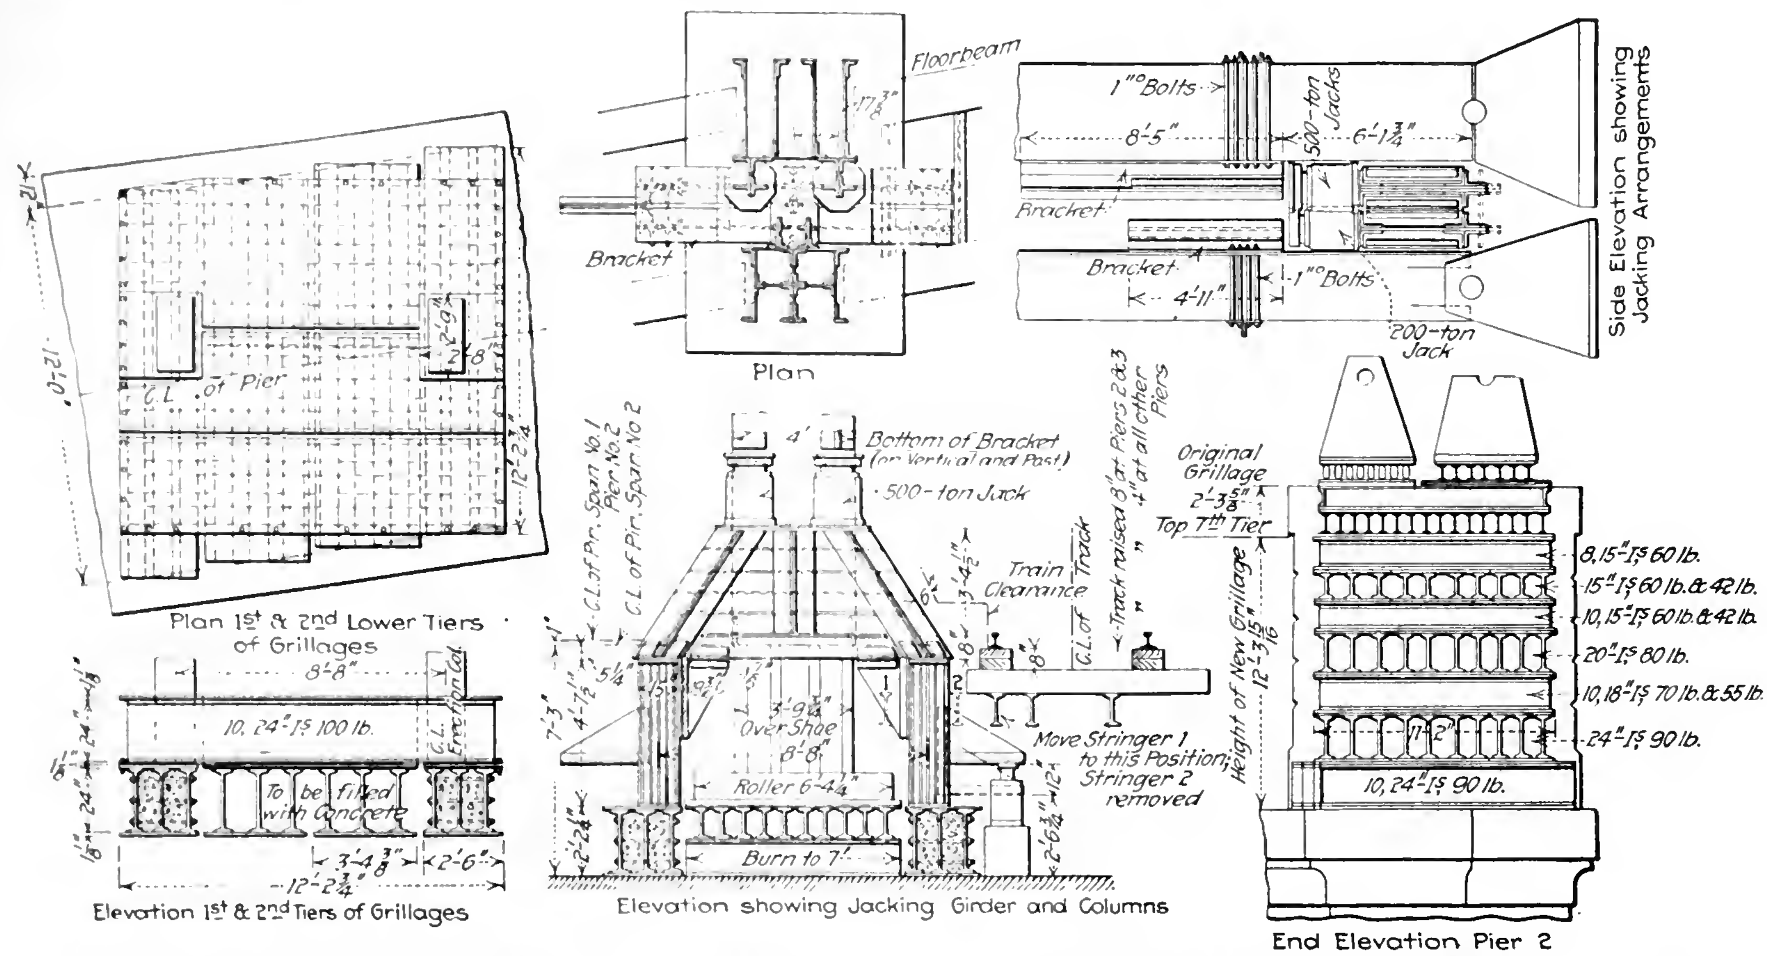
All that the men who were operating the inlet valves of the hydraulic jacks had to do was to watch carefully to see that the water in the glass tube was kept constantly at the level shown by the rubber-band indicator. After some practice this could be successfully accomplished with less than ⅛-in. variation.

The hydraulic jacks were operated from a single steam pump placed on a platform carried by cantilever supports on the north side of span No. 2. The main line



SPECIAL LONGITUDINAL BRACING ANCHORAGE AT ABUTMENT

of 1½-in. pipe extended the full length of the five bridge spans and connected to 1-in. pipes running parallel to each pier, to which copper pipe was attached and connected through the supply valve with each jack on the various piers. These valves were operated by capstans above the floor of the bridge, as indicated in one of the photographs. Stop valves were placed on each side



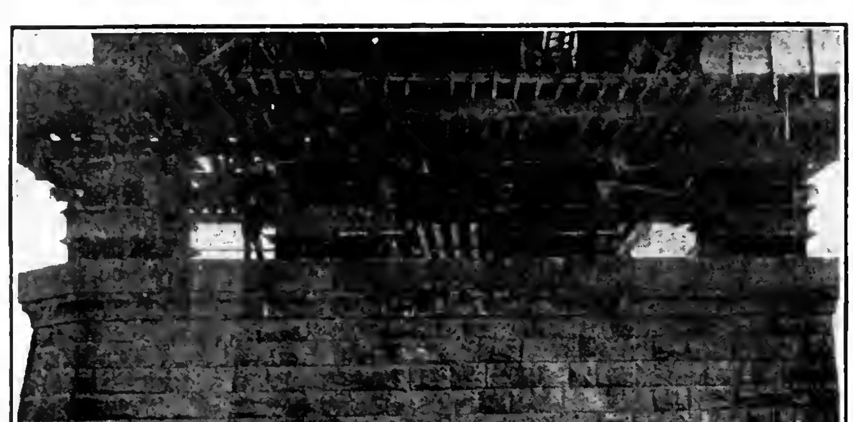
JACKING GIRDERS AND COLUMNS WITH I-BEAM GRILLAGES SATISFY CLEARANCE REQUIREMENTS—PIER NO. 2

of the connection between the pump and the longitudinal 1½-in. pipe, also just beyond each pier, in order to govern the flow of the water to any set of jacks on any pier desired. A discharge valve was also placed at the connection for the copper supply pipe for each set of jacks, allowing the mixture of water and 50% alcohol used in the winter to be saved by catching it in buckets and returning to the pump.

Placing Steel Grillages—Timber platforms were hung from the trusses on each side of the main piers at a level just high enough to allow the steel grillages to be rolled into place on pipe rollers. Platforms on both sides of the pier were required because grillage units of alternate tiers had to be made double, each half being placed from opposite sides of the pier to allow space for the jacking columns. In order to avoid delay in obtaining material it was found necessary to use I-beams for these grillages from whatever source was available. For example, 15-in. I-beams from the old Louisville bridge were obtained and many other beams were furnished by the railroad. The height of the last tier was fixed by the required total lift at the given pier. These grillage units were fabricated at the site, using as cover plates the old Quebec bridge hangers which had been utilized in lifting the suspended span. These were 1¼ in. thick for those from the old span which was lost in the river, and 1½ in. thick for the hangers last used.

The mortar beds between the grillage tiers made up about 4½ in. of the varying difference between the net height of the steel and the height of the concrete encasement forming new caps for the piers. The concrete encasement was carried up to the top of the seventh tier; the concrete was placed by first filling the I-beam grillages with 1 : 3 : 6 gravel concrete, then placing the heart, 10½ ft. wide between the grillages, of the same mix. The outside width of 13 ft. was then made up by 1 :2 : 4 mix, using gravel screened to ¾ in. and working the mortar against the forms so that no stone would show after the base was rubbed.

Vertical joints were made to prevent the development of cracks in the concrete at the corner of the steel grillages where it joined the large mass of heart concrete, by using a steel plate nailed to the forms in a narrow V shape, this plate being removed with the forms and the opening pointed up after the concrete had set. The horizontal construction joints were made at any coursing joint, the latter being formed by triangular nailing strips spaced about 2 ft. 2½ in. apart vertically. The care used in the location of the con-



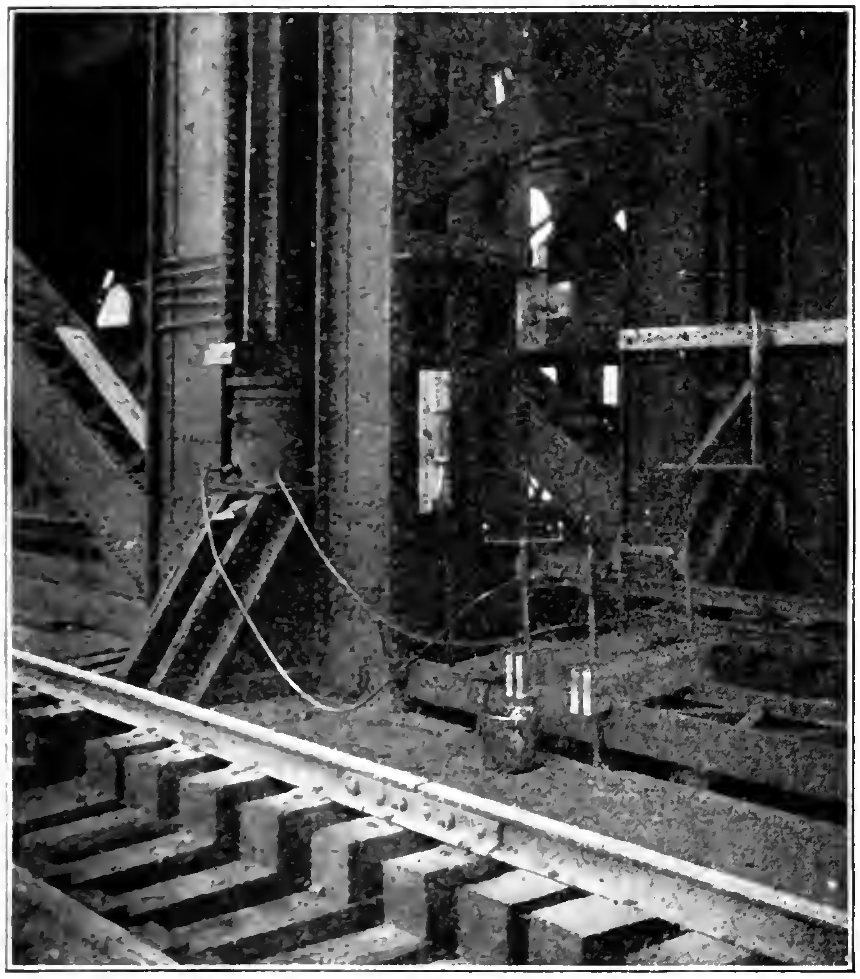
GRILLAGE BEAMS IN PLACE UNDER THE FOUR MAIN TRUSSES AT PIER NO. 4

struction joints has resulted in the fact that no crack whatever has appeared, although several months have elapsed since the work was completed.

Repairing Corroded Struts and Floor-Beams—The locomotive gases and blast were found to have caused very severe loss in section of the transverse struts and floor-beams on the upper level above the floor tracks. It was therefore found necessary to replace the 4 x 4-in. angles of the struts by splicing in new sections in both flanges, usually 3 to 4 ft. long, and spliced by 3½ x 3½ x $\frac{7}{16}$-in. angles. In some cases plates 10⅝ x ⅜ in., about 5 ft. long, were riveted to the lower strut angles. Cast-iron protection plates to prevent future corrosion were bolted to the bottom of these struts in the upper

deck throughout the length of the bridge. The corroded floor-beams were rebuilt by adding web plates to both sides of the old webs and reinforcing the lower flange angles.

The work was performed under the general supervision of J. C. Bland, engineer of bridges, Pennsylvania Lines West of Pittsburgh, and was carried out by the Seaboard Construction Co., Philadelphia, Penn., under the personal supervision of S. P. Mitchell, president, with H. S. Goodloe as superintendent in charge of field operations. W. W. Priest, assistant engineer of bridges,



JACKS ON JACKING GIRDERS—INDICATOR TUBE AND VALVE CONTROLS

Pennsylvania Lines West, was in immediate charge of all field work. The grillages and other steel work were fabricated at the site by the Seaboard Construction Co., and bracing, column extensions, miscellaneous steelwork, etc., were furnished by the McClintic-Marshall Co. and the Fort Pitt Bridge Works, both of Pittsburgh. The estimate of the cost (made April, 1917)

NEW BASES SPLICED TO VIADUCT COLUMNS
Jacking brackets are seen on far columns to the right

was $500,000, but owing to the increase in the costs of all kinds of labor and material during the progress of the work, and loss in efficiency due to the unusually severe cold of the winter of 1917-18, the final cost was from $750,000 to $800,000. The exact cost is not known, as accounts are not yet closed.

Physical Properties of Marbles

ELABORATE tests on marbles were carried out by the Bureau of Standards during the past year to determine the relative value of the different available types and grades for building and for other uses. They covered 52 different marbles, and dealt with strength, water absorption, porosity, specific gravity, loss on repeated freezing, thermal expansion, electrical conductivity, and the like.

In compressive strength (dry) the marbles ranged from 7850 to 50,205 lb. per square inch. After immersion in water for two weeks most of them showed a slightly lower strength, the greatest loss being over 25%. Resistance to freezing and thawing, as determined from 30 cycles, showed equally variable results. But some samples showed little or no loss, and a few actually showed a gain in strength. To put the matter to the test of a longer series of freezing-and-thawing cycles, a device has been set up which will automatically shift a specimen back and forth between a cold chamber and a warm chamber at fixed intervals. By this means it will be possible to expose a specimen to a large number of cycles, and determine the effect of freezing more accurately. The same machine is to be used for testing other building stone.

The heat expansion of marble exhibited a varying rate even at ordinary temperatures, so that a single coefficient cannot be given. More important, however, is the fact that after expansion under heat the marble did not return to its original dimensions after cooling, part of the increase of size being permanent; and successive heatings showed a continuous effect; that is, a progressive increase of dimension.

Measurement of electrical resistivity of different marbles showed a large range of values, so that marble for electrical uses must be specially selected.

Rough Faces Do Not Strengthen Glue Joints

Comparative strength tests of glued joints made with smooth and tooth-planed contact surfaces at the Forest Products Laboratory of the United States Forest Service at Madison, Wis., last year showed that there is no advantage in roughening the faces. It has been commonly believed among woodworkers that scratched or tooth-planed surfaces make a stronger glued joint than smoothly planed faces, but the tests distinctly disprove this belief. Pairs of hard maple blocks were used as the test specimens. They were glued together with a high-grade hide glue, allowed to stand for a week, and then sheared apart in a testing machine. Eleven sets of tests, each test comprising four joints of the smooth and four of the tooth-planed type, gave practically identical average strengths for the two types. In seven of the eleven sets the smooth joints showed the higher strength; the average of all the smooth joints was 2040 lb. per square inch, and that of the tooth-planed joints 1988 lb. per square inch. The area of wood on the fracture surface was counted in every case; the average wood face percentage for the smooth joints was 47 and that for the roughened-face joints 45, which would indicate if anything a greater glue strength for the smooth-face joint. With respect to strength, the 11 tests gave quite consistent results. The figures for the smooth-face joints (each figure an average of four test-pieces) ranged from 943 to 3086 lb. per square inch, those for the roughened-face joints from 1366 to 2409.

Engineering Societies Organize to Push Public Works Department Bill

Seventy-Four Societies Represented at Conference in Chicago—Principles Adopted With Reference to Character of Proposed Department

REPRESENTATIVES of seventy-four engineering societies, having a combined membership of over 100,000, met in Chicago last week and as a result of discussions occupying two full days formed an organization to promote the passage by Congress of a bill creating a Federal Department of Public Works. Principles were adopted for determining the character of the proposed department, and specific recommendations were made as to the services and bureaus to be incorporated therein. The drafting of the bill itself was left to a committee with full power, and the management of the organization to an executive committee, which was authorized to appoint a finance committee to which, in turn, will be left the problem of raising the necessary funds. A campaign committee was also authorized, and, in part, appointed.

Sessions were also devoted to a consideration of Government coördination in mapping the United States and to the relations of nonmember organizations to Engineering Council. Reports of these sessions will be found in the news section of this issue.

A dinner was given to the delegates by the General Committee of the Technical Societies of Chicago, F. K. Copeland, chairman, while the Western Society of Engineers placed its meeting hall, with stenographic and other facilities, at the disposal of the conference.

The Conference

J. Parke Channing, as chairman of Engineering Council, whose National Service Committee called the conference, set forth in a brief introductory speech, reprinted in full on an adjoining page, the purpose of the conference and the general reasons why engineers had repeatedly urged the formation of a Federal Department of Public Works. He made it clear that Engineering Council desired, in connection with the conference, to afford only the means of bringing the delegates together, and that it had no desire to be a determining factor in the conclusions reached. For that reason. Engineering Council, and its members who happened to be present, would have no voice in the proceedings.

Thereupon, upon a call for nominations, M. O. Leighton, chairman of the National Service Committee, was elected chairman of the conference, and E. S. Nethercut, secretary of the Western Society of Engineers, was elected secretary. It was unanimously voted that the members of Engineering Council and the National Service Committee, who were present but did not hold delegates' credentials, receive the privileges of the floor, without, however, the right to vote. The chair was authorized to appoint committees on resolutions, text of bill, Government engineering activities, and credentials.

Upon completion of the organization details the designated work of the conference was taken in hand, the initial step being the presentation by Philip N. Moore, of St. Louis, of the report of the National Service Committee on the project for a Department of Public Works. The report will be found in full on an adjoining page. The burden of it was that the public good demanded the coördination of the engineering activities of the Government, and that this demand was so fundamental that sooner or later it was sure to be complied with. It would be better, he contended, that engineers should be instrumental in bringing about the necessary coördination than that it should be left to others.

Principles Governing Constitution of Proposed Department

From the outset it was apparent that the delegates were unanimous in the belief that a Department of Public Works should be formed, and all of the speakers addressed themselves rather to the principles to govern its formation than to the question of the advisability of its creation. Almost the first question raised was as to the amount of engineering work included within the activities of a given service or bureau necessary to make it eligible for inclusion in the proposed department. It was apparent that the general sentiment was in favor of including only those services and bureaus whose work is *chiefly* of an engineering character. There was some sentiment in favor of the proposal to separate the engineering functions from bureaus which had acquired engineering activities which are, plainly, not essentially connected with their main work, such as the supervision of hydro-electric licenses on the public lands by the Forest Service. Eventually the sentiment prevailed that services and bureaus should be transferred *in toto*, and that those having primarily a function other than engineering should at the outset be left where they are now rather than be transferred to the new department. W. D. Blair, representing the American Institute of Architects, stated that the architects favored the formation of a department with broad scope, which should cover all construction work, including the design and erection of buildings. Speaking for the American Chemical Society, Julius Stieglitz declared that the chemists desire that the chemical bureaus of the Government should be transferred to the proposed department. He pointed out that chemistry was not engineering, but that the alliance of the two was such that the chemical bureaus properly belonged in a department of public works.

The ideas and principles thus developed in the discussion were referred to the resolutions committee, which brought in the following report covering the subject:

"This conference of the delegates from engineering and related organizations respectfully recommends to the public and to Congress that legislation be enacted covering the following principles:

"1. That the services and bureaus of the national Government having to do chiefly with matters of engineering and architecture be grouped in one department to be known as the Department of Public Works.

"2. That the Department of Public Works comprise those works which are built and operated for the use of the public.

"3. That the Department of Public Works be made available when desirable for the performance of special engineering and architectural work for the use of other Government bureaus.

"4. That there be a systematic classification and organization of engineers, architects and other emp'oyees, whose status shall be such that they may be recruited and maintained on merit."

These resolutions were discussed very fully, the chief discussion centering about the drawing of a distinction between military and nonmilitary work. The sentiment was plain that the de'egates believed that only nonmilitary work should be handled by the proposed department, and the question revolved merely about the desirability of including the terms "military" and "nonmilitary" in the statement of principles. The resolutions committee explained that the second principle, as it had been drafted, was intended to exclude military works, because they obviously are not built and operated for the use of the public, and after full discussion the conference decided that this was a full and sufficient distinction. In the discussion, it was also pointed out that the heads of practically all Government services and bureaus having to deal chiefly with engineering work had already been approached with reference to the proposal to form the department and that no opposition had developed.

Services and Bureaus To Be Included

Following the adoption of the statement of principles, discussion was taken up in committee of the whole as to the specific services and bureaus which should be included in the proposed department. The purpose of this discussion, and any action that might be taken, was not to bind the conference, but to serve as information for the benefit of the committee on Government engineering activities, which was directed to bring in at a later session a report on details regarding the formation of the department.

By constant reference to the principles reported above, the conference rather quickly decided the disposition of the various bureaus and activities having engineering functions. The results of the votes are shown in the accompanying table.

Rather full discussion took place with reference to the disposition of the Public Health Service, the Construction Division of the Army, the Forest Service and the Bureau of Standards. The Public Health Service was eliminated because its duties were considered not to be chiefly engineering, while the Construction Division of the Army was included because its work was plainly that ordinarily performed by civilian rather than by military engineers.

The Forest Service was included chiefly because of its important engineering function of supervision over water-power development on the public lands, and also because of the large mileage of roads which it builds. The proposal was considered to recommend the splitting of the work, the silviculture and the strictly agricultural features remaining where they now are, and the engineering features being transferred to the new department. On motion, however, the view prevailed that the whole service should be transferred.

Final decision that the Bureau of Standards would best be in the new department was reached on representation by a number of the delegates of the important engineering functions of the bureau. The Panama Canal was not to be included because its work now is that of maintenance rather than of engineering design and construction.

It was also decided that it would be best to advocate the changing of one of the existing departments into a Department of Public Works rather than to work for the creation of a new department, making a new cabinet position. A motion also prevailed that no changes be made in the personnel, organization and methods of operation of the various bureaus, but that they be taken over into the proposed department just as they now are.

A motion to include in the proposed department a bureau whose purpose would be to promote by means of publicity the construction industries of the country, similar to the promotional and educational work that the Department of Agriculture does for agriculture, was lost.

BUREAUS TO BE INCLUDED IN PROPOSED PUBLIC WORKS DEPARTMENT AS DETERMINED IN COMMITTEE OF THE WHOLE

("Yes" means that it should be included; "No" that it be excluded)

Department of the Treasury	
Public Health Service	No
Supervising Architect	Yes
Department of War	
Public Buildings and Grounds	No
Construction Division of the Army	Yes
Rivers and Harbors	Yes
Mississippi River Commission	Yes
California Débris Commission	Yes
Department of the Interior	
General Land Office	Yes
Indian Affairs	No
Geological Survey	Yes
Reclamation Service	Yes
Bureau of Mines	Yes
National Park Service	Yes
Alaska Engineering Commission	Yes
Department of Agriculture	
Forest Service	Yes
Weather Bureau	No
Public Roads	Yes
Department of Commerce	
Bureau of Standards	Yes
Bureau of Lighthouses	No
Coast and Geodetic Survey	Yes
Unattached Functions	
The Panama Canal	No

(*N. B.*—Some of these decisions were reversed by vote on report of committee on Government activities, which see.)

Report of Committee on Government Engineering Activities

Basing its conclusions upon the discussion which had taken place in the committee of the whole and upon the statement of principles which had been adopted, the committee on Government engineering activities on the following morning presented the following report which, with minor amendment (said amendments being incorporated in the report as printed below) was adopted. The report, as adopted, is as follows:

Your committee charged with a consideration of the question which Government activities should be coördinated in a national Department of Public Works recommends:

1. That the establishment of a national department of public works should be accomplished by grouping those Government bureaus, services, commissions and other activities whose functions are predominantly of an engineering or architectural character in what is now the Department of the Interior, and thereafter designating that department the Department of Public Works.

2. That the transfer of any bureau, service or commission from any other department to a Department of Public Works should be accomplished without change of personnel, compensation and general plan or organization, leaving the coördination of the several activities, the simplification of organization and the establishment of additional bureaus—such, for example, as a bureau of chemical engineering—to be effected as the need for the same may from time to time become apparent.

3. That in transferring river and harbor work and other work nonmilitary in character, but now in charge of the Engineer Corps of the United States Army, to a Department of Public Works, the relation of the Army engineer to such work be not changed, and that there should be no relinquishment of nonmilitary duty by the Army engineers now on such duty until transfer of these engineers to military duty can be made without detriment to the public interests.

Your committee finds that among the bureaus, services and activities which logically belong in a Department of Public Works are the following:

A Bureau of Public Roads.

The United States Reclamation Service.

The Alaska Engineering Commission.

The Construction Division of the United States Army.

A Bureau of River, Harbor and Canal Work, including such functions as are now exercised by the Mississippi River Commission and the California Débris Commission.

A Bureau of Architecture.

A Bureau of Surveys, including the Coast and Geodetic Survey.

A Bureau of Mines.

The Geological Survey.

The Forest Service—at least until the same is divorced from the supervision of water-powers and road building.

The Bureau of Standards.

Your committee believes it would be unwise to determine at this time to what extent the proposed department of public works should control the engineering activities of the General Land Office, of the National Park Service, of the Bureau of Lighthouses, of the Bureau of Indian Affairs, and of the Public Health Service and of various commissions, such as commissions on buildings and grounds, and therefore suggests that such matters may well be deferred for consideration to a later date, preferably until the department has been organized.

Permanent Machinery for Pushing Bill

Much time was given to the discussion of the permanent machinery that should be established in order to promote the passage of the proposed bill. There was general appreciation of the necessity for organizing the profession down to the last Congressional district, in order that the merits of the proposed measure might be brought home to members of Congress through the public and through engineers resident in each Congressional district. The lack of national organization of the profession was brought up repeatedly and much deplored, the discussion at times broadening out to include suggestions for the coördination of all elements of the profession. J. Parke Channing, chairman of Engineering Council, pointed out that the council was still in its formative stage, and so far had included only national engineering societies. An amendment was pending, however, which, if adopted, would permit the affiliation of local societies as well. He was of the opinion that engineers might learn from the American Federation of Labor, which is very loose in its organization and admits all bodies that can contribute to its ends—not merely the craft unions, but the industrial unions as well. In fact, the headquarters organization of the federation has the power to organize unions on its own initiative, without having them subordinate to state organizations or to general craft unions. This permits all classes of labor organizations to come in under the coördinating influence of one body. Concluding, he offered the services of the National Service Committee to the conference in its work of promoting the Public Works Department bill. This offer was promptly accepted, with hearty thanks, by the conference.

With reference to methods of promoting the bill, W. H. Hoyt, of Duluth, maintained that there was need for a journal devoted to the public and civic interests of engineers. Mr. Channing agreed with Mr. Hoyt on the need for such a paper, pointed out that it had been considered by Engineering Council but that the council could do nothing in the matter for lack of funds. E. J. Mehren, on behalf of the McGraw-Hill Co., Inc., offered to the conference space in the journals controlled by that company in the promotion of the bill, as much space as necessary being allocated weekly to the committee. A similar offer was immediately made by the *American Architect*, and similar offers were received at later sessions from the *Railway Age* and from the International Trade Press, Inc., the latter controlling a number of papers.

On the question of financing the campaign, J. L. Harrington, of Kansas City, proposed that an appeal be made to all local engineering societies to pledge an appropriation of $1 per year per member for this work. Philip N. Moore of St. Louis, on the other hand, believed that the financing could and should be done by the four national engineering societies, and urged that to that end the members of those bodies impress upon their directors the importance of the Public Works Department movement, and the advisability of appropriating the necessary funds. Leonard Metcalf, of Boston, pointed out the condition of the treasuries of some of the national societies, and recited how necessary activities had been curtailed because of the shortage of funds. He felt, therefore, that the funds should be raised by an appeal to the profession generally, rather than by asking the national societies alone to shoulder the burden.

As the result of the discussion on organization and financing, a resolution was presented by F. A. Vaughn, of Milwaukee, providing that the conference be made permanent and that the object be the promotion of this bill. The resolution was referred to the resolutions committee and was finally adopted by the conference in the following form:

"Resolved, that this conference be known as the Engineers', Architects' and Constructors' Conference on National Public Works, that it continue in existence until dissolved by its own action, and that its officers and committees be empowered to further the organization and development of a national department of public works."

Three Committees Appointed

Upon motion by Frederic H. Fay and Leonard Metcalf, the conference adopted as its machinery of permanent organization the following three committees: (1) An executive committee, which was empowered to appoint a finance committee and also to add to the other committees to be authorized; (2) a committee on text of bill; (3) a campaign committee.

A committee to determine the personnel of these three committees was then authorized, and after recess brought in the names reported at the close of this report, making it clear, however, that in the time available there was not opportunity to canvass the situation thoroughly by geographical districts and by branches of the profession, and that the personnel committee expected that the executive committee would fill the necessary gaps by enlarging the campaign committee, particularly.

The method of financing the work of the organization was left entirely in the hands of the finance committee.

The advisability of the conference's indorsing the formation of the proposed Department of Transportation was discussed, and while many views favorable to such indorsement were expressed, two successive resolutions introduced thereon by the resolutions committee were tabled, and no action was taken.

At the concluding session resolutions were adopted thanking the Western Society of Engineers and the General Committee of Technical Societies of Chicago for their hospitality and for the facilities they had provided for the handling of the details of the conference. The thanks of the conference were also extended to the McGraw-Hill Co., Inc., the *American Architect*, the *Railway Age*, and the International Trade Press, Inc., for the offer of magazine space to the conference in its work of promoting the passage of the proposed bill.

The following committee appointments, reported by the personnel committee, were approved:

Executive Committee: M. O. Leighton, Washington, D. C., chairman; Francis H. Blossom, D. A. Garber, Cass Gilbert, W. H. Nichols, New York; F. K. Copeland, C. F. Loweth, C. B. Burdick, Chicago; C. E. Grunsky, San Francisco; P. Junkersfeld, Morton C. Tuttle, Boston; Philip N. Moore, St. Louis; F. H. Newell, Urbana, Ill.; W. O. Winston, Minneapolis.

Committee on Text of Bill: M. O. Leighton, Washington, D. C., chairman; J. W. Alvord, A. S. Baldwin, E. H. Lee, I. K. Pond, Isham Randolph, Chicago; Charles T. Main, Boston; Lincoln Bush, New York; G. S. Williams, Detroit; W. K. Hatt, Lafayette, Ind.; H. V. Winchell, Minneapolis.

Campaign Committee [to be enlarged by Executive Committee]: M. O. Leighton, Washington, D. C., chairman; J. Parke Channing, F. S. Cranford, G. W. Fuller, E. J. Mehren, Robert D. Kohn, A. T. North, H. W. Buck, W. D. Blair, New York; C. H. Blackall, Boston; R. A. S. Penrose, R. H. Fernald, Philadelphia; Morris Knowles, Pittsburgh; W. C. Beahan, Cleveland; E. G. Bradbury, Columbus; Julius Stieglitz, W. A. Rogers, Chicago; Baxter L. Brown, E. J. Russell, St. Louis; W. H. Hoyt, Duluth; W. O. Hotchkiss, Madison; Lloyd B. Smith, Topeka, Kansas; W. C. Armstrong, St. Paul; Hennen Jennings, Washington, D. C.; H. S. Crocker, D. W. Brunton, Denver; R. H. Thompson, Seattle; C. F. Swigart, Portland, Ore.; W. L. Huber, Louis Mulgardt, Robert Sibley, F. W. Bradley, San Francisco; P. M. Norboe, Sacramento; J. C. Ralston, Spokane; R. C. Gemmel, Salt Lake City; George A. Damon, J. B. Lippincott, Los Angeles; J. C. Greenway, Bisbee, Ariz.; J. J. Knoch, Fayetteville, Ark.; J. L. Harrington, Kansas City; T. U. Taylor, Austin, Tex.; F. A. Jones, Dallas; W. B. Gregory, New Orleans; Wilmer Waldo, Houston, Tex.; J. F. Coleman, Mobile; L. C. Datz, Birmingham; E. F. Scott, Atlanta; S. B. Earle, Clemson College, S. C.; C. E. Ferris, Knoxville, Tenn.

Roster of Delegates to the Conference and Societies They Represented

Following is a list of the delegates to the conference:

W. L. Abbott,	Am. Soc. Mech. Eng'r
W. C. Armstrong,	Eng'rs' Soc. of St. Paul and Minn. Surveyors' and Eng'rs Soc.
Warwick M. Anderson,	Eng'rs and Architects' Club of Louisville
Bion J. Arnold,	Soc. Automotive Eng'rs
A. S. Baldwin,	Am. Soc. Civil Eng'rs
W. D. Blair,	Am. Inst. Architects
E. G. Bradbury,	Eng'rs Club of Columbus and Ohio Engineering Soc.
Baxter L. Brown,	Eng'rs Club of St. Louis
Chas. Brossman,	Indiana Eng'rg Soc.
Webster B. Bushnell,	Eng'rs Club of Quincy
J. P. Channing,	Mining and Metallurgical Soc. of America
H. H. Clark,	Ill. Gas Ass'n and Am. Steel Treaters' Soc.
Louis Clousing,	Eng'ng Club of Minneapolis
F. K. Copeland,	Am. Inst. Mining and Met. Eng'rs
W. W. DeBerard,	Eng'ng Committee, Chicago Ass'n Commerce
Geo. C. Dent,	Soc. Industrial Eng'rs
F. W. DeWolf,	Am. Ass'n State Geologists
C. E. Drayer,	Nat'l Drainage Congress
W. H. Emmons,	Geological Soc. America
Frederic H. Fay,	Boston Soc. Civil Eng'rs
W. H. Finley,	Am. Ass'n Eng'rs
H. G. Gardner,	Am. Soc. Refrigerating Eng'rs
Lloyd Orr Goble,	Soc. Constructors of Federal Bldgs.
S. A. Greeley,	Am. Public Health Ass'n
W. B. Gregory,	Louisiana Eng'ng Soc.
C. E. Grunsky,	Pacific Ass'n Consult. Eng'rs
R. B. Harper,	Am. Gas Ass'n
Chas. H. Hammond,	Illinois Soc. Architects
Jas. N. Hatch,	Struc. Eng'rs Ass'n of Illinois
John L. Harrington,	Eng'rs Club of Kansas City
W. K. Hatt,	Am. Concrete Inst.
Jas. Herron,	Cleveland Eng'rs Soc.
C. J. Hogue,	Oregon Soc. Eng'rs
W. H. Hoskins,	Am. Inst. Chem. Eng'rs
W. O. Hotchkiss,	American Ass'n State Highway Officials
W. H. Hoyt,	Eng'rs Club of Northern Minnesota and Duluth Eng'rs Club
Peter Junkersfeld	Nat'l Elec. Light Ass'n
W. G. Kaiser,	Am. Soc. Agricultural Eng'rs
Lewis H. Kenney,	Eng'rs Club of Philadelphia
Frank B. Knight,	Brooklyn Eng'rs Club
E. H. Lee,	Am. Ry. Eng'rs Ass'n and Soc. Terminal Eng'rs
D. B. Luten,	Scientech Club of Indianapolis and Indiana Eng'rs Soc.
C. H. Mayer,	Swedish Eng'rs of Chicago
E. J. Mehren,	Am. Road Builders' Ass'n
Leonard Metcalf,	Am. Water-Wks. Ass'n
E. C. Millard,	Am. Civic Ass'n
F. H. Newell,	Washington Soc. Eng'rs
A. T. North,	New York Soc. Architects
C. E. Paul,	Nat'l Lumbermen's Mfg. Ass'n
E. T. Perkins,	Illinois Soc. Eng'rs
Willard F. Pond,	Rochester Eng'n'g Soc.
W. B. Powell,	Eng'n'g Soc. of Buffalo
Isham Randolph,	Franklin Institute and Western Soc. Eng'rs
A. M. Richter,	Indiana Limestone Quarry Ass'n
W. A. Rogers, Edw. Haupt (alternate),	Assoc. General Contractors of America
W. F. Schulz,	Memphis Eng'n'g Club
E. C. Shankland,	Am. Inst. Consulting Eng'rs
C. E. Skinner,	Am. Inst. Elec. Eng'rs
Lloyd B. Smith,	Kansas Eng'n'g Soc.
Julius Stieglitz,	Am. Chem. Soc.
F. W. Ullius,	Eng'n'g Soc. of Wisconsin
F. A. Vaughn,	Illuminating Eng'n'g Soc.
B. C. Wheeler,	Portland Cement Ass'n
G. S. Williams,	Detroit Eng'n'g Soc.
Sylvester N. Williams,	Iowa Eng'n'g Soc.

Engineering Council:

C. E. Skinner	Philip N. Moore
C. F. Loweth	M. E. Cooley

N. A. Carle

National Service Committee:

Charles B. Burdick	M. O. Leighton
E. J. Mehren,	*Engineering News-Record*

On the following pages will be found the introductory remarks by Mr. Channing and the report of the National Service Committee on the projected department:

Introductory Remarks at Conference on the Proposed Department of Public Works, by J. Parke Channing, Chairman of Engineering Council

This is the latest of a large number of conferences called together during the past half century for the purpose of considering and prosecuting a plan for a national department of public works.

The plans wrought by previous conferences have in many cases been admirably conceived, but they have come to naught for several reasons, the controlling one being that the engineers, architects, builders and constructive thinkers of the country have not given united support and have exerted no strong and persistent push behind the movement.

This conference is in many respects the greatest that has ever been brought together to consider an engineering project, being a conclave of 74 organizations representing a total strength of 99,304 men [revised figures put it at over 100,000], not mere idealists and exhorters given to the exploitation of intangible ideas, but practical, flat-footed men who know what they want and are accustomed to achieve. When we say that this is the latest of a series of conferences, we hope that if we are of determined mind this conference is the last that will be needed.

The last few months have created new conditions and emphasized new necessities—we shall never again tread the paths we trod two years ago; that the changes and reforms that we considered merely desirable then have become the real necessities of the present; that in the present and future urgencies and complexities our Government and our people can, if they would survive, tolerate only those methods and policies that are the most efficient, most business-like and most purposeful and must tear asunder from those which, however old and revered, are but the expedients of a former time inadequately expanded to render present-day service.

Our Government has become the greatest industrial plant in all history—investigating, surveying, building and operating—and its various functions are being conducted with practical independence one with another, and with so little coördination and so complete a lack of common purpose that practically the only occasions when the various elements become conscious of each other is when they overlap and attempt to crowd each other off the map; that any private or corporate business conducted according to the methods of Government would speedily become bankrupt and would deserve such fate. There are twelve Federal organizations engaged in making surveys, more than a score in chemical investigations, some of them competing and quarreling for preference under the same departmental roof. In the Congressional Directory there are listed 29 bureaus and agencies of Government engaged in construction of one or another kind. Four Government departments are engaged in fuel tests, while four Government bureaus are maintaining coast fleets each independent of the other, in the same waters, and engaged in work that has so many points of contact that not one person in twenty realizes that they are separate. These are only a few illustrations of a condition which can be tolerated by no considerate person.

We have come together, each qualified in his own line, to render service to the people, to point out the wastes and extravagances, the chaos and inefficiencies, and to offer some sane and practical solution to the country—so practical and so self-evident that it will carry its own conviction. To do this it will be necessary for each delegate to bear an open mind, and, while expressing freely the convictions that are his, to take part in that mutual concession which alone can bring concerted action among full-grown men.

Engineering Council has invited these conferees to meet for a common purpose and extends welcome, but it does not seek to dominate the deliberations—not even claiming the right to send a voting delegate. As chairman of the council I merely call the conference to order and preside until it effects its own organization.

Report of National Service Committee on the Project for a Department of Public Works, Presented by Philip N. Moore, of St. Louis

For a generation the dream of the civil engineers of this country, using the word in its ancient contrast with the first known form of the profession, represented by our military brethren, has been that one great department of our executive government, under the trained control of an experienced engineer, might achieve charge of all the nonmilitary engineering tasks of the nation. Time and again great engineer presidents, from their official pedestals, in salutatory and valedictory have voiced this vision. Time and again civilian subordinates doing civil-engineering work under military domination have raised their protests and complaints in the professional press and at our gatherings.

But, due to increased specializing of the profession and the engineer's desire, after he differentiated himself, to foregather with his colleagues, he has multiplied societies; and, while increasing their dividends to himself in personal acquaintance, relative influence and gratified vanity, he has not built up any organization with sufficient political potence to achieve in legislation the ideals of the profession.

Of the merits of some plan that shall coördinate under one head the vast engineering activities of the United States Government which now function through a dozen or more bureaus, directed by six secretaries, there will probably be in this meeting few opponents.

That opponents will be found elsewhere, fortified in power, we who favor shall soon realize.

Time Opportune for Realization

Never before were conditions so favorable for realization of this ideal. Reconstruction is a common thought and word. Engineers have borne a great and honorable part in the closing contest. Never before have their services been so publicly and generally recognized. Never before has there been so keen realization of the complexity and unsystem of engineering bureaus of the Government. Bureaus which in the past have competed with one another and grasped jealously for new activities and accompanying appropriations now approve a more logical system, while realizing that unification must leave some heads without bureaus.

Even one cabinet minister, head of more civilian engineers than any other officer in the world, has expressed the opinion that the change is not alone logical and economical but inevitable.

More than two years ago the United Engineering Society, representing the four great national bodies of the profession, with headquarters in New York, established a committee representative of all four to deal with all public matters affecting the engineering profession at large, to be called Engineering Council. That council, serving at first as a convenient referee for all the crank propaganda which came to the founder societies, and spending hours of its supposedly valuable time in saying "No" to impossible propositions, limited in its constructive work by financial resources so narrow that it could scarcely buy a new broom with which to sweep the ancient cobwebs from the windows of the engineering structure, where they had been accumulating since the days of Leonardo da Vinci, at last determined on a constructive task of the first order.

There was established a National Service Committee, with headquarters in Washington, for the purpose of finding opportunities of service to the nation on the part of the organized profession.

It chose ts first task—the establishment of a national department of public works. Such action has, of course, met criticism. Particularists unfortunately abound among engineers. Possibly the intense specialization of our training inevitably leads that narrow way; but one of the penalties thereof, equally inevitable, is restricted vision. Disregarding such protests in the interest of the profession at large (enabled by the generous and broadminded underwriting of one of our far-sighted brethren), the National Service Committee is functioning.

Its first effort to that end is the gathering to which I have the honor of speaking. If I be not mistaken, it is more representative of the profession than any hitherto assembled. Upon its decisions, and upon the support of the societies which it represents, will depend the speed with which we achieve our object. Engineering Council seeks support of the entire profession throughout the nation. If the unanimously expressed will of the council be followed by the founder societies, it will offer membership to every dignified recognized engineering society in the United States, and thereby become the true and powerful voice of the profession.

If we undertake it forget not, gentlemen, tnat our task will be successful in direct proportion as it is patriotic and unselfish, and that results which may come to the profession, of dignity, of national recognition, and of reward, will come more surely if we conduct our campaign with dignity and unselfishness. Engineering Council has opened the way. It has undertaken the task; it has climbed the barbed fence of false ethics; and has put the profession squarely into the great field of national policies or, if you choose to call it, national politics. In that field grow thorns and briars, as well as good grain. Engineering Council has put the hand of the profession to a new plow. It will not look backward; it will plow no crooked furrows. Some of them may be shallow; some of them may be faulty; but, from that field, unless the speaker be mistaken, gentlemen, there will come a harvest of efficient grain, which, but for the service of the profession, would never have been planted.

Upon you, gentlemen, and on those whom you represent, will rest the result. From you must come the power which keeps that plow in the furrow. Without your support the tough clay of poverty or the ancient stumps of professional particularism and conservatism may halt it.

Unless your speaker be a false prophet, it can be halted only for a time. Under some other impulse, the action will be renewed. Coördination and simplification of the present complex situation in national service must come in the end. It can be delayed. It cannot be stopped. It is inevitable. It were better for the honor of the profession, for our own self-respect, that we, and we alone, carry it through. In your hands, gentlemen, the task abides. To its discussion, broadminded and without selfishness, the National Service Committee invites you.

Miami Conservancy Construction Work Not Damaged in Flood

A HEAVY storm over the valley of the Miami River in Ohio, Mar. 15-17, with a total precipitation of 3½ in., caused a sharp flood in the Miami River and its tributaries, where the conservancy district flood-protection works are now being built. The conservancy construction plans had from the start been developed in such a way as to take account of the likelihood of floods of every magnitude (up to that of the extreme 1913 flood); the five dams of the project are the critical points, both with respect to damage to the work under construction and damage to the property in the valley, while the levee and channel-widening operations are a minor factor. The precautions taken in the planning proved to be ample for all conditions imposed by the March flood. A description of the storm and of its effect on the work in progress is given in the April, 1919, issue of the *Miami Conservancy Bulletin.*

Forecaster and flood-warning service provided by the district gave effective notification of the coming storm and probable flood to the construction offices and to the communities and inhabitants of the valley. All construction plant was promptly made safe or, as in the case of excavators in exposed positions, moved back to safer ground.

Pump installations at the construction cofferdams were in most cases so low that the motors were likely to be flooded. Provision for this risk had been made at the time of building the pump houses, by setting beams over the motors so that at any time these machines could be lifted up above flood level. At Taylorsville this was done after the first 24 hours of rainfall, the motors being hoisted up 4 or 5 ft. and lashed in place. Elsewhere extra pumping was done to cut down excessive seepage through cofferdams and permit the resumption of concreting without delay.

The dragline excavators on channel work at Dayton and Hamilton, three or four of which were at work in the channel, were not underscoured or otherwise injured. Slight wash of the new levees occurred in both cities at the level of the top of the flood.

In substance, the effect of the flood upon the construction work was limited to producing from one to five days' delay in the operations, and calling for a small amount of extra work to make plant and materials safe before the water rose.

Reorganization of the Engineering Standards Committee

Effect of Engineering Standards Movement on Technical Societies—Reorganization to Give Broader Representation—Association May Be Formed To Elect the Committee—Formulating Safety Codes

By Edward B. Rosa
Chief Physicist, Bureau of Standards, Washington, D. C.

For the first time an explanation of the American engineering standards movement is presented to engineers. Dr. Rosa, to enlist general support of the movement, tells of the organization of the committee formed last October, and of its proposed broadening into an association. This proposal, now before the councils of the societies, is to be acted upon in the near future. Together with Prof. C. A. Adams and H. W. Forster, Dr. Rosa served on a committee which prepared plans for consolidation of the safety-code conference with the standards committee. Having been intimately concerned with all phases of this planning, he writes from the fullness of knowledge. In the absence abroad of Professor Adams, the leader in the standards committee movement, no more commanding utterance on the subject could be offered to engineers than the present.—Editor.

Two recent editorials in *Engineering News-Record* (April 10 and 17, 1919, pp. 700 and 751) discuss the relations of engineering societies to the American Engineering Standards Committee, particular reference being made to the American Society for Testing Materials. The suggestion is made that the influence upon this and other societies of the Engineering Standards Committee, especially as it is proposed to be reorganized, would be harmful, and that these societies would do well to reconsider their action in establishing this committee.

If participation in the work of the committee and closer coöperation with other engineering bodies should lead to a decline in the influence and usefulness of the American Society for Testing Materials, it would be unfortunate; if it had the same effect also on all the other strong and useful engineering societies concerned, it would be a calamity. But I believe the result will be the opposite, and that these societies will be strengthened, and not injured. Without question, the work of engineering research and standardization in this country will receive a powerful impetus if the present plans for the reorganization of the American Engineering Standards Committee are approved by the founder societies and carried out in the spirit in which they are conceived. Unfortunately, these plans, so very recently formulated, are not yet generally understood.

Principles of the Standards Association

The cardinal principles of the proposed American Engineering Standards Association are fair play and coöperation. Each society retains its integrity and initiative, and yet recognizes the existence and the rights of others; each society or Government body manages certain work of research and standardization itself as now, but with the coöperation of representatives of other agencies invited to participate because of their interest in the subject and the information they can furnish. The practicability of this method of standardization has been abundantly demonstrated by the American Society for Testing Materials itself, as well as by the American Institute of Electrical Engineers, the Society of Automotive Engineers and other engineering bodies. Indeed, one can truly say that the procedure of the proposed new organization is almost identical in principle with that of the American Society for Testing Materials, but expanded and applied to a large number of organizations acting in harmony, with a definite method for preventing or dealing with conflicts, and with a democratic spirit pervading the whole.

Need for a Coördinating Agency

The authority of the American Society for Testing Materials and other societies, which they enjoy by virtue of the representative character of the men composing their committees and the quality of their work, will remain undisturbed by the new organization. The Engineering Standards Committee will approve a standard because it is certified by some sponsor society and its coöperating committee, not because the central committee has itself examined it and passed an independent judgment upon it, which that committee will not attempt to do. The quality standards of the American Society for Testing Materials, the electrical standards of the American Institute of Electrical Engineers, the codes and standards of the Bureau of Standards, will derive their authority largely from the reputation of the sponsor bodies that prepare and certify them. They will, however, possess the added advantage that the Engineering Standards Committee, made up of representatives of all engineering and commercial interests and the Government, will certify that the procedure of the committee has been complied with, that all interests concerned have been heard and there is every reason for accepting the sandard and putting it into general use. This guarantee by a thoroughly competent and authoritative body will be worth much, even in the case of the strongest societies and Government bureaus.

In addition to a few conspicuous societies and Government departments concerned in the making of standards, there are scores of others that coöperate in and to some extent initiate such work. Heretofore each has had to find out for itself what work other societies were doing or contemplating, and establish connections as best it could for coöperation or for adjusting matters of conflict. There has been no central agency to keep a record of all standardization work in progress or being organized, to assist in securing the proper degree of coöperation and to avoid conflict and duplication of effort. The need for such a central coördinating agency has been felt for years; it was only a question of how it should be realized. The present committee has not yet attempted to meet this need. The reorganization proposed looks toward accomplishing this important result in an adequate manner.

The British Engineering Standards Committee has been in successful operation for a number of years and

has been carefully studied by American engineers. It largely initiates research, appoints the chairman of the committee for a particular piece of work and nominally, at least, supervises the work. It was generally agreed that conditions here in America favored a different method of procedure. Engineering and commercial organizations and Government departments were already active in standardization work, and were in many cases coöperating in a very satisfactory manner with one another, as has been pointed out by *Engineering News-Record*. It was desirable to continue and extend the methods that had been found successful rather than to set up a new method.

The procedure adopted by the American Engineering Standards Committee leaves the initiation and management of the work, and the selection of the coöperating committee, with the sponsor society. This sponsor society may be any responsible agency competent to do the work and entitled to do so by virtue of its relation to the subject. The Standards Committee advises and approves, and having done so will support and encourage the sponsor body in its work. But it does not control the sponsor body, and should not in any way embarrass it.

Reasons for Reorganization

The present Engineering Standards Committee is composed of 15 men of the highest standing who represent five leading engineering societies; it was planned also to have representatives of the Government. If no one objected to having so restricted a committee perform the important functions of coördinating and encouraging engineering standardization by all private and Governmental agencies, and dealing with similar organizations in other countries on questions of international standardization, there would have been less occasion to reorganize the committee.

To be sure, a larger representation would secure a more generous financial support and better coöperation in creating standards and getting them into use. Nevertheless, if everybody was satisfied and the small committee had the confidence and good will of all the interests concerned, and was willing to give it the requisite amount of time, it could have gone along with its work successfully and satisfactorily. It appeared, however, that such was not likely to be the case.

Ours is a democratic country, and this is a democratic age. We believe in equitable representation. To be successful in the performance of its important functions an engineering standards committee should be representative of all the interests concerned and should be supported by a strong public sentiment.

This, it appeared, could only be secured by giving representation to all organizations and Government departments interested in the preparation of engineering and industrial standards. The larger societies should, of course, have a larger number of representatives than the smaller. Since there are many scores of societies and Governmental agencies that may be expected to desire representation in such an organization, it would obviously soon become too large for a working standards committee. The evident procedure was to call the large representative body an association instead of a committee, and let there be formed within the association a standards committee.

The association should then be subdivided into groups or divisions. The details of such subdivision have not been agreed upon, but for the sake of a clear conception of the work of the association there can be no harm in describing one plan that was submitted to the committee for consideration.

Suggested Divisions of the Association

According to this plan, there would be 10 divisions of engineering and industrial organizations and two representing the Government, as follows:

1. Electrical engineering and electrical industries.
2. Mechanical engineering and allied industries.
3. Mining and metallurgy and allied industries.
4. Civil engineering, architecture and building.
5. Chemical engineering and chemical industries.
6. Materials of construction (A. S. T. M. division).
7. Miscellaneous manufactures.
8. Steam and electric transportation.
9. Automobiles, aircraft and other automotive vehicles.
10. Fire protection and safety engineering.
11. Federal bureaus and commissions.
12. Associations of state and municipal agencies.

The divisions would contain in some cases five to 10 and in other cases as many as 20 or more national societies and manufacturers' organizations having a certain common interest. Two or three examples of such divisions may be mentioned, to illustrate its working.

Electrical Division—There would be from 10 to 20 national engineering societies and manufacturers' organizations in the first division, of which the Amercan Engineers is most conspicuous and most active in matters of electrical standardization. Its Standards Committee has a splendid record of achievement and carries on its work in a spirit of fair play and coöperation. The institute invites into its Standards Committee as coöperating members representatives of the Illuminating Engineering Society, the Institute of Radio Engineers, the Electric Power Club, the Bureau of Standards, and other organizations having an interest in the subjects covered by its standardization rules. Sometimes general agreement is difficult to secure; in such cases discussion and study of the question are continued, investigations are undertaken if necessary, and the subject is not considered settled until substantial unanimity is reached. Some of the members of the committee represent large or small manufacturing interests, others are consulting engineers, college professors, Government officials. It would be difficult to find, anywhere, a finer example of a standards committee which is thoroughly representative, competent, energetic and imbued with high ideals.

If the standards association comes into existence with its central standards committee, the committee of the Institute of Electrical Engineers would go on with its work just as now, reporting to the board of directors of the institute as heretofore. The board would approve the work and transmit it to the association for its approval, having previously submitted the names of the men representing other organizations which sit in its Standards Committee, so that it would be evident that all interests are represented and that standards prepared by such a committee deserve to be approved and to be labeled "American Standards." In fact, the procedure of the American Engineering Standards Committee was devised expressly with this in view, for it was recognized that any requirement that seriously embarrassed the work of the large engineering societies would be fatal to the success of the movement.

(*To Be Concluded*)

Cost-Plus Contract Incentive To Close Management

Contractor Creates a Clientele of Customers and Not Merely a Chance to Bid Again, Says Prominent Cost-Plus Advocate

(Editorial Interview)

IS THERE a greater incentive to good construction management in the cost-plus contract than in the lump-sum contract? Discussing this question with the editor, Morton C. Tuttle, of the Aberthaw Construction Co., developed a line of thought which, though possibly not new, will repay attention by contractors. For the concern performing the whole or a large part of its work on a cost-and-profit basis, there is, asserted Mr. Tuttle, a tremendous incentive to satisfy each engineer or owner for whom work is done. Then he continued:

It is clear that the anxiety which a contractor feels for his own financial interests may vary greatly as between a lump-sum and a day-work contract. If he is satisfied to do one job for one customer and to leave that customer dissatisfied, he undoubtedly has a chance on a cost-plus contract to pile up cost, and, short of provable negligence, will be reimbursed for all expenses incurred. At the end of the job he will receive the agreed profit and will be left with an impaired good-will. A few repetitions of this situation should remove him completely from the field of cost-plus work. It is inconceivable that large jobs will be placed with any contractor until after his references have been thoroughly looked up.

One dissatisfied customer will prevent a great deal of future profit. In one case which has received rather wide publicity a dissatisfied customer had a considerable part in ultimately bankrupting a once prominent building concern

Builds Up a Clientele—It is apparently not clearly understood in the building trade that a reputation for carrying on honestly and successfully—and, above all things, economically—a cost-and-profit business leads to the establishment of a clientele of customers who turn all their work to a concern which has once satisfied them. In the case of my own company 58% of our business in the past five years has come from concerns for which we have worked before, and very commonly we do all building work for many of these customers. Had our business been done on a bid basis we should have earned with each of these customers simply a chance to bid again. To establish business relationships as intimate as this, leads necessarily to vigilance as to each detail of every operation. A concern carrying on cost-and-profit work primarily must be honest, and it must have vision enough to understand the necessity of carrying on its work satisfactorily to each and every engineer and owner. It is so easy to start a reputation for extravagance, for inefficiency or for careless workmanship that vigilance has to be exercised at all times. To allow slackness on any one job, or to allow higher costs than are justifiable, would be suicide.

The two types of contract are really difficult of comparison. Under the percentage form of contract it will be assumed that the engineer or architect has specified exactly what he wants and is entitled to exactly that which he has described. Under the lump-sum form of contract an attempt is commonly made to see how far it is possible to depart from the more expensive items specified. The questions of allowances and extras are always troublesome and generally are not frankly handled. With the lump-sum contract there is a tendency to give less thought to the quality of the work and more thought to the first cost—a procedure which shows up later in the cost of upkeep. With the lump-sum contract there is less coöperation between the engineer and the builder, a condition which has again and again resulted in needless expense, loss and faulty workmanship.

That the quality of work should be better under the cost-plus form of contract is undoubted. As to cost, it would be interesting to see a tabulation showing the bid prices and the final costs of, say, twenty-five jobs. Very commonly the original bid and the final cost would not be recognizable as applying to the same work.

No Perfect Lump-Sum Contract—Some day, so close to the millennium that the question of building shelters may be neglected, some engineer or some architect will make an absolutely clear set of plans and specifications which will describe accurately some big job from start to finish. Then he will invite a limited number of perfectly honest and perfectly competent contractors to make independent and honest estimates, each estimate to contain a reasonable item of profit, and with these estimates will come an honest statement of the length of time each of these contractors will require to carry out that work. Under these conditions, we shall all agree, the lump-sum contract is a most excellent thing because an honorable concern has employed an infallible engineer and architect to describe exactly what it will require and an honest and able contractor has agreed to furnish these things, and has assured himself of a reasonable profit for furnishing them exactly without substitution.

Until this combination is secured there will be a good chance to argue with any owner that he is more likely to get what he wants in the time in which he wants it by some arrangement which secures the coöperation of his contractor with his engineer, with the assurance on the part of both that they will be reasonably compensated for the work that they do.

Efficient Labor Due to Efficient Supervision—The common explanation of any slackness of labor on a cost-plus job is that the laborers know that their employer's interest will not suffer if they loaf upon that particular job. To anyone familiar with the building trade, how much anxiety labor feels toward the financial interests of its employer is a subject for profound speculation.

As to the performance of the labor under the two forms of contract, it seems reasonable to suppose it will produce the most economical and satisfactory results on the job where it is best directed and best led, regardless of the contract arrangements. C. S. H.

British Women Engineers Organize Union

British women engineers, one of the war discoveries, have banded together in the Women's Engineering Society, a trade union. The women want, among other things: Admission to the Amalgamated Society of Engineers; to become members of institutes of civil engineers, naval architects, iron and steel and other bodies now closed to women; to serve on the boards of universities, and to become eligible for technical branches of the higher civil service.

A New Principle in the Theory of Structures

Professor George F. Swain Gives Formula for Computing the Rotation in Elastic Distortion Similar to That for Deflection

MAKING use of the principle underlying the Maxwell reciprocal theorem, Prof. George F. Swain of Harvard University gives in the March issue of the *Proceedings* of the American Society of Civil Engineers, p. 75, a new formula similar to that by which the deflections of trusses and other frames are determined, but defining distortional rotation instead of deflection. Like the deflection formula, it may be used in connection with the problem of computing the stresses in constrained (statically indeterminate) frames, by first computing the distortion when the constraint is removed and then finding the moment required to neutralize this distortion. The formula is simple and easily remembered, being a close analogue of the deflection formula.

As first published in this country by Professor Swain in 1883 (in the *Journal of the Franklin Institute*), the formula for deflection at any point of a frame is

$$\Delta = \Sigma \frac{stl}{EA}$$

in which t = stress in a member due to a load of unity acting at the point whose deflection is desired, and acting in the direction of that deflection;

s = stress in the same member from the actual loading.

l, A, E = length, sectional area and modulus of elasticity of the member.

In the case, for example, of an arched roof truss over an assembly hall, where it may be desired to find the horizontal movement of the expansion end due to the loads on the truss, the procedure would be as follows: Apply a horizontal outward force of 1 lb., at the two ends of the truss, and find the stress in each member due to this force, calling such stress t; compute the stresses in the several members under the actual roof loads and call them s; then obtain the product stl for each member, divide by the sectional area and by the modulus of elasticity, and add the resulting figures for all members of the truss. The result will be the horizontal outward deflection of the truss in inches, provided the lengths of the members, l, were taken in inches.

The method implied by this formula is applicable also to solid members in flexure; for this case, if M_t is the bending moment at any section caused by unit force acting at the point of deflection in the direction of the desired deflection, M_s is the bending moment at the same section due to the actual loads, and I is the moment of inertia of that section, then

$$\Delta = \int \frac{M_s M_t dl}{EI}$$

The New Formula—When the angular rotation of any point in a member or a frame is to be computed, the new formula now proposed by Professor Swain furnishes a means. The formula in its simplest form is

$$\alpha = \Sigma \frac{rsl}{EA}$$

in which r = stress in any member of length l and cross-section A produced by a couple of unit moment acting at the point whose rotation is desired and in the direction of the desired rotation;

s = stress in the same member produced by the applied loads.

The formula is derived as follows: Apply at the point of rotation a unit moment, and consider the (external) work expended by this moment in rotation. It equals the product of the moment by half the rotation α_1 (in angular measure), since the moment is bound to increase uniformly from zero to its full value of 1 as the distortion comes into existence; or $W_e = \frac{1}{2}\alpha_1$. The work of the internal forces must be just equal to this amount. If r is the stress in any member of the structure caused by this unit moment, and Δl_1 its change of length, then the internal work of that member will be $\frac{1}{2}r\Delta l_1$, and the total internal work for all members will be $W_i = \frac{1}{2}\Sigma r\Delta l_1$. Equating this to the external work,

$$\tfrac{1}{2}\alpha_1 = \tfrac{1}{2}\Sigma r\Delta l_1, \text{ or } \alpha_1 = \Sigma r\Delta l_1$$

It follows that under the action of this unit moment the rotational distortion α_1 due to the deformation of *any one member alone* is $\alpha_1 = r\Delta l_1$. However, there is a purely geometrical relation between the angular rotation at the point of the structure in question and the change of length of any member, irrespective of the kind of loading. Therefore the change of length produced in that member by any other system of loading will bear the same proportion to the resulting rotational distortion as in the above expression. Then if the change of length Δl due to the actual loads on the structure be substituted for the value Δl_1, the angular rotation α_1 due to unit moment may be replaced by the actual rotation α due to the actual loading, or $\alpha = r\Delta l$. Now the change of length Δl under the actual loads, which produce the stress s in the member, will be $\frac{sl}{AE}$, and upon inserting this value in the preceding expression,

$$\alpha = \frac{rsl}{EA}$$

Summing this expression for all members of the structure the result is the total actual rotation of the point in question, or

$$\alpha = \Sigma \frac{rsl}{EA}$$

In this expression r is the stress on the member of length l and cross-sectional area A produced by a couple of moment unity acting at the point whose rotation is desired, while s is the total stress in the same member due to the applied loads.

As here demonstrated, the formula applies only to the case of direct (axial) stress in every part of the structure. For the general case, where there is bending as well as direct stress in any or all parts, the quantities r and s must be expressed by the products of the actual unit stress at the different points of each cross-section of the member multiplied by the element of area; for example, when the direct stress is T_s and the bending moment M_s, the product in question for a point at distance y from the neutral axis of the cross-section is

$$s = \left(\frac{T_s}{A} + \frac{M_s y}{I}\right) dA$$

and similarly for r. Inserting these values in the above equation and carrying out the multiplication, it will

be found that certain terms of the result vanish because the integral of $y\,dA$ is zero for an axis passing through the center of gravity of the cross-section (the value of the moment of inertia, I, is of course also computed around a gravity axis). The final result is

$$x = \Sigma \frac{T_s T_r l}{EA} + \Sigma \int_0^l \frac{M_s M_r dl}{EI}$$

Because of the way in which the products of the direct stresses under actual and hypothetical loading, and the products of the corresponding moments, appear in this equation, it is evident that the *flexure in any member of the structure may be neglected unless* both the actual loads and the hypothetical unit moment cause flexural stress in it. Similarly, the *direct stress in any member may be neglected unless* both the actual loads and the hypothetical unit moment produce a direct stress in it.

When every member is uniform in cross-section from end to end, the integral sign in the first member of the above expression disappears, and the differential dl is to be replaced by l, the length of the member.

Several illustrations of the application of this principle are given by Professor Swain. One of these may be cited here to aid in understanding the formula.

To find the slope at the right end of a beam of constant cross-section loaded with a single concentrated load P at a distance a from the left end, the span of the beam being l. The left-hand reaction will be $P(l-a)/l$, and the moment at any section to the left of the load, at a distance x from the left end, will be $M_s = Px(l-a)/l$. Similarly, in the right-hand segment of the beam the moment is $M_s = P(l-x)a/l$. For an applied unit moment (anti-clockwise) at the right-hand end, balanced by appropriate vertical reactions of $1/l$ at the ends of the beam, the moment at any point of the beam will be $M_r = x/l$. Using these values in the formula, the first term disappears because there are no direct stresses to be considered. The rotation therefore is

$$\alpha = \int_0^l \frac{M_s M_r dl}{EI} = \frac{1}{EI}\left[\int_0^a \frac{Px(l-a)}{l}\frac{x}{l}dx + \int_a^l \frac{P(l-x)a}{l}\frac{x}{l}dx\right] = \frac{1}{EI}\left[\frac{P(l-a)}{l^2}\frac{a^3}{3} + \frac{Pa}{l^2}\left(\frac{l^3}{2} - \frac{la^2}{2} - \frac{l^3}{3} + \frac{a^3}{3}\right)\right] = \frac{Pa}{6EIl}(l^2 - a^2)$$

Other cases of beams, and cases of trusses, may be dealt with just as simply.

Six Years of Rapid-Transit Progress in New York

Construction Enterprise Greater Than Panama Canal Carried On at Remarkable Rate Despite War Interference—Over Four Times as Much Work Accomplished as On Old Subway

By D. L. Turner

Chief Engineer, Public Service Commission for First District, New York City

In the six years since the signing of the dual contracts for rapid-transit construction and operation in New York City, the system involved in those contracts has been nearly completed. In terms of total cost for labor and material of city-owned lines (excluding car-storage yards) it is approximately 86% complete; in terms of excavation on city-owned lines, the largest single item of expense in subway construction, 97½% complete; in terms of steel, the largest single item of material, 90% complete. Of the entire mileage, 95% is under contract and 70% of the total track mileage to be constructed or reconstructed is now in operation.

Approximately as much newly constructed track has already been put in operation as was being operated in 1913 in the subway and on all elevated lines in New York and Brooklyn combined.

Under the most favorable conditions this would be a noteworthy accomplishment. But when it is remembered that one year and four months after the dual contracts were signed the world war began, and that for one-third of the six-year period this country has been a participant in the world's greatest war, involving as it did the almost immediate and complete diversion of all kinds of material and manpower to war work, the achievement is nothing short of remarkable.

Old and New Rapid Transit Systems—Under the dual contracts, signed Mar. 19, 1913, six years ago, the city entered into a partnership with two rapid-transit companies whereby city and companies joined in the con-

struction of new subways and elevated railways, and in the third-tracking, reconstruction and extension of the existing elevated lines, with provision for pooling receipts and expenses and sharing net returns on the entire unified systems (excepting only the old tracks of the Manhattan elevated lines). To protect the city's interests in this partnership arrangement the Public Service Commission was charged with the direct and full supervision of the construction of all city-owned

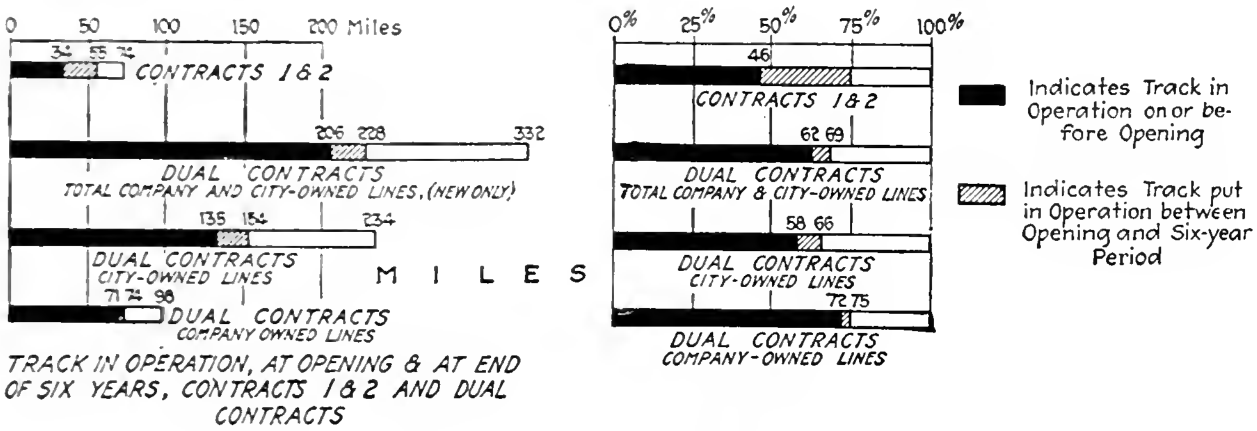

FIG. 4. COMPARISON OF WORK ACCOMPLISHED IN SIX YEARS, 1900-1906 AND 1913-1919

Contract No. 1 signed Feb. 21, 1900; opening, Oct. 27, 1904 or $4\frac{2}{3}$ years after signing. Dual contracts signed Mar. 19, 1913; opening of "H" system, Aug. 1, 1918 or $5\frac{1}{3}$ years after signing. The diagram does not include the trackage on the East River bridges and sections of the Fourth Avenue (Brooklyn) subway and Centre Street Loop under contract prior to Mar. 19, 1913.

lines and a general supervision of all company work, which included reconstructing, third-tracking and extending the company-owned lines, and equipping the entire system. The magnitude of this project and the progress which has been made in the six years since the signing of the contracts are illustrated by the accompanying maps, diagrams and tables.

Six years ago, on Mar. 19, 1913, there were in operation about 273 miles of track on all the rapid-transit

TABLE I. NEW YORK'S RAPID-TRANSIT SYSTEM IN 1913 AND AFTER COMPLETION OF DUAL CONTRACT LINES (EXCLUSIVE OF YARDS AND SIDINGS)

Lines in Operation Mar. 19, 1913	Miles Single Track
City-owned subway and elevated extensions operated by Interborough Rapid Transit Co.	74
Manhattan elevated lines	93
Brooklyn Rapid Transit Co. elevated lines	106
Total, all rapid transit lines	273
New Rapid-Transit Lines According to Dual Contracts	**Miles Single Track**
Company-Owned Lines	
Manhattan elevated lines, third-tracking and extensions	24
Brooklyn elevated lines, reconstruction, third-tracking, and extensions	74
Total, company-owned lines	98
City-Owned Lines	
For Interborough R. T. Co. operation	146
For New York Municipal Ry. Corporation (B.R.T.) operation	119
Total, City-owned lines	265
Grand total under the dual contracts and related certificates	363

lines. Under the dual contracts and related certificates provision was made for about 363 miles of additional track. Both systems are itemized in Table I. The total track mileage on the entire rapid-transit systems will be approximately 616 miles of single track. To illustrate by a comparison with familiar distances, the subway and elevated lines being constructed under the dual contracts are about equivalent to a two-track subway and elevated line from New York to Baltimore or more than a similar four-track line from New York to Philadelphia. The total system (including old and new lines) when complete would form approximately a four-track line from New York to Philadelphia with a two-track extension to Washington. The diagram, Fig. 1, shows graphically the relative magnitude of the project compared with the subway and elevated lines in operation six years ago, which had been constructed piecemeal over a period of nearly half a century.

As Compared With Panama Canal—Heretofore the Panama Canal has been considered our largest construction undertaking. As a matter of fact, the dual subway project, while not as romantic as the joining together of two oceans, surpasses it in size and intricacy. It will cost more, and the engineering difficulties have been greater and more complex. One of the great difficulties in the Panama Canal construction was the sliding of earth into the canal after the excavation had been nearly completed. To picture the relative difficulties of the two projects imagine the catastrophe that would have resulted from even a relatively small slide of earth into a partially completed subway cut. Remember that the foundations of many buildings 20 or more stories in height have been rebuilt. Then add the fact that the subway construction has been carried on under the streets practically without interference with their use, so that few of New York's population passing daily over these streets have had a glimpse beneath the surface at the gas and water pipes, electric

TABLE II. TOTAL MILES OF ROUTE AND TRACK TO BE CONSTRUCTED UNDER THE DUAL CONTRACTS AND THE PORTION IN OPERATION MARCH 19, 1919 (EXCLUSIVE OF CAR STORAGE YARDS, SIDINGS, ETC.)

Including Centre Street Loop and Fourth Avenue (Brooklyn) Subway

	Total Track Miles	Total New Route Miles	In Operation March 19, 1919: Track Miles	Track %	New Route Miles	New Route %

RELATIVE PROGRESS IN PLACING TRACK IN OPERATION, OLD SUBWAY AND DUAL CONTRACT SYSTEM

FIG. 5. NEW RAPID-TRANSIT LINES PLACED IN OPERATION PROGRESSIVELY DURING CONSTRUCTION PERIOD

Contracts Nos. 1 and 2 include old subway from Atlantic Avenue to Bronx Park and Van Cortlandt Park.

conduits and other structures which had to be maintained in constant use in order that the life of the city might go on unaffected by the gigantic work progressing rapidly under its feet.

For construction, the city-owned lines were divided into 87 major sections, of which 83 sections, or 95%, have been contracted for (Fig. 2). Of the four remaining, the two sections of the Nassau St. line have been temporarily postponed on account of war conditions; one section, extending the Queensboro Subway to Times Square, could not be undertaken until after the opening of the main east-side and west-side subways (Interborough), and its beginning then was deferred because of the war; and on the fourth, the elevated extension of the 14th St. Eastern line, bids were received and rejected for lack of sufficient engineering force to supervise the work properly. Contracts for station finish and track have been let, and the installation of equipment by the companies has proceeded as rapidly as the progress of the work under the construction contracts permitted.

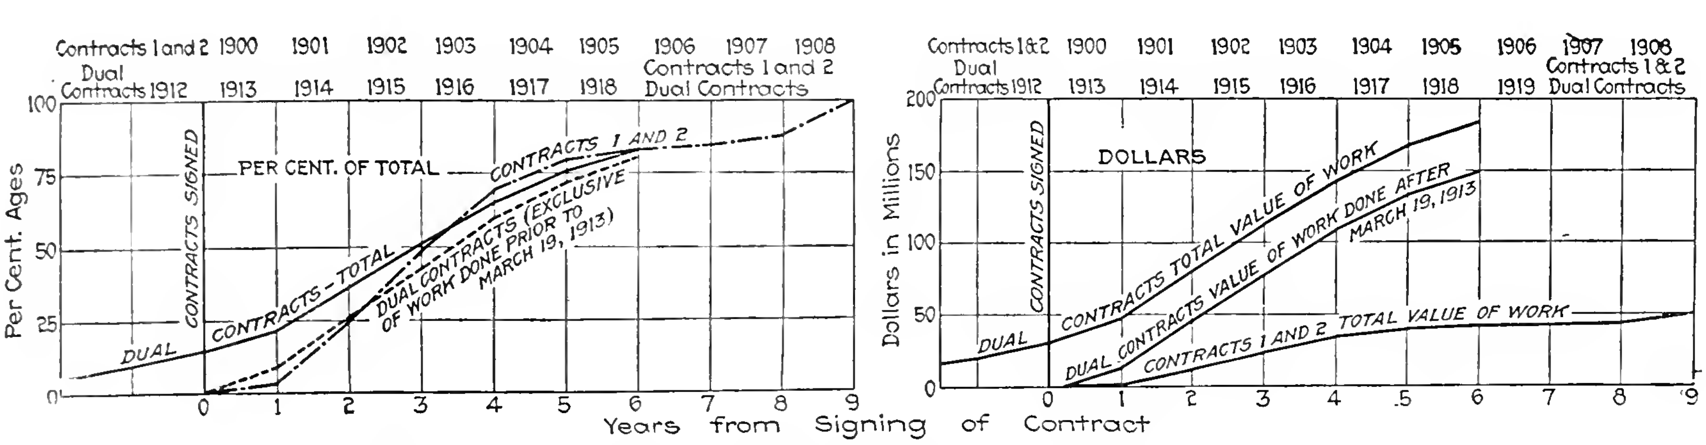
Expenditures to Dec. 31, 1918, for construction, additions, extensions and equipment (including interest and sinking-fund charges, superintendence, etc.), total about $375,000,000, which is between 80% and 90% of the total present estimated cost of all construction and equipment required for full operation under the dual contracts. On city-owned lines the expenditures for labor and material, the truest measure of progress of actual construction, total 86% of the entire estimated cost for these items, excluding car-storage yards, or 84%, including these yards.

A further idea of the actual advancement of the construction may be gained from the progress which has been made on two of the main items, excavation and steel. Excavation is by far the largest single item of expense in subway construction, and steel is by far the largest item of material entering therein (in elevated-railway construction the cost of steel is several times greater than the cost of all other items combined).

Excavation and Steel—Although one elevated and three subway sections have not yet been contracted for, the total excavation required for the city-owned lines is 97½% completed. The total excavation will be approximately 15,100,000 cu.yd. of earth and rock, excavated partly in tunnels under the river, partly in rock tunnels far below the streets, but chiefly immediately under the temporary street surfaces. This excavation is equivalent to a circular hole 3½ ft. in diameter 8000 miles long or a distance equal to the diameter of the earth, and the material excavated, if uniformly spread out over Manhattan Island, would form a layer nearly a foot deep.

The dual project, including city- and company-owned lines, when completed will have required the use of approximately 675,000 tons of steel, of which over 600,000 tons, or a little less than 90%, has already been delivered in New York. This steel would construct 21 buildings similar to the Equitable Building (the largest in the world) and to transport it would require approximately 30,000 cars, which would form a continuous train from New York to Washington.

Progress in placing lines in operation, in terms of miles of single track, miles of new route, and the percentage of each as compared with the total is shown in Table II. It should be noted in this connection that additional miles of track placed in operation indicate in a general way additional service, while additional route mileage indicates in a general way additional territory served.



VALUE OF LABOR AND MATERIALS ONLY — CITY-OWNED LINES

FIG. 6. VALUE OF WORK DONE, COMPARED FOR OLD AND NEW LINES

The figures given for city-owned lines operated by the New York Municipal Railway Corporation, as shown in the left-hand group, include the mileage across the Williamsburgh and Manhattan bridges and also the mileage in the Centre St. Loop and portions of the Fourth Ave. subway in Brooklyn which were under contract for construction when the dual contracts were auguration of the "H" operation on the Interborough system, which may be considered the formal opening under the dual contracts, occurred Aug. 1, 1918, 5⅓ years after the contracts were signed. That this opening was materially delayed by war conditions is beyond question and without doubt under normal conditions could have been advanced at least six months. It is therefore

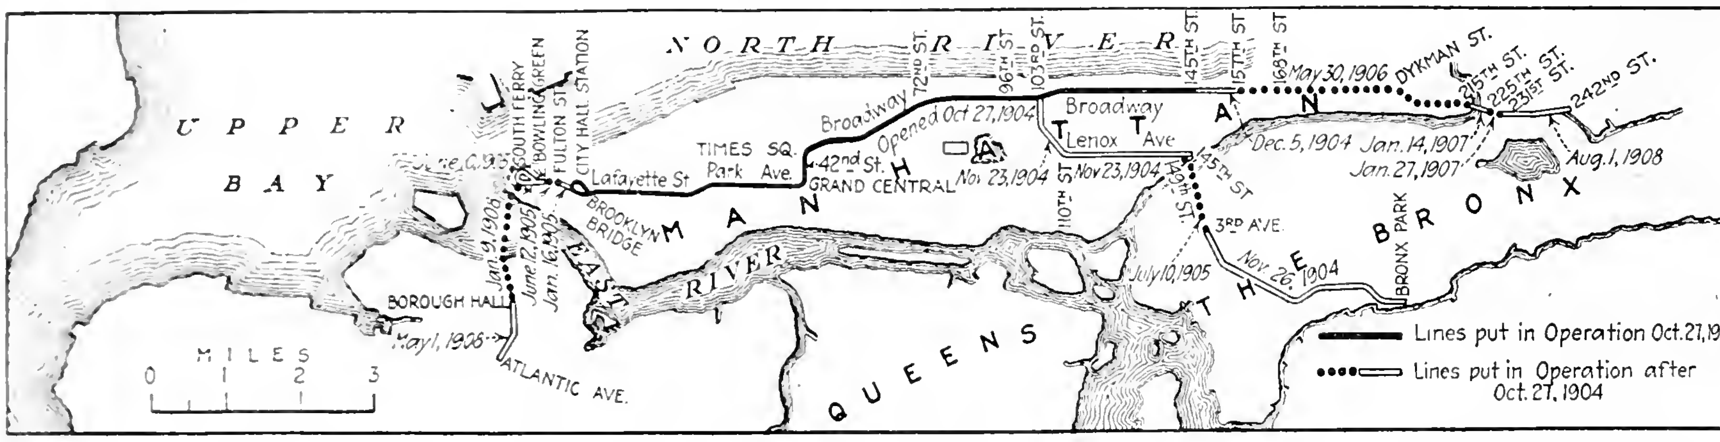


FIG. 7. MAP OF OLD SUBWAY (CONTRACTS NOS. 1 AND 2) WITH DATES OF OPERATION

signed. If these mileages are eliminated the totals and corresponding percentages are as given in the right-hand group.

In other words, of all the track to be constructed under the dual contracts, 70% is now in operation. The situation may be visualized by reference to the map of the dual system, Fig. 8.

On June 22, 1915, two years and three months after the dual contracts were signed, five miles of track, for which construction contracts were let during this period, were put in operation. From that date to the present time additional tracks have been put in operation at a fairly uniform rate, as shown especially in the diagram, Fig. 5.

Construction of the city's old subway, with 73 miles of track, extended over a period of more than eight years, but the formal opening was on Oct. 27, 1904, 4⅔ years after the contracts were signed. In-fair to compare the progress under contracts Nos. 1 and 2 for the 4⅔-year period with the progress under the dual contracts for the 5⅓-year period.

On Oct. 27, 1904, 34 miles of track were put in operation, approximately 46% of the entire project. On Aug. 1, 1918, 135 miles of track on city-owned lines alone (excluding the East River bridges and the portions of the Fourth Ave. subway and Centre St. loop which had been contracted for prior to the signing of the dual contracts) and about 71 miles of company-owned lines, or a total of 206 miles of track, had been put in operation. In percentages of total, 58% of city-owned lines, 72% of company-owned lines, or 62% on all lines, was in operation.

As a large section of track on contract No. 1 was put in operation soon after the opening, it might be fairer to compare these dual contract figures with the track in operation on contracts Nos. 1 and 2 two months

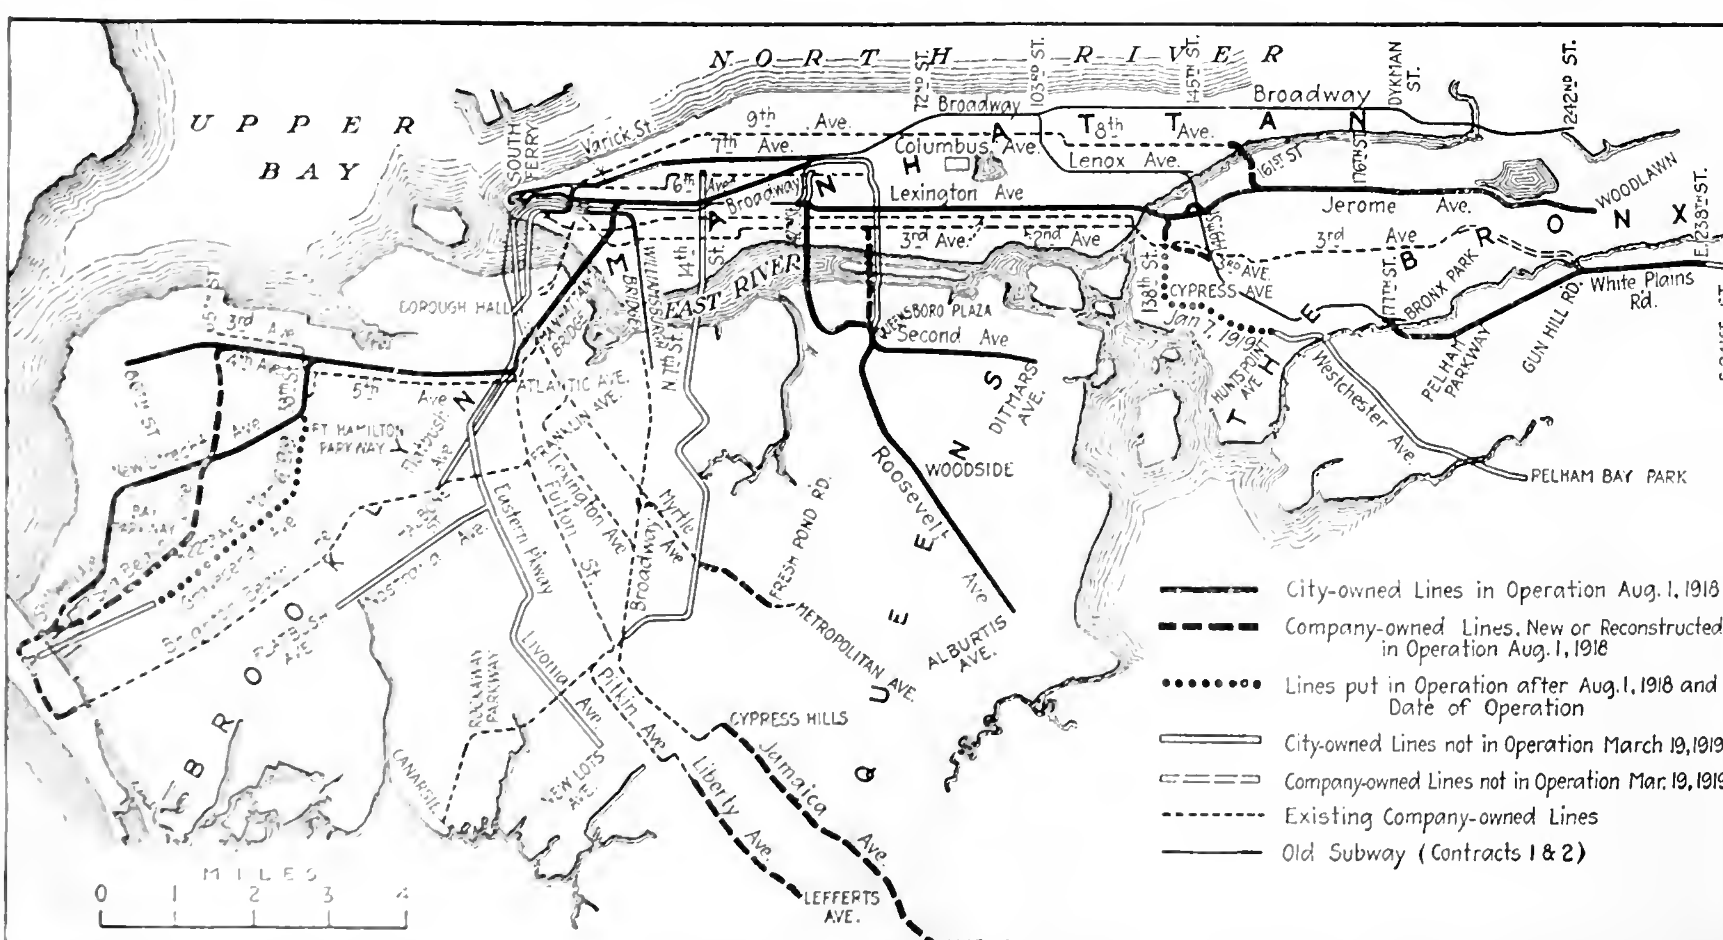

FIG. 8. NEW SUBWAY AND ELEVATED LINES, AND COMPLETED SYSTEM

after the formal opening, when 50 miles of track had been put in operation, or 68% of the total. More than four times as much track under the dual contracts was in operation as on contracts Nos. 1 and 2 for a corresponding period (although the percentage of the total was slightly less). A comparison of the maps showing the old and new systems (Figs. 7 and 8) will help to visualize the relative sizes of the undertakings and the relative progress in getting them in operation.

On Dec. 31, 1918, approximately $185,000,000 had been expended for labor and materials on city-owned lines under the dual contracts, or approximately 84% of the estimated total. On Dec. 31, 1905, the corresponding expenditures under contracts Nos. 1 and 2 had been $42,000,000, or approximately 83% of the total cost. In point of cost, therefore, the work on the old subway was only 23% as large as the work done in a corresponding period under the dual contracts.

Work Done Rapidly—A general impression has been current that the work under the dual contracts has lagged. From whatever angle it is viewed, it is evident from the data herein given that this has not been the case, and that, in fact, extraordinary progress has been made. The progress on contracts Nos. 1 and 2, constructed in normal times and with wide-open street excavations, was considered eminently satisfactory at the time (1900 to 1906), and the initial opening in 1904 was hailed as the accomplishment of a wonderful achivement. *Yet five times as much has been completed on the dual contracts project* in an equal period of time, and this during war, and with all excavations carried on under street decking, thereby greatly increasing the difficulty of the work and retarding progress. Although this new system is five times as large as the first subway enterprise, it has advanced at practically the same rate in percentage of the whole.

In summary, today, after six years, it is 95% under contract, 86% completed and 70% actually in operation.

Fundamentals in the Make-Up of a Concrete Mixture

Thirteen Points Offered by A. N. Talbot Governing the Physical Conditions Which Affect Concrete Making

CLEAR thinking on the subject of concrete as a material will be helped by a study of the remarks made by Prof. A. N. Talbot of the University of Illinois at the recent annual convention of the American Railway Engineering Association. In discussing the report of the committee on masonry, Professor Talbot said in part:

Recently I talked with two engineers concerning improvements in making and placing concrete. Both agreed that changes in procedure might be made with advantage. One described a method which he favored, but said it required an artist to carry it out. The other criticised a proposed specification and said it was "only more of this artists' stuff." I have no doubt there are many who feel that much of what is proposed for the improvement of concrete is unnecessary and impractical — mere "artists' stuff." Familiarity with mixing and placing concrete is likely to breed contempt for rules and regulations, especially when the ill effects of the disregard of proper precautions and workmanlike methods are not apparent to those doing the work. Discussions on how to produce good concrete must add to our information, help to make us better workmen and to secure much better concrete.

Concrete is a complex product. Many elements enter into the development of its strength. As it is well to have some idea of the physical conditions which affect concrete in its making, I have jotted down a number of items which seem to me to bear on the effect of the make-up of the mixture; these are offered as suggestive of the way in which the amount of water used in mixing and the gradation or variation of size of the particles making up the combination of fine and coarse aggregate may be expected to influence the strength of the concrete. These statements may seem elementary; in many respects they are crude. They are presented, however, with the thought that even a general conception of the physical conditions will be helpful in understanding the effect of changes in amount of mixing water and of variations in the size of the fine and coarse aggregate. It is to be understood that there are limitations and qualifications that will not be expressed here. Here are the items:

1. The cement and the mixing water may be considered together to form a paste; this paste becomes the glue which holds the particles of aggregate together.

2. The volume of the paste is approximately equal to the sum of the volume of the particles of the cement and the volume of the mixing water.

3. The strength given by this paste is dependent upon its concentration—the more dilute the paste, the lower its strength; the less dilute, the greater its strength.

4. The paste coats or covers the particles of aggregate partially or wholly and also goes to fill the voids of the aggregate partially or wholly. Full coating of the surface and complete filling of the voids are not usually obtained.

5. The coating or layer of paste over the particles forms the lubricating material which makes the mass workable; that is, makes it mobile and easily placed to fill a space compactly.

6. The requisite mobility or plasticity is obtained only when there is sufficient paste to give a thickness of film or layer of paste over the surface of the particles of aggregate and between the particles sufficient to lubricate these particles.

7. Increase in mobility may be obtained by increasing the thickness of the layer of paste; this may be accomplished either by adding water (resulting in a weaker paste) or by adding cement up to a certain point (resulting in a stronger paste).

8. Factors contributing to the strength of concrete are, then, the amount of cement, the amount of mixing water, the amount of voids in the combination of fine and coarse aggregate, and the area of surface of the aggregate.

9. For a given kind of aggregate the strength of the concrete is largely dependent upon the strength of the cement paste used in the mix, which forms the gluing material between the particles of aggregate.

10. For the same amount of cement and same voids in the aggregate, that aggregate (or combination of fine and coarse aggregates) will give the higher strength which has the smaller total area of surface of particles, since it will require the less amount of paste to produce the requisite mobility and this amount of paste will be secured with a smaller quantity of water; this paste, being less dilute, will therefore be stronger. The relative surface area of different aggregates or combination of aggregates may readily be obtained by means of a surface modulus calculated from the screen analysis of the aggregate.

11. For the same amount of cement and the same surface of aggregate, that aggregate will give the higher strength which has the less voids, since additional pore space will require a larger quantity of paste and therefore more dilute paste.

12. Any element which carries with it a dilution of the cement paste may in general be expected to weaken the concrete. Smaller amounts of cement, the use of additional mixing water to secure increased mobility in the mass, increased surface of aggregate, and increased voids

n the aggregate all operate to lower the strength of the product.

13. In varying the gradation of aggregate a point will be reached, however, when the advantages in the reduction of surface of particles is offset by increased difficulty in securing a mobile mass, the voids are greatly increased, the mix is not workable, and less strength is developed in the concrete. For a given aggregate and a given amount of cement, a decrease in the amount of mixing water below that necessary to produce sufficient paste to occupy most of the voids and provide the lubricating layer will give a mix deficient in mobility and lower in strength.

A certain degree of mobility is necessary in order to place concrete in the forms in a compact and solid mass, the degree varying considerably with the nature of the work, and generally it will be found necessary to sacrifice strength to secure the requisite mobility. It is readily seen, however, that the effort should be made to produce as strong a cementing layer of paste as practicable by selecting the proper mixture of aggregate and by regulating the amount of mixing water.

More thorough mixing not only mixes the paste and better coats the particles, but it makes the mass mobile with a smaller percentage of mixing water, and this less dilute paste results in higher strength. Any improvement in method of mixing which increases the mobility of the mass will permit the use of less dilute paste and thereby secure increased strength.

Cost of Highway Concrete Delivered Wet by Trucks

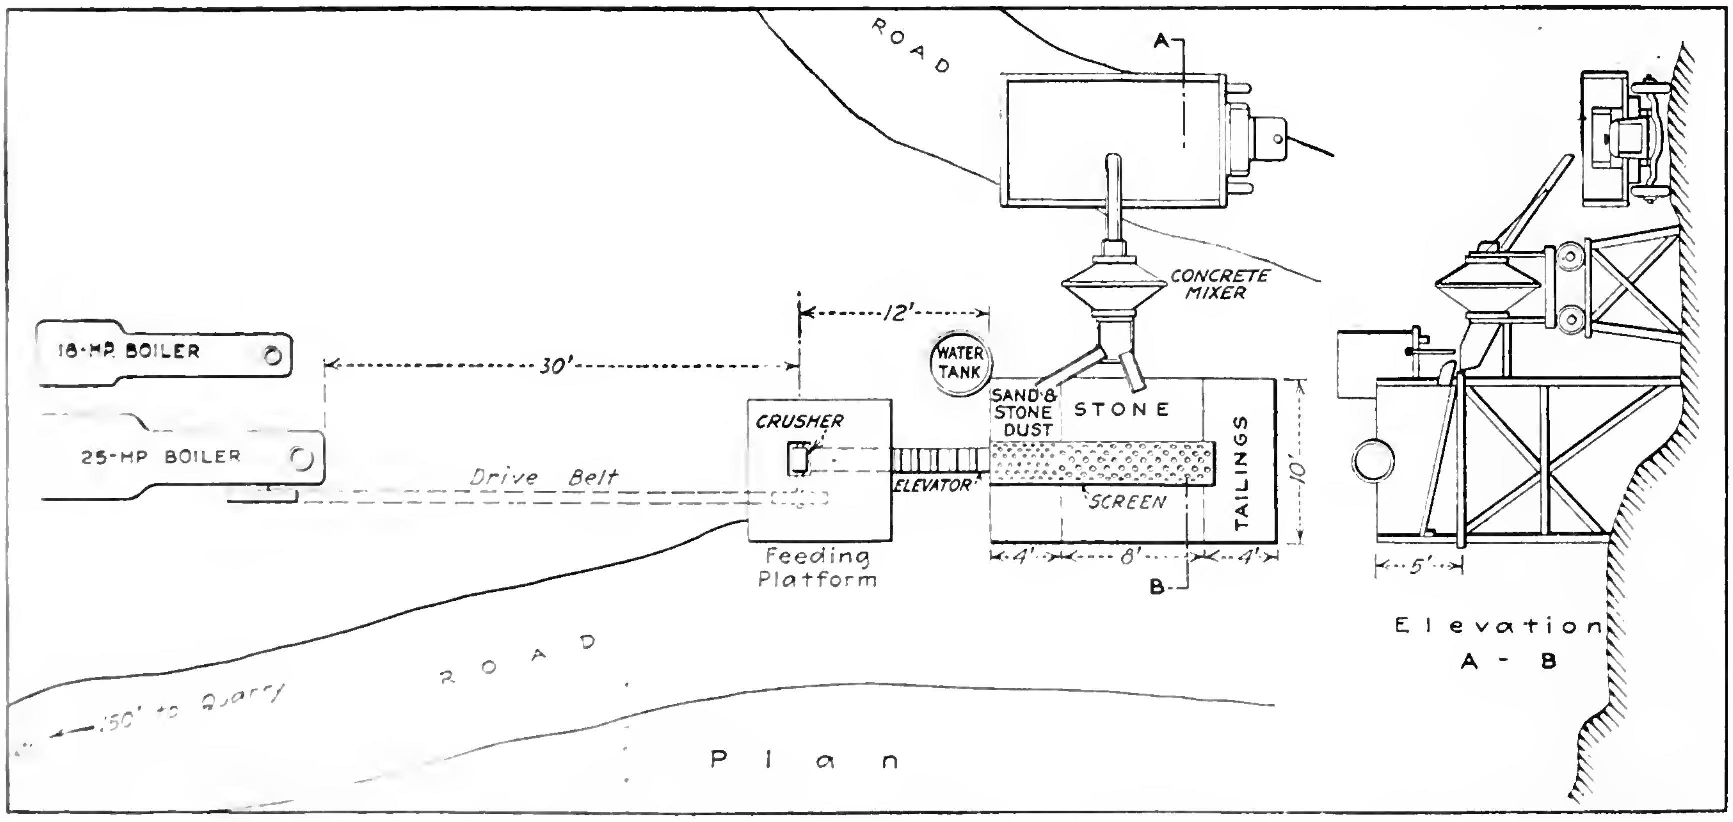
Central Crushing and Mixing Plant Set Up at Quarry — Concrete Aggregate from Crusher Bin Run Directly Into Mixer and Thence Into Trucks

DELIVERY of wet concrete, from a central crushing and mixing plant, to the road surface, by motor trucks, over hauls ranging from ¼ mile to four miles, is being satisfactorily accomplished on the Belair Road of the Maryland State Road Commission. By this method extensive rehandling of materials is dispensed with, thus reducing the cost, and the speed of the trucks is such that for the distances named there is no apparent injury to the quality of the concrete mixture. The maximum time required to transport the concrete from the mixer to the road is 35 minutes.

Most of the roads built by the State Road Commission in the past have been of the waterbound-macadam type. These have since received a surface treatment or have been covered with bituminous macadam. Recently the surfaces of the roads have shown signs of failure where subjected to heavy traffic, such as has been common during the past two years, due to heavy motor-truck freight routes.

While there has been some wearing of the central part of the road, most of the failure has occurred near the edges, accompanied in most cases by a spreading of the road crust. The conditions led to two conclusions: (1) That the roads are too narrow, and (2) that support is needed at the edges to overcome the spreading action of the traffic.

The design finally decided upon to overcome these difficulties was adopted for the Baltimore-Washington Boulevard and was described in *Engineering News-Record* of Nov. 28, 1918, p. 990. It provides for the laying of a 3-ft. strip of concrete 8 in. thick on each side of the macadam road, and connecting it with the old road with new macadam. One of the illustrations shows a stretch of the Belair Road of this design, with one shoulder completed and connected with the old road. After both shoulders are completed, the entire road receives a seal coat of bituminous material and stone chips, which is allowed to cover the concrete shoulder, giving a pavement 20 ft. wide of uniform appearance, as shown in an illustration.



LAYOUT AT CENTRAL CRUSHING AND MIXING PLANT FOR HIGHWAY CONCRETE

As there was excellent stone in most of the hills adjacent to the road, the contractor decided to save handling labor by mixing the concrete at the quarry and hauling it to the road in motor trucks. A location about midway of the contract was selected, a quarry was opened and a crushing and mixing plant was set up.

The general arrangements at the plant are shown in the accompanying sketch. Two portable boilers of the locomotive type were used; one, a 25-hp. boiler and engine, furnished power to run the crusher and mixer, the other, an 18-hp. boiler, furnished steam for the rock drills at the quarry and for pumping the necessary water for the boilers and the concrete.

A jaw crusher was placed under the platform upon which the stone from the quarry was dumped. After being crushed, the stone is elevated into the bin and separated into the desired sizes by a rotary screen.

ONE SHOULDER COMPLETED AND CONNECTION MADE WITH OLD BITUMINOUS ROAD

There are three general sizes of stone: The chips which pass a ⅝-in. screen go into the sand bins; the crushed rock passing a 2½-in. screen goes into the coarse aggregate bin, while the larger stone goes out as tailings. What tailings cannot be used for repairs on the construction road are taken out and again fed through the crusher. As the crusher does not produce enough fine material, sand is also delivered upon the platform and fed through with the stone and elevated into the sand bin.

Gravity is utilized to the utmost throughout the operations, from the quarry to the mixed product in the truck body. The plant is situated at the foot of a hill down which the quarried rock is hauled in carts to the crusher platform. After crushing, the stone and sand are fed directly into the mixer from the bins, care being taken to proportion them properly. Water is supplied from the elevated tank shown in the sketch. The bin and the platform for the concrete mixer are placed at such height that the mixer can discharge directly into the trucks.

On the road the dumping of the concrete follows a different plan than would be employed if the entire road section were being covered, as in the case of constructing a concrete road. As the shoulder which is being constructed is of small section, it is necessary to dump the mixed concrete upon the surface of the old road and shovel it into the forms on the side. One truck load of concrete fills about 35 ft. of forms, and extra handling is necessary, which of course increases the cost above what it would be if an entire road surface were being built.

Convict labor is utilized for common labor upon this road, a camp being built at the quarry to house and feed the laborers. Guards are provided by the prison officials

ITEMIZED COST OF LAYING THREE-FOOT CONCRETE SHOULDERS FOR MACADAM ROADS

Quarrying and Crushing Stone per Day	
1 foreman at 65c. per hour	$5.85
1 engineer at 44 4/9 c. per hour	4.00
1 blacksmith at 44 4/9c. per hour	4.00
17 laborers at 27 7/9c. per hour	42.50
3 carts at 55 5/9c. per hour	15.00
Equipment at $7.50 per day	7.50
25 lb. dynamite at 30c. per pound	7.50
Total cost per day for 36 cubic yards of stone and 4.4. cubic yards of dust	$86.35
Cost of rock per cubic yard in quarry	$2.137
Royalty	.15
Total cost rock per cubic yard	2.287
Sand per Day	
Sand in pit, 13.6 cubic yard at 85c. per cubic yard	$11.56
Hauling sand and cement by truck, $30 per day	30.00
Three laborers at 27 7/9c. per hour	7.50
Total cost per day	$49.06
Total cost per cubic yard	$3.61
Mixing Concrete per Day	
3 men at 27 7/9c. per hour	$7.50
Equipment $7.50 per day	7.50
Total cost per day for 40 cubic yards	$15.00
Total cost per cubic yard	.375
Hauling Concrete to Road per Day	
1 truck at $18.00 per day	$18.00
1 truck at 25.00 per day	25.00
1 truck at 27.50 per day	27.50
Total cost per day for 40 cubic yards	$70.50
Total cost per cubic yard	$1.762
Placing Concrete per Day	
1 foreman at 55 5/9c. per hour	$5.00
2 laborers, build forms 27 7/9c. per hour	5.00
Placing, 4 laborers at 27 7/9c. per hour	10.00
Total cost per day for 40 cubic yards	$20.00
Total cost per cubic yard	.50
Cost of Concrete in Place per Square Yard	
Cement, 1.5 bbl. at $2.50	$3.750
Sand, 0.34 cubic yard at $3.60	1.227
Dust, 0.11 cubic yard at $2.287	.252
Stone, 0.9 cubic yard at $2.287	2.058
Mixing, per cubic yard	.375
Hauling, per cubic yard	1.762
Placing, per cubic yard	.500
Total cost per cubic yard	$9.924
Total cost per square yard, 8 in. thick	2.205
Grading per Square Yard	
1 foreman at 55 5/9c per hour	$5.00
8 laborers at 27 7/9c per hour	20.00
Total for 180 sq.yd	$25.00
Cost per square yard	$0.138
Total cost per square yard	2.343

for watching the convicts, but the contractor furnishes the foremen to supervise the work. The contractor reports that this labor is quite satisfactory. In the construction of the shoulders steel forms are used, and the finishing is done as described in the article published in *Engineering News-Record* of Nov. 28, 1918.

Approximate costs for carrying work on under this

COMPLETED ROAD HAS UNIFORM APPEARANCE

system are given in the accompanying table, the basis used being an average haul of 3½ miles for 6975 ft. of shoulder laid in a period of 13 working days. The average day's work was thus 535 lin.ft. or 179 square yards.

Quarrying and crushing the rock cost about $2.29 per cubic yard, while the mixing was about 38c. per cubic yard. Sand cost $3.61 per cubic yard and the hauling for the average haul was $1.76 per cubic yard. The total cost of the concrete shoulders, including the grading, was about $2.34 per square yard. These costs include interest on investment and depreciation of equipment.

No figures are available as to the cost of connecting up the concrete shoulder with the old surface, this depending largely on the amount which it was necessary to excavate, due to the ravelled condition along the edge. In all probability, this would be about the same as patching with this material.

Comparison of the relative cost of laying shoulders by hauling the wet concrete as against that of distributing the materials on the road and mixing at the site shows on the Maryland work a considerable saving in favor of the former method. The table shows that the cost per square yard by the wet-hauling method was $2.34 for the section for which costs are given, while the cost upon the Baltimore-Washington Boulevard constructed by the other method was $3.24 per square yard.

The large saving was in handling materials. Mixing, placing, forms, curing and protection on the boulevard cost 84c. per square yard, while the same operation on the Belair Road cost about 20c. per square yard. The average haul for the entire road is about 2½ miles, and the costs given were taken for an average haul of 3½ miles. This would also decrease the average cost per square yard in place for the entire road.

The work on the Belair Road is being done by the Maryland State Roads Commission, of which Frank H. Zouck is chairman, and J. N. Mackall is chief engineer. Edwin Friese is resident engineer for the commission, and the American Paving and Contracting Co., of Baltimore, is the contractor for the work.

Factors Governing Selection of Industrial Site

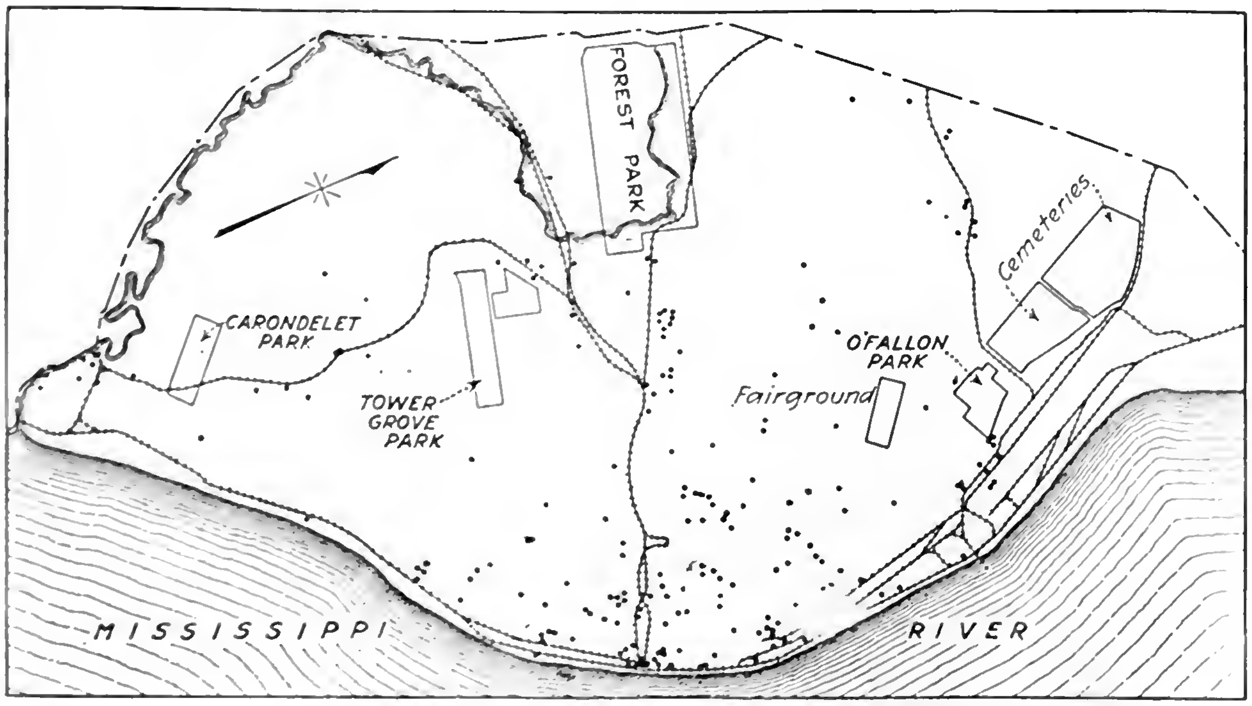
Railroad Facilities and Land Values Have Little Effect on Choice—Motor Trucks Supply Transportation Needs

By Harland Bartholomew
Engineer, City Plan Commission, St. Louis, Mo.

THAT the location of industrial plants appears to depend less upon direct railroad connections than is generally supposed is indicated by maps and figures prepared in connection with the St. Louis zone plan. Studies of the location of all industries in the city show that probably 50% have no direct railroad facilities and are more or less removed from what are generally termed industrial districts. In fact, there is increasing evidence that the motor truck is meeting transportation needs.

Many other considerations such as prevailing prices of land for industrial purposes, source of labor supply, local transit facilities, switching charges, water-supply, character of industry, etc., enter into the matter of locating industrial plants. However, knowledge of local conditions in St. Louis indicates that a relatively small number of plants have selected their sites solely from the standpoint of low land value. This being the case, the necessity of regulating the location of industries in the interest of sustaining land values is readily seen.

Among the maps mentioned above, there is one showing the distribution of new industrial plants located in St. Louis during the five years from 1913 to 1917. This map, which graphically illustrates the conditions as stated, is reproduced herewith. Only plants having a structural cost of $5000 or more were considered—warehouses, power plants, additions to existing factories, etc., being excluded. Of 170 such plants, 106, or 62½%, did not have direct railroad connections. The map shows that the majority of these were located in the central eastern section of the city, which is already largely built up. In other words, they disregard land values in favor of proximity to labor supply, inasmuch as the densest population is in the central eastern part of the city. One concern which manufactures a line of commercial electric specialties and employs several hundred operatives, including many women, recently erected a plant just west of Grand Ave., an important business street, this being the first large factory to invade this residential section. The location was chosen in preference to several other less expensive sites considered because it offered better surroundings than the usual industrial district, making it attractive to women workers, and because it was adjacent to the car line which



DISTRIBUTION OF NEW INDUSTRIAL PLANTS LOCATED IN ST. LOUIS FROM 1913 TO 1917 WITH RESPECT TO RAILROADS

gave quickest access to all residential sections. These considerations, in the opinion of the owner, were more important than direct railroad connections or a less expensive site. In other words, the owner figured that the extra cost of land and of transporting his product to the railroads by motor truck was more than offset by the advantageous labor conditions to be obtained. And the conclusions of this manufacturer seem to be typical of those of the majority.

Congestion of railroad terminals in large cities has caused shippers to depend more and more upon the motor truck for short-haul traffic, either for direct delivery to the consignee or to the railroad. One of the largest shippers in an Eastern city, though located on a railroad, found it cheaper to carry all of his freight by motor truck to the terminal of another railroad, a distance of three or four miles, than to load the freight upon railroad cars at his plant and wait for them to be switched to the railroad over which they were to go. In this particular city there exists no belt-line or connecting railroad, and switching charges may be unusually high, but it is a well known fact that the terminals of the railroads in most large cities are being taxed to their capacity, and shippers undoubtedly are finding the motor truck a time saver as well as a money saver.

One of the limiting factors in the capacity of a railroad terminal or of a railroad itself is the number of tracks that exist or that can be built and maintained economically. Certainly, no terminal or railroad can provide as many tracks as there are streets in a city. If the streets are well planned and well paved, so that transportation by motor truck is unimpeded, the transportation problem is greatly simplified, the burden on the railroad terminals is reduced and the capacity of the railroads for through traffic increased.

Regulation of the location of industries in the interest of the welfare of the city is therefore necessary. To permit industries to invade residential districts, especially just now when labor supply is a large factor, would be to invite economic disaster, since no residential district would long maintain its values under such conditions. If invasion of residential districts is allowed to proceed without abatement, the city becomes the loser in taxes, while new residential districts farther away from the city's center are built, and the cost of providing additional utilities, such as water, transit, pavements, lighting, etc., must be met in greater or less part from the city's treasury. To establish certain well defined industrial districts, on the other hand, should prove advantageous, since an intensive development would permit cheaper services, such as power from a centralized station or stations; and the presence of such a district, with its large opportunities for employment, would tend to attract a more or less adequate supply of labor to the adjoining residential districts.

Cities as well as manufacturers must give more than casual thought to the communal problems of industry. When these are properly solved, there is much more economic value in the solution for both the city and the manufacturer, than in many of the wasteful, haphazard methods of the past. Here is a reconstruction measure worthy of serious consideration.

Line Revision on Cincinnati Southern Railroad

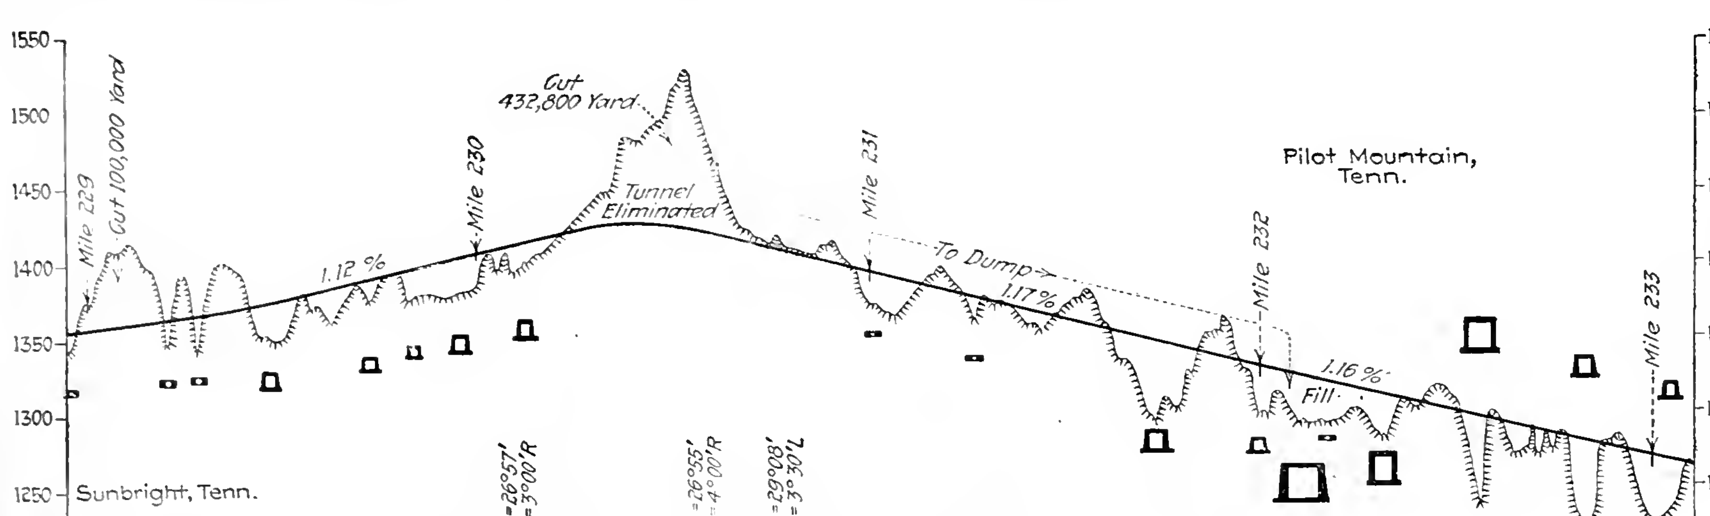
Heavy Rock Cuts, but Few Bridges—Stream Diverted Through Old Tunnel to Avoid Crossings

SINGLE-TRACK and double-track relocations or cutoffs, to improve alignment and profile and to eliminate tunnels, are part of the improvements being made by the Southern Railroad Lines in the extension of double-tracking on the Cincinnati Southern line between Cincinnati, Ohio, and Chattanooga, Tenn. One of the abandoned tunnels will be utilized in stream diversion to avoid a double crossing. Heavy rock excavation, with long and deep cuts and fills, is a feature of the revision, the heaviest work being in mountain country between Helenwood and Lancing, Tenn.

A 4000-ft. stretch of line revision south of Helenwood eliminates two tunnels 364 ft. and 367 ft. in length, reduces curvature and brings the grade above flood level. The old line here followed the west bank of Phillips Creek, and was at such an elevation that after heavy storms the water occasionally rose over the tracks and flowed through the second tunnel, beyond which it returned to the natural channel. In the fall of 1917 such an occurrence caused interruption to traffic.

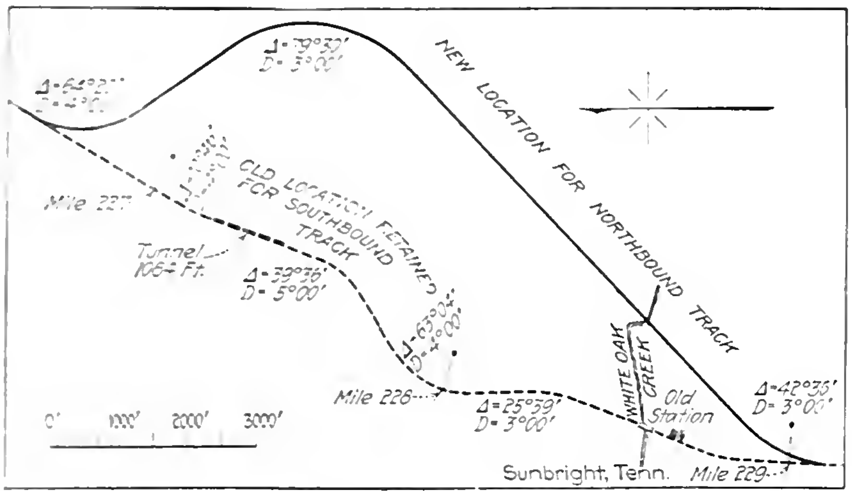
The new location here, as shown in one of the drawings, is on the east side of the creek, the line being straightened and put at an elevation of about 15 ft. above the old grade. To avoid two stream crossings on the relocation, a cut-off channel is excavated, thus eliminating a sharp bend of the creek. The second abandoned tunnel is utilized as part of this channel, its floor being lowered 6 or 8 ft. below the original grade.

Relocations requiring the heaviest construction on



TYPICAL HEAVY GRADING ON RELOCATION OF CINCINNATI SOUTHERN RAILROAD

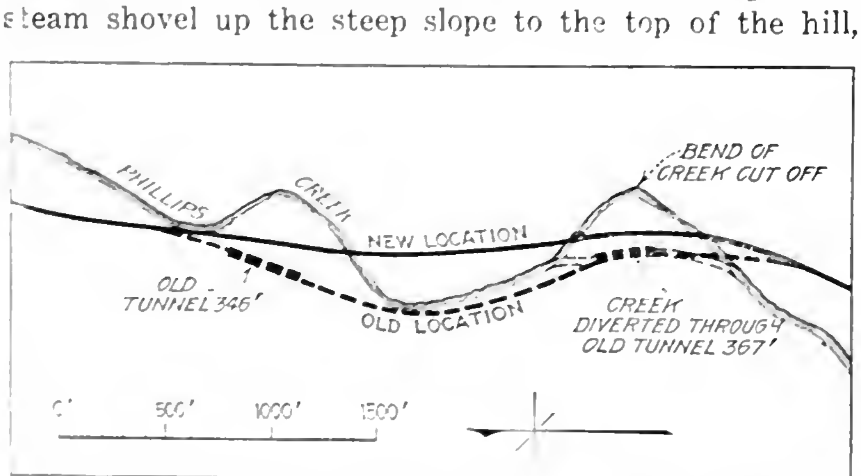
the whole of the present improvement are included on the 12-mile stretch between Huffman and Lancing. In the first place, there is a single-track cutoff for northbound traffic only, the old line being satisfactory for southbound trains. This is shown on one of the drawings. It is nearly three miles long and keeps about half a mile from the old line, avoiding one tunnel and several curves, besides giving a more favorable profile. Following this is a double-track revision for about 2½ miles, which closely parallels the old line, but is on the opposite side of the valley. This eliminates one tunnel and several curves of five and six degrees, but the old line here will be retained for use as a passing track. Two other revisions of about 2000 ft. each avoid tunnels 630 ft. and 403 ft. in length. Another tunnel only 204 ft. long will be eliminated by a double-track cut. Elimination of these old tunnels reduces the smoke nuisance and avoids difficulties due to the limited clearance for large modern equipment.



DOUBLE TRACKING AT SUNBRIGHT, TENN., HAS NEW LOCATION FOR SECOND TRACK

Long and deep cuts, having 90% of the excavation in hard sandstone, are encountered on these relocations; part of a typical profile on this section of the line is shown in an accompanying drawing. Although the work is along steep sidehill slopes, through cuts are generally required. The largest cut is about 435,000 yd., with a maximum depth of 100 ft. and a length of 2500 ft. Two others are of 200,000 yd. and 125,000 yd., both about 90 ft. deep and 900 ft. long.

Well drills are used to open up the cuts, with steam drills to finish them to shape and grade, and steam shovels to remove the material. Blasting is done mainly with 40% and 60% dynamite, in order to get quick and shattering action in the hard rock. Usually a narrow through cut is made first, the shovel then returning to the starting point to widen this along one side. At one deep cut a hoisting engine was used to get the steam shovel up the steep slope to the top of the hill, and this engine also operated the dump-car trains by cable on a steep incline. At another similar cut it was proposed to build a switchback track on the hillside, in order to obtain a grade enabling the dump-car trains to reach the steam shovel.

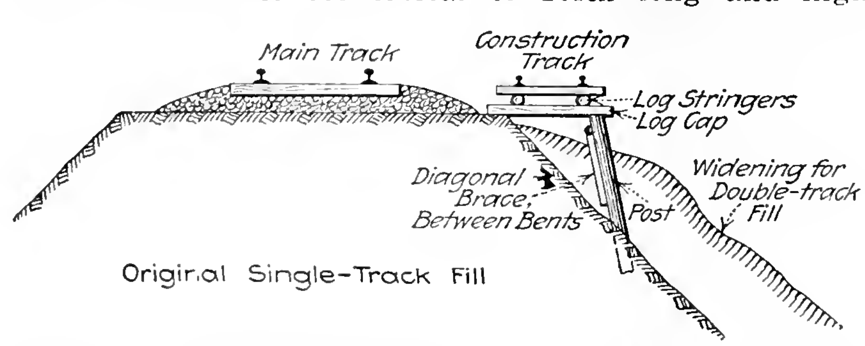


LINE REVISION INCLUDES DIVERSION OF CREEK THROUGH ABANDONED TUNNEL

Narrow-gage construction equipment was installed by the contractor on this section, using 8-yd. double-truck dump cars and four-wheel dinkey locomotives. With a haul of two or three miles, however, these dinkeys could not handle the work satisfactorily. In fact, the engineers considered a haul of 3000 to 4000 ft. the economic limit for such engines. The railway then handled this work with standard-gage 16-yd. cars and 50-ton locomotives. This equipment was not operated on the main track, however, as traffic conditions necessitated keeping the work trains almost exclusively on the construction tracks.

Temporary trestles of round timber were used for most of the fills. Peg-leg trestles were used mainly in starting to widen existing fills, thus carrying the construction track clear of main-line traffic. Each bent had a single batter post set in the old slope and supporting one end of a cap whose other end rested on the edge of the old fill. These bents were spaced about 12 ft. apart, carrying log stringers and being braced longitudinally by pole diagonals. The widening was then completed with the construction track on the new fill.

Structures of importance are relatively few on the new lines, partly because the roadbed is largely benched in solid ground and partly because the amount of excavation made it economical to form long and high



PEG-LEG TRESTLE CARRIES TRACK FOR WIDENING FILLS

fills with culverts to accommodate drainage. At Phillips Creek, where the grade necessitated a low and wide opening, the necessary waterway was obtained by a six-barreled concrete box culvert having rectangular openings 6 ft. wide and 12 ft. high.

A five-span, single-track bridge with 100-ft. plate-girder spans on concrete piers 90 ft. high is the largest new structure. This has its center line 40 ft. from that of the old steel viaduct, which will remain in use for the northbound track. Solid rock, almost at the ground level, forms the foundations. For the piers the mixer plant was located at the bottom and served an elevator tower with chutes. For the abutments the mixer was placed beside the track, and the concrete was wheeled to the forms. Another structure was a concrete bridge having two 43-ft. spans composed of two side girders and two center girders supporting a deck slab. This design allowed building of half the bridge first without interference with traffic. A general contract for the work described above was awarded to H. H. Thrasher, of Knoxville, Tenn., and a part of the work is being done by company forces. Labor shortage has been serious, as floating labor is very limited, and negroes are not found in this section. Few of the white natives care for this kind of work, although they will work on

the section gangs. Camps with houses are provided at a few points, but as a rule the men live in boarding trains.

All construction work is under the direction of E. M. Durham, Jr., chief engineer of construction, Southern Railroad Lines. R. W. Jones, Jr., is district engineer, at Lexington, Ky., with P. R. Shields and R. H. Small as assistant engineers.

Rainfall, Absorption and Run-off on Small Rural Drainage Area

Study of Heavy Rain, Total Run-off With Soil Absorption and Run-off for Small Plats —The Hydraulic Jump

By Ivan E. Houk
Assistant Engineer, Miami Conservancy District, Dayton, Ohio

INTERESTING data on rainfall, soil absorption, and run-off were obtained on Moraine Farm, the home of Col. E. A. Deeds, during a flood that occurred in September, 1916.

Moraine Farm is situated among the hilly, glacial deposits, known as moraines, about five miles south of Dayton. The greater part of the farm, with some area to the south and east—amounting to about 2.6 square miles in all—is drained by a small creek having an average fall of about 100 ft. per mile in its total length of about two miles. The approximate natural slope of the ground over the drainage area varies from 1 to 20 ft. per 100, averaging 3 or 4 ft. About 7% of the surface is wooded. The surface soil, which is a clay loam, containing some sand and gravel, is underlain by comparatively thick glacial deposits of sand and gravel. Careful records of rainfall, run-off and soil absorption have been maintained on this watershed by the Morgan Engineering Co. and the Miami Conservancy District since March, 1915.

The observations and studies will later be published in detail in the "Technical Reports" of the Miami Conservancy District.

Rainfall Observations

The flood for which the data are here given occurred on Sept. 5. Although some rain fell over a considerable part of Ohio on that date, the precipitation did not seem to be unusually heavy, except in the Miami Valley.

At the Dayton coöperative Weather Bureau station the total for the 24 hours which ended about 10:30 a.m., Sept. 6, was 4.85 in. At the local office of the United States Weather Bureau, about two miles west of the former station, a total of 3.83 in. was recorded; and at Moraine Farm, about five miles south of the Weather Bureau office, the readings of the three gages maintained by the Miami Conservancy District were 4.09, 4.30, and 4.33 in. for the same period of time. Of the last three gages, the two reading 4.30 and 4.33 in. are within 100 ft. of each other and are about a quarter of a mile northwest of the one reading 4.09 in. At the local office of the United States Weather Bureau the maximum intensities, determined by the triple register, were 0.43 in. for 5 min., 0.79 in. for 10 min., and 1.75 in. for 30 minutes.

The periods and amounts of rainfall as shown by the same instrument were as follows:

P. M.	In.	P. M.	In.
3:03 to 4:00	0.97	7:00 to 8:00	0.99
4:00 to 4:41	0.89	8:00 to 9:00	0.05
4:57 to 6:00	0.47	9:00 to 9:40	0.01
6:00 to 7:00	0.13		
		Total	3.51

While the rain began at 3:03 p. m., as noted above, the heavy rain did not begin until 3:44 p. m. From 3:44 to 4:16, 1.75 in. fell; from 5:01 to 5:11, 0.32 in.; from 7:16 to 8:00 p.m., 0.96 in. About 0.27 in. fell in 10 minutes about 9 a. m. the following day.

The ground was comparatively dry when the rain began. There had been only a normal amount of rainfall during August, and this had been well distributed through the month. About 0.06 in. fell from Aug. 26 to 28, inclusive. There was no precipitation on Aug. 29, 30, or 31. On Sept. 1 about 0.33 in. fell. Then there was no more rain until Sept. 5.

The amounts of moisture in the soil in percentage of the dry weight were determined both before and after the heavy rainfall. Soil samples, weighing about 2 lb., were taken where the ground was nearly level, by digging with a spade. No attempt was made to secure an exact volume. The samples were carefully weighed on scales weighing to the nearest tenth of a gram, and were then dried in the furnace room at the farm and reweighed until their weight became constant.

The samples taken Aug. 28 and Sept. 6 showed the following percentages of moisture:

Depth Below Ground Surface, In.	Moisture Content, Per Cent 8-28-16	9-6-16	Remarks
6	3.1	15.1	Under cultivated cover
12	3.3	5.4	Under cultivated cover
18	4.1	6.8	Under cultivated cover
24	4.4	8.7	Under cultivated cover
6	8.0	13.9	Under sod cover
12	8.2	15.9	Under sod cover
18	10.3	15.3	Under sod cover
24	10.6	16.5	Under sod cover
Average	6.5	12.2	

These results show an average increase in moisture content of about 5.7%. Assuming the weight of 1 cu.ft. of earth in place to be 100 lb. when perfectly dry, 5.7% of moisture would correspond to about 1 in. of rain per foot of depth or to about 2 in. in the total depth in which the samples were taken. This amount does not represent the total absorption of the soil, however, since the material deeper than 2 ft. is almost entirely gravel, and the water could move downward at a comparatively rapid rate once it reached this stratum.

Run-off from Small Plats

Measurements of the total run-off during the flood were obtained on four small plats, each 5 ft. square. Two of these were situated on the side of a hill within a few feet of the rain gage reading 4.30 in. The other two were situated on level ground close to the rain gage reading 4.33 in. In each case the surface covering in one of the plats was kept spaded up, in a cultivated condition; while the surface in the other consisted of a heavy bluegrass sod.

No run-off at all occurred in either of the plats in which the sod covering existed. The grass, which was from 3 to 6 in. long, held back the water so that it could soak into the ground. Considerable run-off occurred on the plats in which the surface was cultivated.

In the plat on the level ground the total amounted to more than 1.9 in., or over 44% of the rainfall. The can in which the run-off is caught was filled entirely full and some water ran over, the amount of which there was no way of determining. In the plat on the hillside the total run-off amounted to 1.66 in., or 37% of the rainfall—somewhat less than on the level ground, probably due to differences in cultivation.

The maximum rate of run-off from the total drainage area was determined from high-water marks and cross-sections taken a few days after the flood. The survey covered a length of about a half mile, where the creek had been diverted into an artificial ditch. This ditch was straight, and was lined with concrete through a length of about 1300 ft. Six cross-sections were taken, three of the concrete-lined channel and three of the earth channel. In calculating the discharge, corrections in slope were made to allow for changes in velocity, and the parts of the cross-sections occupied by trees, in the earth channel, were omitted. Kutter's formula was used, taking a value of n of 0.015 for the concrete channel and of 0.045 for the earth sections.

The computations gave an average maximum rate of run-off of 900 sec.-ft., or 346 sec.-ft. per square mile. This is equivalent to a rate of run-off of about 0.54 in. per hour.

The Hydraulic Jump

An interesting hydraulic jump of about 2 ft. occurred at the lower end of the concrete-lined channel. Following the notation used by Professor Woodward (Miami Conservancy District, "Technical Reports," Part III, "Theory of the Hydraulic Jump and Backwater Curves," by S. M. Woodward) the conditions of flow were as shown in the table at the head of the next column.

Immediately below the end of the concrete channel, before the jump occurred, the actual depth was 2.55 ft., the neutral depth was 3.80 ft. and the critical depth was 3.41 ft.; that is y was less than y_c and y_c was less than y_n. These conditions correspond to Professor Woodward's Case C. According to his theory, then, the surface, on leaving the concrete channel, would slope upward until the depth became equal to the critical depth, the curve approaching a condition of verticality as y approached y_c; and then, since there is no curve by which the water can flow smoothly with the depth increasing from y_c to y_n, the increase in depth, which had to be made since the water could not flow through the earth channel at a depth equal to y_c, must be made by the transformation known as the hydraulic jump.

CONDITIONS OF FLOW IN CONCRETE-LINED CHANNEL

	Average Condition: In Concrete Channel	Average Condition: In Earth Channel
Actual depth y	3.04	4.30
Neutral depth y_n	2.96	3.80
Critical depth y_c	4.07	3.41
Surface curve	Case E	Case A

While the high-water marks obtained were not sufficiently accurate or in sufficient number to show the curvature of the surface in the different sections of the channel, they showed definitely that a rise in water surface of about 2 ft. did occur abruptly as soon as the water entered the earth channel, this rise taking place within a length of 50 feet.

Progressive Erosion in a Dredged Drainage Channel

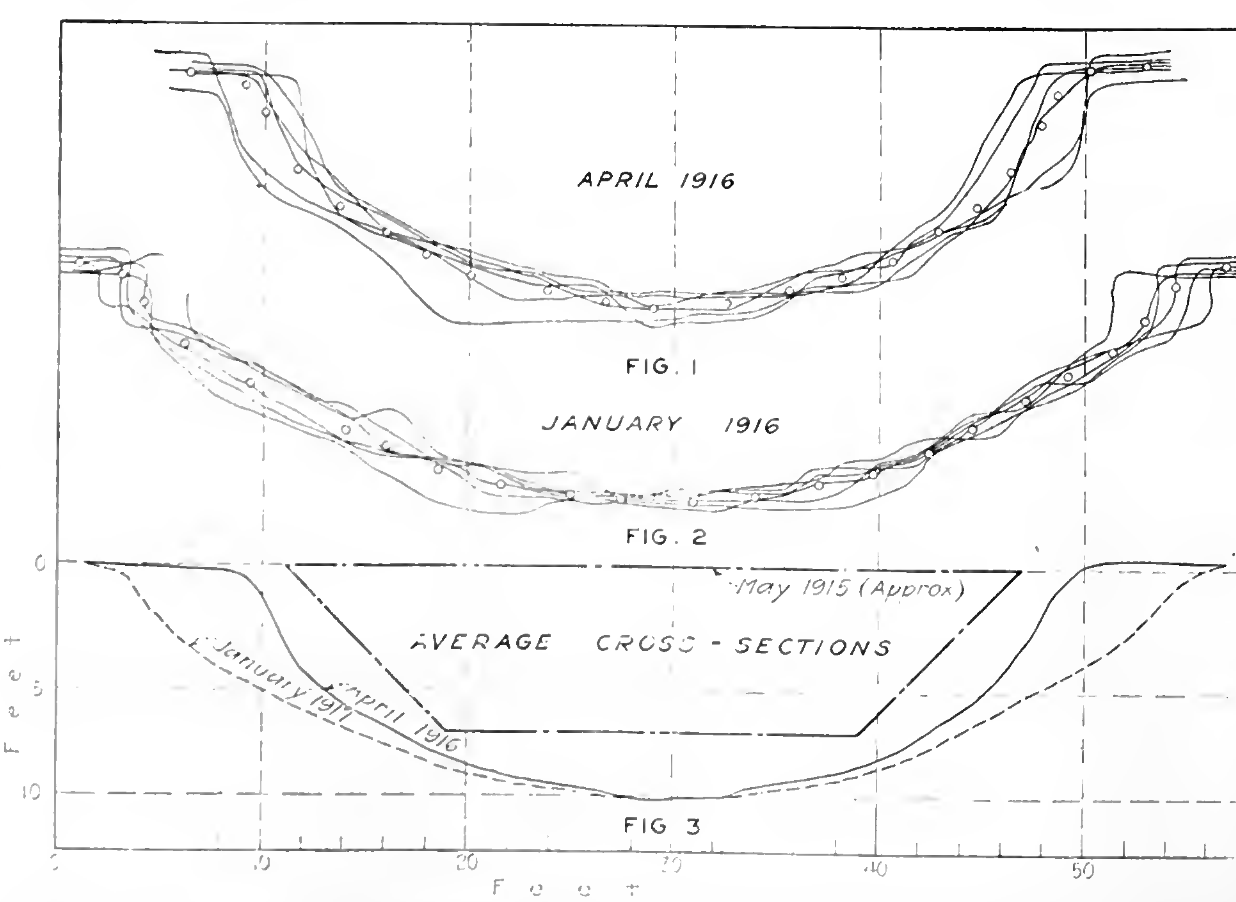
Observations on Enlargement and Effect on Capacity, Together With Computations of Value of n in Kutter's Formula

By C. E. Ramser

Senior Drainage Engineer, Office of Public Roads and Rural Engineering, United States Department of Agriculture. Washington, D. C.

IT IS generally known that drainage channels enlarge under certain conditions of soil and slope, due to the erosive action of the moving water. Very little information has been obtained to show the rate and amount of the enlargement, or the effect of the enlargement upon the capacity of the channel. To obtain definite data on this subject, measurements of the cross-sectional areas and computations of the values of n in Kutter's formula were made on the North Forked Deer River drainage channel, near Trenton, Tenn.

The portion of the channel selected for observation was constructed in May, 1915. Measurements of six cross-sections of the channel along a course of 700 ft. were made in April, 1916, and again in January, 1917. The hydraulic gradient and the discharge of the channel were also measured for use in the computation of values of n.



FIGS. 1 TO 3. EROSION ENLARGEMENTS OF CROSS-SECTION OF DREDGED CHANNEL OF NORTH FORKED DEER RIVER, TENNESSEE, FROM APRIL, 1916, TO JANUARY, 1917

Figs. 1 and 2 show the cross-sections of the channel in April, 1916, and May, 1917. The platted points represent the average of the six cross-sections. A comparison of these figures shows in this particular instance that, after a certain amount of erosion had taken place in a dredged channel erosion does not tend to increase the irregularity of the channel.

The average cross-sections represented by the platted points in Figs. 1 and 2 are platted together in Fig. 3. It is apparent from this figure that very little increase in the depth of the channel occurred after April, 1916, and that the greatest amount of enlargement occurred near the top of the channel on both sides. The original cross-section of the channel at the time of construction, May, 1915, is also drawn in Fig. 3 according to the specified dimensions as given in the engineer's report. It is likely that the channel was dug somewhat deeper than these dimensions show, but some increase in depth of channel occurred since construction, due no doubt to a natural adjustment of the bottom slope along the channel.

As given in the report of the engineer, the channel was designed for a slope of 0.0007, or a fall of about 3.6 ft. per mile. The maximum slope of the water surface as actually measured was found to be 0.00052, or about 2.75 ft. per mile.

Figs. 4, 5 and 6 are views of the channel taken during April, 1916, November, 1916, and January, 1917. Figs. 4 and 6 were taken looking downstream along the course of the channel where the cross-sectional measurements were made. Fig. 5 was taken just below the course but is, however, representative of the condition of the channel along the course. The caving of the banks as shown in Fig. 5 occurred during the fall season after the last high-water stage, some time in July. The first high stage that occurred at the end of this low-water period washed away all of the loose earth in the channel and left the channel clean and fairly smooth, as shown in Fig. 6. The soil in the channel varies in character from a silty loam at the top to a heavy, silty clay at the bottom.

Between April, 1916, and January, 1917, the average cross-sectional area of the channel increased from 331 to 409 sq.ft. The values of n in Kutter's formula obtained for high stage during the years of 1916 and 1917 were 0.0271 and 0.0267, respectively, from which it is seen that the roughness coefficient was practically the same before and after the erosion occurred. Using these values of n, the average cross-sectional areas and a slope of 0.0005, the capacities of the channel for these two sets of values were computed by Kutter's and Chezy's formulas and are given in the following table:

Date	Cross-Sectional Area, Sq.Ft.	Hydraulic Radius, Ft.	n	c	Mean Velocity, Sec.-Ft.	Discharge, Sec.-Ft.
April, 1916...	331	6.69	0.0271	77.0	4.45	1,473
January, 1917..	409	6.95	0.0267	78.3	4.60	1,881

From the table it is seen that the mean velocities in the channel were about 4½ ft. per second, and that the discharge capacities for 1916 and 1917 were 1473 and 1881 sec.-ft., which represents an increase of 27.7% for the period from April, 1916, to January, 1917. The increase in cross-sectional area was 23.5%, which is less than the percentage of increase in capacity.

The engineer who designed this drainage channel foresaw the probable effect of erosion, and accordingly did not attempt to provide for a rate of run-off that would give satisfactory drainage at the start. A considerable financial saving was thereby effected. The bottom lands benefited by this channel are now very satisfactorily drained, and in the meantime much of the land was being made ready for cultivation.

Some of the factors that were favorable to the erosion of this channel and to the absence of silting were a straight alignment, a good slope with resulting high velocity in the channel, soil susceptible to erosion, the absence of retardation in velocity due to backwater, and only very little vegetation in the channel. Special attention is called to these factors to avoid the possibility of a general inference being made that all drainage channels enlarge due to erosion. On the other hand, the conditions may be such that practically no erosion takes place and, instead, silting or filling up of the channel occurs. For instance, erosion is often prevented or its progress checked by the growth of vegetation in channels, which growth in turn often promotes the rapid silting of channels. Cross-sectional measurements of a large number of drainage ditches, where the conditions affecting erosion have been quite varied, have been made by the Bureau of Public Roads and Rural Engineering for the purpose of obtaining reliable data on silting and erosion. Reports on these investigations will be prepared and then can be obtained from the bureau.

FIGS. 4 TO 6. REPRESENTATIVE VIEWS TO SHOW EFFECT OF EROSION ON DREDGED RIVER CHANNEL

Vault Will Hold Two Freight Cars

To foil thieves who make a practice of stealing raw silk from freight cars—a very common practice—the Cheney Bros. silk firm at South Manchester, Mass., is building a vault big enough to hold two freight cars. The structure is 90 x 16 ft. in plan, with brick walls, a concrete roof and regulation vault doors at either end. The builder is the Aberthaw Construction Co.

Defects in Surface of Bituminous Pavement Due to Concrete Base

Data Collected at Oak Park, Ill., Indicate That Cracks and Other Objectionable Features Are a Minimum Where Flexible Foundations Are Used

By H. W. Skidmore
Construction Engineer, Department of Public Works, Oak Park, Ill.

PRACTICALLY all the defects in bituminous pavement, as now constructed in Oak Park, Ill., may be traced to the concrete base. Investigations by the engineering department show that these defects are greatly reduced where flexible foundations, such as macadam, have been used. This has led to the conclusion that homogeneity and a certain amount of resiliency are far more valuable in bases for such pavements than rigidity. The question arises as to whether bituminous concrete bases, which have been employed with great success in many cities, should not be substituted for the rigid form. Whichever type is used, good drainage is essential, as cement concrete has failed to bridge over weak subgrades.

Much has been said recently regarding changes in design of bituminous pavements, and observation of the action of these pavements has led many engineers to consider these changes seriously. For years the presence of cracks in pavements has been treated lightly by engineers with the statement that, as a rule, cracks are not a serious defect; but now the cracks seem to be receiving considerable attention, and efforts are being made to minimize or prevent them. In all these discussions there has been a significant lack of actual data. Just what effect cracks, depressions due to failure of base, upheavals, etc., have on the life of the pavement, and the cause of these defects, with the remedies therefor, are still matters of conjecture, and there are about as many different answers as there are engineers giving the problem thought.

With the idea of collecting accurate data the writer decided during the winter of 1916-17 to start an investigation. Plans were made for conducting a thorough inspection about twice a year. The kind of information needed was determined, and forms for recording such data were devised.

Inspections are made in the early spring and in the hot summer weather, the latter to determine the tendency toward hot weather cracking and the extent to which the subgrade retains moisture throughout the year. At first, the data obtained in the field and the subsequent deductions were tabulated on one large tracing which contained the record of all pavements. After making an analysis of the information obtained in our first inspection, it was decided that an individual record of each job would prove more satisfactory. A sample of the forms now used for record is shown herewith. These cards are easily filed and may be sorted and arranged, so that any specific set of figures may be taken off easily. Such data as may not be tabulated in columns by means of numbers are included in the "remarks."

In connection with these files we also have a complete card index of all pavement repairs which have been made during the writer's connection with the department. This record includes repairs made from 1914 to date. No record was kept prior to that year; consequently, analyses are somewhat imperfect so far as the older pavements are concerned.

As soon as the 1918 inspection was completed, summaries were made of the results. These summaries include various groupings of pavement, and also consider the various groups in relation to one another on the basis of length of service, the kind of asphaltic cement used in the wearing course, contractors, etc. The table given groups the pavements as to the type of consruction, and analyzes them with reference to the kind of asphaltic cement used and the age.

A comparison with relation to the kind and character of the subgrade was desired, but this could not be made, comprehensively, owing to a lack of necessary data concerning the older pavements. Such studies will be made, however, as pavements laid within the past few years become older, and with a more complete record of later years, analyses may be made on any number of different bases. It will also be possible to trace in-

dividual paving jobs through consecutive years, thus providing interesting comparisons between the average results in individual jobs and those here presented.

In considering the data collected, the significant absence of cracks in pavements laid on reshaped macadam roadways is at once apparent, indicating that the defects in those on concrete base are due to the base. A 4-in. concrete base laid upon old macadam, likewise, shows much less tendency to crack than do pavements on 6-in. base, laid directly upon the natural soil. The conclusion is that the presence of the macadam facilitates drainage immediately beneath the concrete.

We have found on the average that 14% of all cracks in asphaltic concrete pavements, up to seven years old, cause an upheaval of pavement. Most of the heaving is apparent in the late winter and early spring, during periods of alternate freezing and thawing. This leads to the conclusion that the heave is caused by the freezing of water which is admitted through the cracks at each thaw.

The presence of the binder course in sheet-asphalt construction apparently has some effect in delaying the surface reproduction of cracks occurring in the concrete base. With a bituminous mixture serving as an absorbing medium, cracking of the wearing surface is not prevented; it is merely delayed.

Another significant fact is that asphaltic concrete pavements laid over old macadam have shown no sign of "pushing" or "rolling" under heavy traffic, while the same pavements on concrete have given considerable trouble in this respect. In one instance, on a street having both types of construction, this difference has been very marked. Sheet asphalt, including boulevard pavements, has shown almost no tendency to push.

Tendencies toward longitudinal cracks, and cracks resulting in subsequent upheaval of pavement, seem to show the same relation between the types of pavement as those toward transverse cracks. The kind of asphalt used had practically no effect on the number of cracks.

In studying the maintenance rate for the four types of pavement, it is necessary to call attention to the fact that all the maintenance on pavements laid directly upon old macadam could have been prevented, as most of it, with the exception of a few yards of surface replacing of scorched material, was due to settlement of backfilling over trenches. Had these trenches been filled as they now are in Oak Park, this maintenance would have been unnecessary. Our experience with bituminous-concrete pavement has shown that those laid directly upon old macadam not only cost less for construction and maintenance, but also are in much better general condition after several years' service.

In order to minimize the movement of the wearing surface, the concrete base, for those having one, is finished rough. We have found that these pavements are inclined to assume, in a measure, the rough surface of the concrete. In comparison with those laid on old macadam, this feature is quite noticeable. This fact has led the writer to reduce, considerably, the roughness of the concrete surface.

It is well-nigh impossible to repair cracks in a bituminous pavement on a concrete base, so that they will not reappear and again provide means of admitting water. However, it is possible to relieve, in a measure at least, the upheaving at a crack by means of replacing the cement concrete base with bituminous concrete of sufficient extent to waterproof the structure. This, however, is expensive, and contractors dislike very much to make such repairs. Moreover, the practical value of the method is not firmly established. The repair is effected by digging out the base under the crack to a width of 6 or 8 in. and filling with bituminous concrete, upon which a new surface is placed.

That cracks are serious defects, in so far as bituminous pavements are concerned, is evident, and the older the pavement becomes the greater will be the frequency of the cracks as shown by this investigation. Undoubtedly, poor subdrainage is often the cause of cracks in concrete bases and concrete pavements; and, by providing proper drainage and expansion joints, they

may largely be eliminated. The cost of this, however, is often so high that it would mean the death of the proposed improvement, and a cheaper construction with less efficient drainage would be adopted. Furthermore, expansion joints in concrete base under a bituminous pavement cause cracks in the surface material at each joint. Therefore, with three joints to each 100 ft. of base, or 160 per mile, cracks in the surface would be produced at the same rate.

The number and seriousness of defects which result in maintenance expense should be considered as an index to the serviceability and cost of the pavement. If these defects are inherent in the pavement, they may be expected to appear at a certain rate, depending largely on local conditions, as long as specifications and construction comply with good practice. If it be true that certain defects are inherent and unpreventable, but two courses are open—the one to abandon that type of construction, the other to continue the use of the pavement, knowing that certain results must follow.

It has been said that if bituminous concrete is used as a foundation material we must exercise special care in the preparation of drainage and subgrade, and while present practice lays little stress upon these points in concrete-base construction, it is nevertheless true that equal care should be taken, if we are to expect first-class results. The chief argument in favor of concrete has been that it bridges over unstable subgrade. As now laid, concrete has failed in this regard under the stress of modern traffic. There would seem to be no reason for laying the concrete base, save that special effort in subgrade preparation is avoided. Given an ordinarily dry subgrade, good results should be obtained from the use of an all-bituminous pavement.

Large-Capacity Well Installation and Operation

Tuning-up Process with Gravel Insertion Stabilizes Yield—High Overall Efficiency Obtained With Six-Stage Pump

CAREFUL records of methods used in tuning up a 30 to 36-in. bored well having a maximum capacity of 1000 gal. per minute, at the University of Illinois, as well as subsequent data, are given in a paper presented by Prof. M. L. Enger to the Illinois Section of the American Water-Works Association. Early intermittent operation to increase capacity, insertion of gravel, with resulting high yield per foot of draw-down, unusual hydraulic behavior during long-time tests, a clay seal at the top to protect the water from pollution, a recording water-level gage and a simple vertical jet apparatus to measure the flow, are points emphasized in the paper.

Water for the university is obtained from this well and five others, the latter being 8 and 12 in. in diameter, sunk into the glacial drift to a depth of about 140 ft. and yielding 6 to 80 gal. per minute. The new well is 36 in. in diameter for 160 ft. and 30 in. for the next nine feet.

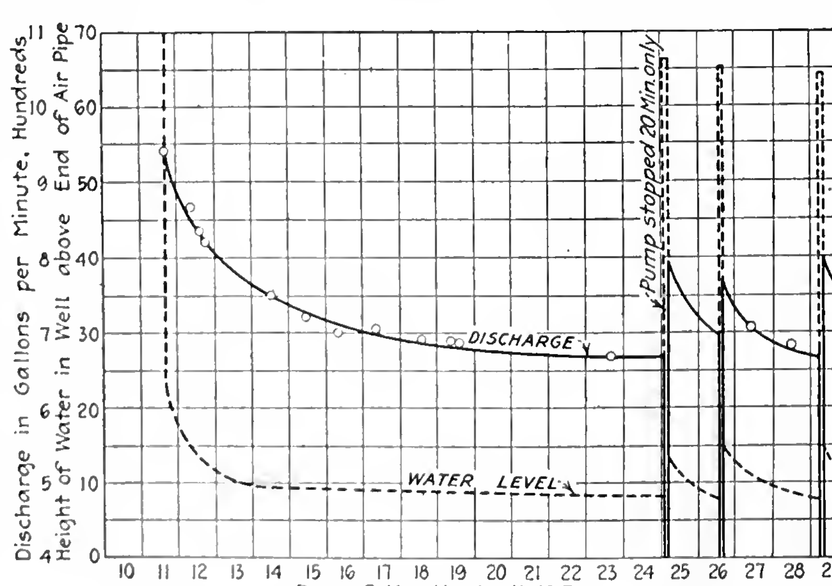
It was drilled in 1916 by the Layne & Bowler Co. by the rotary process in 3½ months, and the payment was on the basis of $19 per gallon per minute after one year's operation, with a guaranteed minimum overall efficiency for motor and pump of 55%. The cost of the previously drilled wells, motor and reciprocating pumps ranged from $934 to $2106.

The driller furnished the following log of the new well: Clay and gravel mixed, 50 ft.; clay and rock, 15 ft.; hard clay and sand mixed, 30 ft.; hard sand and gravel, 47 ft.; very hard and fine sand, 26 ft.; hard sand and little clay, 5 ft. The well was completed by putting in 98 ft. of 24-in. casing; 70 ft. of 24-in. Layne patent shutter screen, and 4 ft. of 16 x 22-in. shutter seal with a 6-in. cypress bottom. The space between the screen and casing and the wall of the well was filled with 1-in. gravel.

The tuning-up process consisted of alternately starting and stopping a temporarily installed turbine pump, in order to break down and wash away the mud wall left by the drilling process, and also to carry out the finer sand in the water-bearing stratum near the well. It was hoped in this way to form a cavity under the heavy clay roof, indicated in the above log, into which the gravel would flow and thus increase the capacity of the well. The driller stated that 30 cu.yd. of gravel were fed in at the top.

A preliminary test showed a yield of more than 1000 gal. per minute with a draw-down of 53 ft., or a specific capacity of more than 19 gal. per minute per foot of draw-down. The well now has a specific capacity of 21.5 gal. per minute. A 12-in. well at the university, tested immediately after its construction in 1906, showed a yield of 108 gal. per minute with a draw-down of 15 ft., or a specific capacity of 7.2 gal. per minute. In 1916 its yield was 4.9 gal. per foot of draw-down per minute. That is, the 10 years of operation reduced its specific capacity more than 30%, while the new well in about two years of normal use has had its specific capacity increased by about 10 per cent.

It was soon found that a yield of 1000 gal. per minute could not be maintained for any length of time without gradually lowering the water level in the new well and in the older wells. A test was begun Apr. 11, 1917,



TEST TO DETERMINE CONSTANT LEVEL

in which it was intended to run the pump continuously until the water level in the well should become constant. The water went down quite rapidly during the first two days of the test and continued to go down slowly until the morning of Apr. 25, when some trouble at the switchboard caused the circuit breaker to blow out, stopping the pump. It was started again about 20 minutes later, but during the interval the hydraulic con-

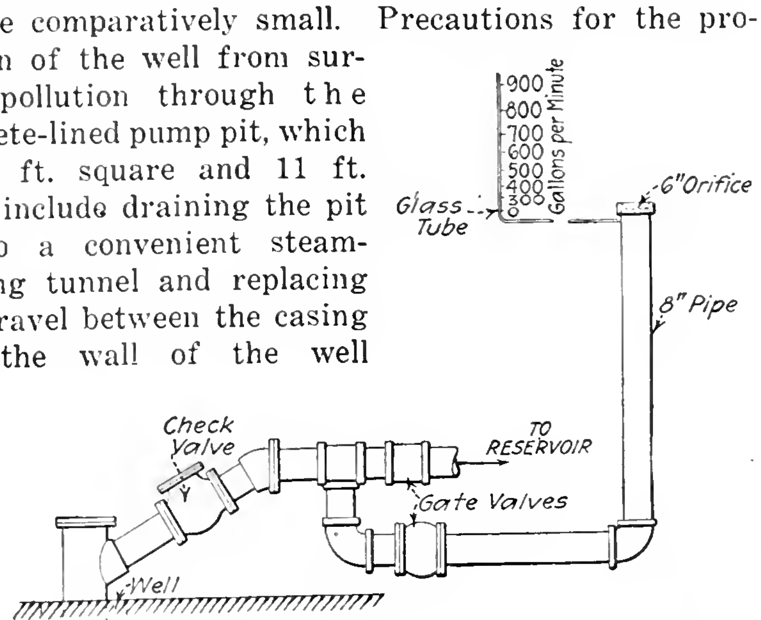
stants of the well had been changed greatly. The discharge had been about 670 gal. per minute for several days. When the pump was started again the discharge was about 790 gal. and 24 hours later was about 710 gal. per minute. The rapid change in the hydraulic constants is attributed to the behavior of the fine sand drawn toward but not into the well during the continuous operation, which by readjustment during the brief cessation of pumping was allowed to wash into the well upon resumption of pumping, thereby leaving the water passages less restricted.

In the acceptance tests made Dec. 28, 1918, the permanent installation, consisting of a six-stage, 15-in. pump, driven by a 50-hp. two-phase induction motor, showed an overall efficiency of 55.6% when delivering 587 gal. per minute against a head of 136.9 ft., and of 59.3% delivering 536 gal. against 156.4 feet.

Compared with the other well equipment at the university, the new one has the disadvantage of 15 ft. greater draw-down. But since it has never been possible

FOOTPIECE PERFORATED IN CASE BOTTOM OF WELL BECOMES SEALED

to maintain the average efficiency of the reciprocating well pumps as high as 50%, the turbine pump will get the water out of the ground with a smaller power consumption than the reciprocating pumps. With the older equipment the cost of maintenance has amounted to about 0.8c. per 1000 gal. The new equipment has not been in use long enough to draw definite conclusions, but the indications are that the maintenance cost will be comparatively small. Precautions for the protection of the well from surface pollution through the concrete-lined pump pit, which is 12 ft. square and 11 ft. deep, include draining the pit into a convenient steam-heating tunnel and replacing the gravel between the casing and the wall of the well with clay to a depth of 6 ft. below the floor of the pit. Frequent tests indicate the water is of excellent sanitary quality.



PIPING IN VERTICAL JET APPARATUS

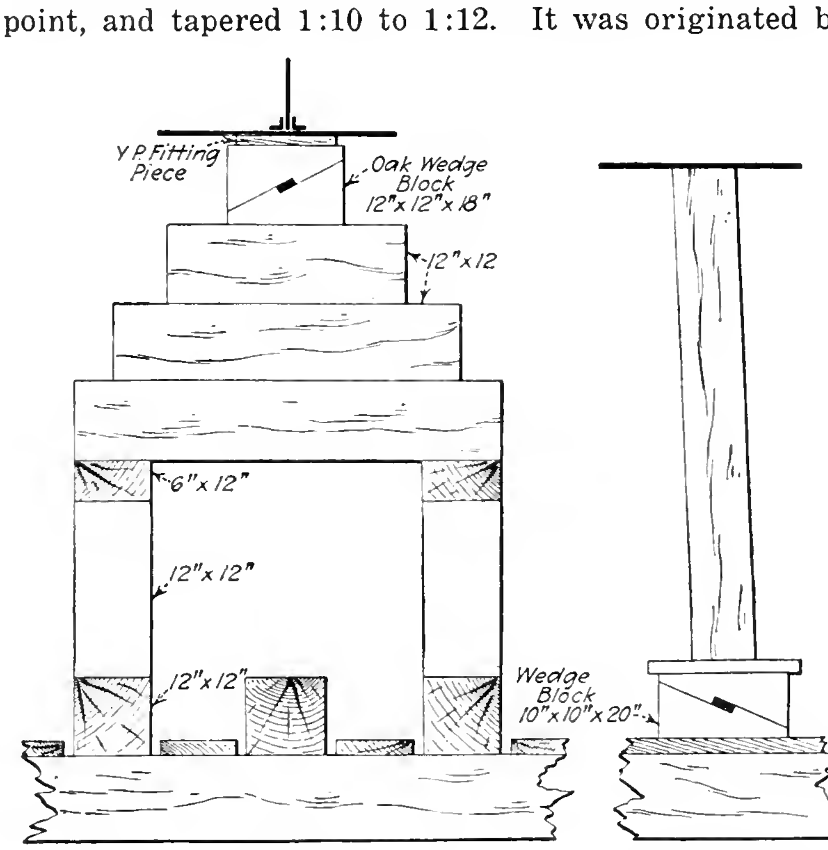
To obtain continuous records of the water level in the well, a recording gage is used to record the pressure required to keep a small quantity of air bubbling from the end of a 1½-in. pipe which hangs in the well and extends below water level at all times. The pressure in the air pipe is equal to the head of water above the end of the pipe, hence the gage shows the submergence of the end of the air pipe. The records show when the pump is started and stopped and are found very useful in the preparation of statistics of operation.

Discussion of the paper brought out three other means of determining the water level. A weighted, small-bore rubber tube is dropped between the casing and the inner pipe. By connecting the top end with a glass U-tube filled with water, the instant at which the lower end strikes water is readily noted. Electrically the level may be determined by protecting the ends of two insulated wires dropped from the sides of the pipes. A telephone battery and buzzer equipment complete the outfit. If the space between the inner and outer pipes is too small to insert anything, the whole concentric space may be sealed off and used as an air pipe, as Professor Enger used his 1½-in. pipe.

A New Quick-Release Keelblock

A WEDGE keelblock of new form, invented by a shipwright at the yard of the Federal Shipbuilding Co., Kearny, N. J., was tried out recently in the launching of the hull of the "Waukegan," a 9600-ton steel ship. The block was used on one of the keel supports and also under a shore, as sketched herewith. It worked successfully.

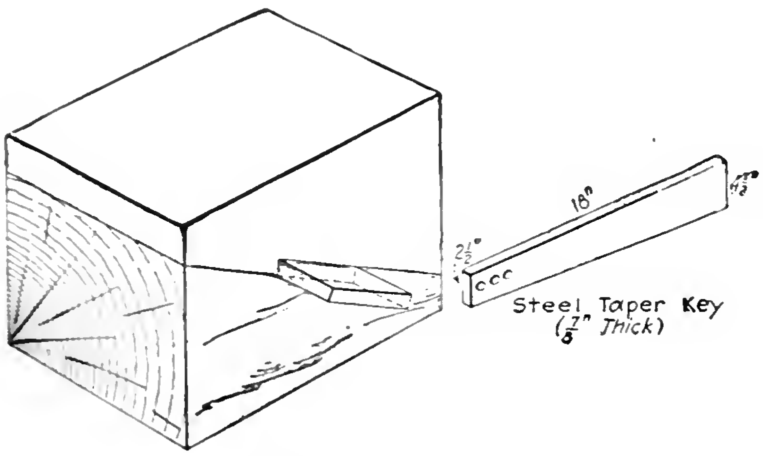
In construction, the block is a pair of wedges with the inclined faces rabbetted to receive a steel taper key holding the halves of the block from sliding. The block itself is 12 x 12 x 18 in. over all, and is cut with an inclination of about 1 on 2 for the wedge faces. The key is about 1 in. thick, 2 to 2½ in. wide at the point, and tapered 1:10 to 1:12. It was originated by



NEW WEDGE KEELBLOCKS AND SHORE BEARING

Eugene Lantz, of Jersey City, N. J., who has applied for a patent on the device.

In the launching of the "Waukegan" the wedge keelblock and a nearby shore supported on a similar but smaller (10 x 10-in.) wedge block were left as the last



QUICK-RELEASE WEDGE BLOCK DEVISED BY E. LANTZ

supports to be removed. They had been placed under the heaviest part of the ship, near the engines, and the gradual settling of the vessel as the shores were knocked out and the keelblocks split away subjected them to an abnormal load. Nevertheless, the shore released itself promptly, with a sharp kick, when a blow with an 8-lb. hammer knocked out the taper key. Thus the use of the self-releasing block eliminated the need for the heavy ramming required to knock out shores as ordinarily supported, which delays the launching and destroys a large number of shore timbers at each launching. In releasing the keelblock wedge the operation was not as quick and automatic, but a light blow dropped the two halves of the block apart after the key had been knocked out.

As a strength test, a model block made one-sixth the size of the original, or 2 x 2 x 3 in., was subjected to compressive load in a testing machine at the mechanical laboratory of Columbia University. The block, made of oak, carried a maximum load of 14,000 lb., at which stage signs of crushing appeared along the lower edge of the block. No sign of failure was noticeable at the taper key recess, and the sliding faces of the wedges showed no effect. The block released under load the moment the key was driven out.

The taper key permits the adjustment of the height of the block, in the laying of a new keel. As a means of locking the block against accidental disturbance of the key, there is a series of holes in the tail of the key to receive a ½-in. bolt.

With a block similar to that shown, but fitted with a double key, a 14-ton stern post was easily lifted off its blocking, and as easily lowered again. The block is not intended for such service, however, and is designed primarily for use as a releasing support on keelblocks and bilge cribs and under shores.

Letters to the Editor

Comment on Matters of Interest to Engineers and Contractors Will Be Welcome

Effectiveness of Strike Weapon in Raising Salaries

Sir—The railroad engineers' conference on salaries, described in your issue of Mar. 27, p. 612, is a marked forward step in this important matter and reflects much credit upon the American Association of Engineers for promoting the conference and presenting the well-worked-out schedule of salaries, but it appears that the conference expressed a temporizing attitude toward a very important question put by one of the conferees.

The account tells that, during the course of an address by W. W. K. Sparrow on "How Shall Proper Recognition Be Obtained?" the question was asked as to what the speaker proposed should be done in the event of the railroads' refusing to accept the salary schedule presented. Mr. Sparrow replied, "I would not strike," and his declaration was greeted with applause.

No positive answer was given to the question except this, "After the lessons of the war I believe men will get what, in justice, they are entitled to get."

It is perfectly true that men, and especially engineers, will get what injustice (written as a single word!) they are entitled to if they still persist in holding to a long since out-of-date standard of ethics which has been taken advantage of by the large employers of engineers.

The proposed salary schedule and all other matters pertaining to the standing and welfare of technical railroad engineers is still, and always will be, for the railroad companies to accept or reject as they choose, unless the engineers are organized and fully prepared to exercise the one final and only really effective weapon of the strike. We should, by all means, use every other possible device to obtain adequate recognition before resorting to the extremity of striking. But if engineers were so organized that they could, and would, strike effectively, it would lend very great weight indeed to fair and just representations that might, from time to time, be laid before the employers of engineers.

Mr. Sparrow suggests that the proper line of action is to organize to give the whole profession a single voice, with licensing and broader education. These are all proper and commendable plans, but they will take a long time to mature, and still longer to bring about the urgently needed increases in engineers' salaries.

Niagara Falls, Ont. REX P. JOHNSON.

Apathy in National Society a Cause of Unionization

Sir—There are two rather significant items in your issue of Apr. 10, 1919, bearing on the present status of engineers. The first is your editorial indicating the apathy of the members of the Am. Soc. C. E. toward the Development Committee of the society, an apathy probably born of the years of hopelessness that any suggestion to make the society a little bit human or to increase the number of its red corpuscles is doomed to failure. The second item, on p. 737, is that Boston engineers have joined the American Federation of Labor.

A matter of somewhat similar interest developed at a recent meeting of the Am. Soc. C. E. when it was asked that the members present discuss a proposed en-

gineering project of importance (the vehicular tunnel to New Jersey) with a view to an expression of opinion as to the feasibility, or otherwise, of the project; in other words, they were to give an opinion for nothing.

In connection with the war, engineers, in common with men in all walks of life, freely gave of their time and experience for little or no compensation of a monetary nature, but in time of peace it seems to me that if our national, state or municipal authorities need engineering advice they should pay for it at the regularly established rates, and not attempt to get it gratis under the guise of reconstruction or any other form of camouflage. Engineers, whether of the national railroads, employees of Public Service Commissions, or others, should be recognized as at least of equal importance with the labor unions, without resorting to strikes to enforce their demands.

Personally, I do not at all like the idea of unionizing under the American Federation of Labor any body of professional civil engineers. There are other ways of succeeding, and engineers really worthy of the name (who realize that their profession is much broader and needs a much broader outlook than the mere technique of running a transit, making a plan, or calculating the stresses in a bridge) will succeed without the aid of any labor union; in fact, the generally understood attitude of the labor union is fatal to the necessary vision of the successful engineer. In order, however, to avoid forcing the younger members into the labor unions, there can be no question that the national engineering societies should be vehicles for the continual promotion of the interests of the engineering profession, not merely by the formal presentation of technical papers but also by such action as that recently taken by the Engineering Council in regard to the wages of railway engineers, and the stimulation of interesting meetings.

I suggested, several years ago, the study of methods of other societies, with a view to making the Am. Soc. C. E. more human. The late J. E. Johnson, Jr., pointed out very recently (see *Engineering News-Record* of Apr. 3, 1919, p. 688) the need for directors chosen for their ability to direct rather than as a pension for past services. The secretaries, particularly, need to be in touch with the world, with the current activities of the profession and in sympathy with the members—not merely editors of technical papers, reporters of meetings and guardians of the treasury, all of whom are necessary and desirable but far from meeting the needs of the profession.

I believe that unless our leading technical societies find a solution of the many social problems confronting the engineer; help him to reëmployment if he needs it; see, so far as it is possible to do so, that he receives adequate compensation; take up actively such questions as those recently developed in connection with the Public Service Commission of New York, etc., many of the younger members will be forced into the ranks of the labor unions. This will be, in the long run, as unfortunate for them as for the whole profession.

I think there is at least beginning to be a realization of the need of this help to younger engineers by the established societies, and I believe that *Engineering News-Record* could do perhaps more good than any other agency by keeping the need, the efforts made to meet it, and the results obtained, prominently before all members of the profession. F. LAVIS.

New York City.

Economic Betterment of the Engineer

Sir—Has this war with all its intrigue and violence been sufficient to awaken us from our apathetic, mesmeric belief that we were too professional to consider the economic betterment of our profession? It is safe to assume that it has, in the majority of the profession. Then, taking it for granted that we are sufficiently awake to realize the new order of world progress, we can no more go back to that sluggish, self-satisfied, every-man-for-himself system, than the oak can return to the acorn.

Now, the problem that confronts us is the obtaining a fair day's pay for a fair day's work. Can we look to the societies and associations for the solution of this problem? Judging from past experiences, No. They in the past have been stupefied by an exaggerated sense of self-importance, dreaming away the hours, unmindful of an economic betterment for members or co-workers; publishing voluminous papers for which no real, live worker can spare the time to extract the useful from a mass of matter. Let us hope that the societies and associations synchronize with the new order of things, and become more progressive, for the complete betterment of all.

Can the individual worker do anything to promote his economic betterment? No. Not while he works alone. Those of us who during the war were connected with Government and municipal work had a chance to realize how insignificant we were individually. In one instance there were about 250 engineers, working from 10 to 14 hours a day and seven days a week, who felt that they were not being treated fairly as regarding pay, and hours of work. They decided to see if there were not some means of obtaining a decrease in the hours of labor, if nothing more; held a meeting; sent a letter to the "chief pundit" asking for an explanation of the Government's attitude in requiring excessive hours of labor, but only eight hours' pay per day.

After waiting an unreasonable length of time for an answer, the committee decided to have a personal interview with the "chief pundit"; and in answer to their demand for a reason for utter disregard of their previous requests they were told that there was not time to take the matter up, and to rest assured that there would be a just settlement, either in shorter hours of work, or a possibility of their being compensated for all overtime.

This seemed satisfactory to all, until it was discovered that every week men were leaving, credited with numerous hours of overtime without receiving compensation for the same. It soon became apparent that something more drastic should be done.

The carpenters on this job decided that they needed a substantial increase in pay; and when their request failed to meet their expectations, about 80% of their number started to leave the works. They were stopped by headquarters and assured that they would be given all they demanded, and that the increase would start from the time they commenced work on that job.

The only possible solution of the problem seemed to be in unionization. When you say "unionize" to a professional man you are sure to meet that threadbare argument; that we are professional men, not laborers. Even so, what, may we ask, have we received in return for all our professionalism? John M. Goodell in *Engineering News-Record* of Mar. 6, 1919, p. 482, says: "It may be found that a very large part of the

work done by engineers is really little more than skilled labor." Assuming he is right, one would naturally suppose that their compensation would be a little more than that of the skilled laborer, instead of being less than that of the so-called common laborer.

After many meetings the engineers of Boston and vicinity decided to obtain a charter from the American Federation of Labor, and now have a union that can give a good account of itself, and which will need to be reckoned with in the future. We know that, in so far as our demands are just they will be granted; that the Golden Rule is applicable to business, and the business that does not apply it in some measure is bound to fail. It is time for us to get together in one strong unit for the economic betterment of all, and in doing so we may dim the fires of Bolshevism, I. W. W. and O. B. U.

LOUIS FISHER.

Waltham, Mass.

Another Formula for Weights of Steel Roof Trusses

Sir—The article in your issue of Mar. 20, 1919, p. 576, entitled "Weights of Steel Roof Trusses by Empiric Formulas," by R. Fleming, was read by the writer with much interest, in view of the fact that he has prepared a table to give close approximate weights of steel roof trusses, for the purpose of preparing preliminary estimates on factory buildings. A print of this table is herewith inclosed.

The basis of this table is the formula shown thereon, which was devised by the writer by combining the two well known formulas of Ketchum and Ricker, referred to in Mr. Fleming's article. Having at hand some accumulated data on the weights of steel roof trusses, which had been detailed by our office, and on others for which we had prepared detailed lists of material for estimates, the writer applied a number of the textbook formulas, hoping to find one which would agree fairly well with our estimate data. But no single formula gave results even approximately close. It was found that the Ricker formula gave weights which were too low and the Ketchum formula gave weights which were too high to agree closely with our data. After making a study of the two formulas, and carefully reading the explanation of the Ricker formula in the University of Illinois Bulletin No. 16, it occurred to the writer to combine the two formulas, thereby making use of the span factors in the Ricker formula and the distance center to center of truss factor and variable load factor in the Ketchum formula.

This was tried and a coefficient for the variable load factor was determined by trial with a slide rule. The following formula resulted, and gave weights which were surprisingly close to our data:

$$W = \frac{P}{92}\left(1 + \frac{S}{25} + \frac{S^2}{6000} + \frac{S}{5\sqrt{A}}\right) SA$$

in which W = total weight of truss; P = carrying capacity of truss, exclusive of its own weight in pounds per square foot of horizontal projection; S = span in feet; A = distance center to center of trusses.

Again referring to Mr. Fleming's article, the weights for the three trusses of 40-, 60- and 80-ft. spans, bays 16 ft., load equivalent to 40 lb., given by this formula are 1356, 2920 and 5156 lb., respectively; and for those trusses of similar spans and bays, but with a load of 56 lb., the weights are 1898, 4088 and 7218 lb., respectively.

It will be noted that in general these weights more nearly agree with the estimated weights than those of either the Ketchum or the Ricker formula, especially for the shorter spans.

The table of weights of steel roof trusses prepared from the formula is self-explanatory. It has proved a reliable guide in checking estimates, in giving the weight of trusses for design purposes, and has been used a number of times by the writer in preparing a preliminary estimate without making any design of trusses.

It would be interesting as well as instructive to have others of your readers apply it to their roof-truss data and report the results obtained.

MARSHALL L. MURRAY,

Steel Superintendent, Concrete Shipyard, The A. Bentley & Sons Company.

Jacksonville, Fla.

Who Can Solve This Contractor's Problems?

Sir—We of course are interested in looking through the "Hints for the Contractor" in your estimable journal, and for a long time have expected to see some contractor come to the front with certain much-needed devices.

One is a device for spreading screenings on water-bound macadam-road work. This work is nothing less than drudgery. All specifications provide that the screenings "shall be whipped on." Dropping or shoveling on will not do, and on any work of this kind you will hear the contractor moaning for some such device.

The writer has an idea and believes it is practical. As now required, screenings must be piled along the work at intervals, say of 15 to 20 ft. My idea is to pile them in large piles 50 ft. apart and then use a mounted blower with a receiving hopper large enough for two

WEIGHTS OF STEEL ROOF TRUSSES

The table gives weight of truss for a capacity of one pound. To find total weight of truss, multiply value in table by capacity of truss in pounds = P.

For general purposes, P = 60 lb.

*Distance c. to c. of trusses in feet = A.

men to shovel into, the blower to have a flexible metal hose say 35 ft. long. The power plant could be a gasoline or oil motor. Mud, muck, sawdust, concrete and a number of other commodities are blown through hose and pipes, why not screenings? Two men shoveling from piles and one on the hose will do more work than six men carrying one shovelful at a time a distance of from 5 to 30 ft. and spreading it. A shovelful of screenings has considerable weight, and, when it is carried all day it doesn't take long for a worker to begin to look for another job.

The other item is a turntable for motor trucks. When the truck owner sees his expensive equipment being nosed into ditches and over rough fields for turning purposes, see-sawing to make the turn in narrow places or backing long distances from places fit to turn in, and realizes the time lost as well as the wear and tear on equipment, it is patent to him that a turning base is an absolute necessity.

We are bringing this to your notice in the hope that you may be able to present something practical on the two subjects. Someone will do real business with contractors if he will bring out practical devices on these lines. FRED C. BEAM.

Lima, Ohio.

The Engineer As a Physical Economist

Sir—May I offer something between definition and discursion?

Engineering is the science of cost analysis. An engineer is a physical economist. Everyman knows the engineer as one who evaluates, although the word evaluate, perhaps, will not occur in Everyman's vocabulary. The engineer is fundamentally an estimator, a man with a mathematical pencil, and is a prover rather than a speculator. He calculates stresses and strains, tests materials, records performance of men, machines, and forces of nature, derives and applies formulas. Why? To arrive at development or production costs by a method superior to cut-and-try, or rule-of-thumb.

Engineers, now as formerly, are military or civil; the former, waymakers for the forces of war and inherently destructive; the latter, always taking the element of economy into account and inherently constructive. When military engineers construct, expediency is paramount to economy. Mining, structural, electrical, mechanical, chemical, sanitary, agricultural, also architectural, are terms which designate the field of activity of the civil engineer. A competent mining engineer, for example, must have at least a working knowledge of hydraulic, mechanical, electrical, and perhaps other branches of civil engineering: yet he is essentially a physical economist, and although he may fancy himself ever so self-contained, he can never fly very far from the parent body on his own tangent.

As between those who toil and those who spin, classify engineers with the latter. A civil engineer usually spins for another, and ever must needs be compensated with a stipend, rational rule ignored. He is neither a producer of wealth directly, narrowly considered, nor yet a parasite on humanity. An outlander in the business world, he is requisitioned, like Daniel, to visualize and interpret dreams; but no one expects him to promote or participate. Does the gambler, or banker, dream of a fertile valley replacing an arid waste? His engineer will interpret the dream in terms of a specified dam and irrigation works. Does the trader dwell in a mansion? His architect schemed it. Utility and efficiency gaging the engineer, utility and beauty guiding the architect. A 4H for the one, a crayon for the other, and in either case "How much will it cost?" and "Good morrow, professor."

Comparing Socialists with engineers, the former expect to reduce work and eliminate profits; the latter are expected to work hard and forego profits. The engineer may be likened to a medieval grist miller grinding corn and retaining barely enough meal for supper. What miller nowadays is satisfied with one little mill, and grinding only? An engineer sometimes gets above (at least more potent than) the purely professorial and single-phased class which remains untouched by the lucre of gain—and becomes successful as a contractor or other master spinner. Whenever he arrives, discovers himself, plays his initiative, his fellows are no longer solicitous as to his status, and seldom bother themselves about his ethics.

Engineers as such do not engineer. They design, construct, valuate, report, or what not that is decent; while promoters, politicians, or schemers, engineer. The noun is honest, but the verb implies astuteness and is taboo.

It seems to me engineers could and properly should engineer, and that without any lowering of ethical standards. At least, they should endeavor to engineer their own fortunes, but there appears to be small hope so long as they remain deficient in everything but efficiency and oblivious to the uses of imagination. Instead of being satisfied when they have determined what it will cost, if they will step over the threshold and interest themselves as to what it will win, realizing that the word "win" implies "venture" and "contest," if they will move their standard up from responsible charge to responsibility, perhaps they may be expected to represent something.

Question: Has the engineer anything that he can capitalize or even enterprise, or is he inherently a peon? What is his logical status? C. P. KEYSER.

Portland, Ore.

Correction

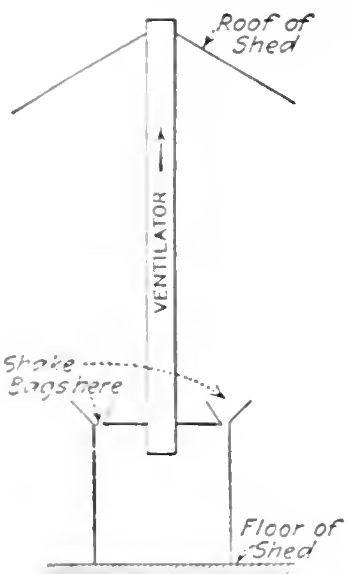
The following corrections should be made in the article, "Field Methods on Rapid Stadia Surveys at Columbus," published in *Engineering News-Record* of Apr. 17, 1919. Starting at line 8, column 2, p. 776, it should read: "Primary traverses averaging 15 miles in length were easily kept within an error in minutes of angle of one-half the *square root* of the length of the traverse in miles, and within a linear closure of 1 in. 1500, while levels always checked between United States Geological Survey bench-marks *in feet*, as well as five-hundredths *times* the square root of the miles of levels." Starting with line 7, column 1, p. 777, it should read: "If the level reading were taken *after* the distance had been read on a shot, it would be taken first on the next shot, thus saving the time necessary to reset the bubble." Loose-leaf notebooks were not used on this work, as indicated by the perforations shown in the illustration, but two ordinary transit notebooks were used alternately, so that the notes in one could be plotted while the other was in use.

HINTS FOR THE CONTRACTOR

DETAILS WHICH SAVE TIME AND LABOR ON CONSTRUCTION WORK

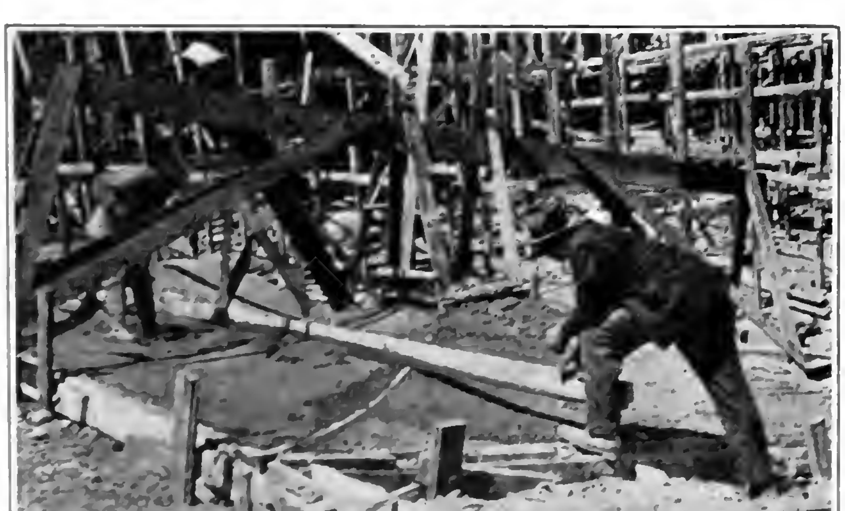
Dust-Bin for Shaking Out Empty Cement Bags

JOHN OWENS, foreman of the Englewood gravel-washing and concrete-mixing plant of the Miami Conservancy District, recently rigged up a simple bin with ventilating stack, in which empty cement bags can be shaken out without the raising of a cloud of irritating dust. The device is shown in the April *Miami Conservancy Bulletin* by the sketch reproduced herewith. It not only does away with dust, but it reclaims fully twice as much cement as shaking out the bags on the shed floor or in an open box, and allows the work to be done twice as fast. From 1500 bags shaken out, 11 bags of cement were reclaimed. The device consists of a box 6 ft. long, 3½ ft. wide, and 3 ft. deep, with a wooden air shaft running from the top of the box up through the roof of the cement shed. Three inches from the top of the box the two long sides flare out, as shown, at an angle of about 45°. The box has a lid narrower than the width of the box, so as to leave an open space about 2 in. wide between the long edges of the lid and the sides of the box, as shown. The empty cement sack is dropped mouth down through this 2-in. slot and shaken into the box. The effect of the ventilator is to prevent dust rising through the slot into the cement shed.



Suspended Angle Irons Form Screeds for Groined Floor

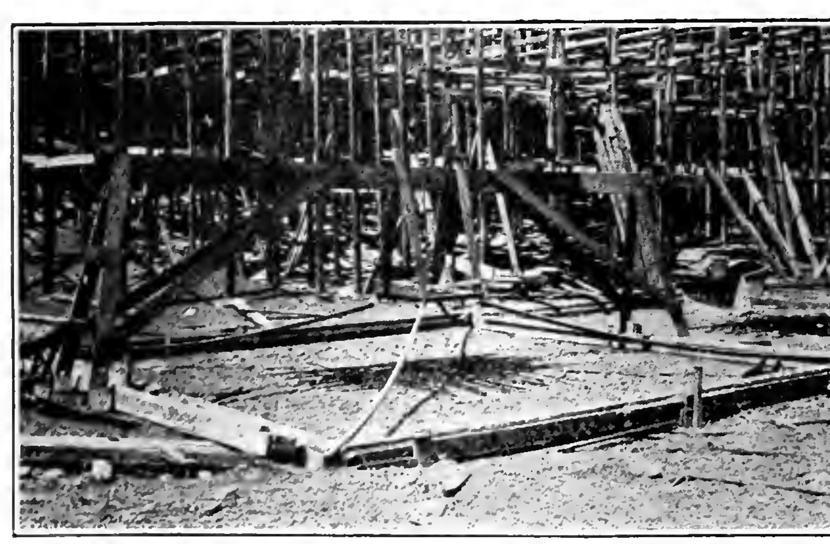
IN THE construction of the low-service reservoir for Dayton, Ohio, last year, the Danis-Hunt Co., contractor, used a special form of screed for the groined floor which is shown in the accompanying views. These



ANGLE IRONS HUNG FROM FRAME FORM SCREED

Other Articles in This Issue of Interest to Contractors:

floor groins were 20 ft. square at the bottom and 30 in. deep, resting on the ground over a reinforcing mat. A timber horse was placed over each groin location, and suspended therefrom was a wood frame carrying a steel frame to the size and shape of the groin. This steel frame was made of angle irons, with an upper square and four dependent corner angles bent to the curve of



SCREEDING THE GROINED FLOOR TO THE ANGLE IRON

the groin, which angles rested at their outer ends on timbers laid to the proper dimensions on the ground.

Concrete was piled into the groin and screeded off against the angles, as shown in the second view. Just as soon as this concrete would hold its position the frame was lifted, and the small opening left by the angle, being pulled out, was filled in and troweled to surface. The work was under the general direction of H. C. Wight, superintendent of water of the City of Dayton.

Cutting Concrete Piles at Port Terminal

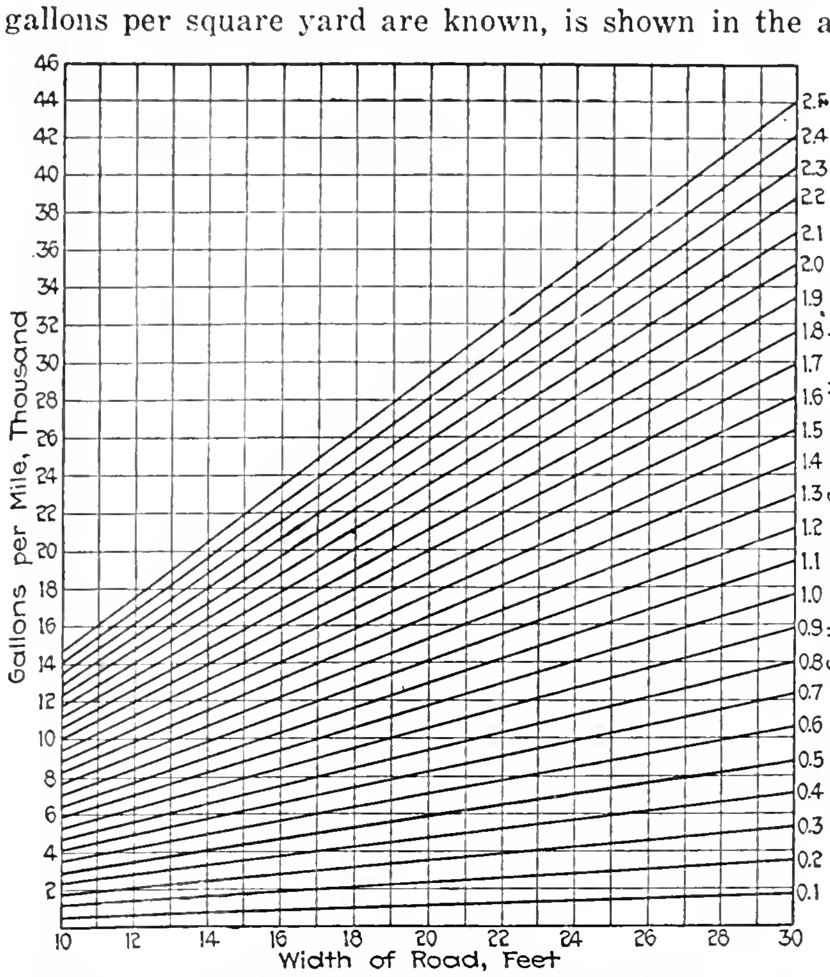
IN THE United States Army base at Charleston, S. C., precast concrete piles were used for a portion of the dock structure. These were cut to proper elevation, as shown in the accompanying view, by sledging off the surface concrete about 3 ft. above the cut-off level and cutting the rods with a gas torch. The concrete shaft

GAS TORCH CUTS RODS ABOVE CUT-OFF, AND PLUG AND FEATHER SEVERS SHAFT AT PROPER LEVEL

was then severed at the cut-off level with plug and feather, and the upper section pulled out by a derrick, leaving the projecting rods, as shown at the left of the view, for bonding purposes.

Number of Gallons of Road Oil Per Mile for Known Width and Rate

A HANDY chart for determining the number of gallons of road oil required to treat one mile of highway, when the width of the road and the number of gallons per square yard are known, is shown in the accompanying illustration. The chart was put out by the Union Oil Company.



GALLONS OF ROAD OIL REQUIRED PER MILE OF ROAD AT GIVEN WIDTH AND RATE

Knowing the width of the roadway, follow vertically upward until the line intersects the diagonal line of gallons per square yard as indicated at the right; then read the number of gallons per mile at the left. Thus, with a 20-ft. roadway and a rate of 1.8 gal. per square yard, 21,000 gal. would be required.

Grease Pump Is Useful to Dry Diaphragm Pumps in Cold Weather

A GREASE pump of about 1-in. diameter and 12-in. length has been used by William G. Cooper, contractor, on the Gravesend Ave. elevated line, Brooklyn, N. Y., for removing water from pumps of the diaphragm type each evening when they might be damaged by freezing during the night. By the sucking of the water into the pump and discharging it on the ground the water is removed quickly and with much greater ease than by the tipping up of the pump to dump it. The pointed nose of the grease pump can reach the smallest crevice and so gets all the water on top of the diaphragm.

Contractor's Canopy Need Not Be Ugly

SEVERAL times in *Engineering News-Record* there have been shown good-looking contractors' structures. The one here illustrated is another proof that these structures need not be eyesores. It was erected

EFFECTIVE CONTRACTOR'S CANOPY COMBINES GOOD APPEARANCE AND ADVERTISING VALUE

on Chestnut St., Philadelphia, by F. L. Hoover & Sons, contractors, at the new store for the A. H. Geuting Co., shoe dealers. The structure speaks for itself, and is a credit to the contractors who erected it.

NEWS OF THE WEEK

New York May 1, 1919

Engineers Want Topographic Maps of Country Completed

Expedition in the completion of the topographic maps of the country by the United States Geological Survey was urged Apr. 25, at Chicago, by the conference on a national department of public works. The conference by unanimous vote asked Engineering Council to present to the President and Congress facts as to the economic necessity of completing the maps at an early date. Already the National Service Committee has taken the matter up with the Secretary of the Interior who is in accord with the idea. He accepted the proposal to ask Congress for an increase in the pre-war estimate of $350,000 per year to $500,000. It is expected that the states will meet this amount with an equal sum.

F. W. De Wolf stated that only 42% of the country was mapped and at the present rate the completion would not be achieved within 80 years. A crisis has arisen in the topographic service because the last Congress cut the $425,000 asked for to $289,000. Fortunately the sundry appropriation bill did not pass and there is still time to amend it.

Meeting of United States Good Roads Association

The seventeenth national convention of the Good Roads Association, combined with the seventh United States Good Roads Show and the third annual convention of the Bankhead National Highway Association, was held at Mineral Wells, Tex., during the week of Apr. 19, and was well attended. The highway association elected the following officers: President, Senator John H. Bankhead, of Alabama; first vice-president, Gov. Charles H. Brough, of Arkansas; second vice-president, Gov. C. A. Larrazarole of New Mexico; third vice-president, R. M. Hubbard, of Texas, and director general, J. A. Rountree, of Birmingham, Ala. The Bankhead association elected the following officers: President T. S. Plowman; treasurer, L. G. Jones; general secretary, J. A. Rountree, and director-at-large, W. W. Heaton.

Competition for Illinois Road Contracts Not Active

Bids were scattered and bidders were comparatively few on the first two groups of sections of Illinois state-aid roads, the construction of which this year was announced. On the nine sections of the Dixie Highway, aggregating slightly over 42 miles of 16- and 18-ft. road, there were eight bidders, only one of which made prices on all nine sections. The largest number of bidders for any section was four, and on four sections only one bid each was submitted. On the Lincoln Highway, aggregating 20 sections and about 70 miles of road, there were 15 bidders. Four bids were the maximum number on any one section; on four sections there was only one bid each.

Itemized prices are not yet made public, but lump-sum prices ran from $17,500 to $29,000 per mile for these concrete roads 16 and 18 ft. wide. Generally, the bids ranged around $21,000 to $24,000 per mile.

Among the bidders were several large construction firms, such as Bates & Rogers, James O. Heyworth and the Foundation Co., which heretofore have not gone into road construction. A large number of constructors attended the lettings and watched closely the run of prices.

Employment

For the convenience of engineers returning from military life, and others, there are listed below agencies which may be helpful to those who are seeking employment:

Engineering Societies Employment Bureau; secretary, 29 West 39th St., New York City.

American Association of Engineers, 29 So. La Salle St., Chicago. Service to members only, but Army or Navy engineers in uniform who are eligible to certified membership may join without payment of entrance fees or dues while in uniform and for six months after discharge.

Engineers' Service Bureau, maintained by the Joint Council of Engineering Societies of San Francisco, Engineers' Club, 57 Post St., San Francisco. Only applications by mail or wire will be considered.

The Federal director of the United States Employment Service in New York State announces the receipt of a letter from J. P. Morgan & Co., in which $100,000 is offered for the purpose of continuing the work of the service up to July 1 of this year. The Professional and Special Section in New York will therefore be continued, but will be located at the main office, 469 Fifth Ave., New York City.

Engineering Council and Nonmember Societies

Chicago Conference Discusses Need for Federation of Engineering Organizations

Following the discussions on the proposed Federal Department of Public Works, the main topic set for the conference of engineering societies in Chicago last week, a session was devoted to the discussion of the relation of nonmember societies to Engineering Council. At times the subject was broadened to cover engineering society activities generally. The drift of the remarks was that a federation of engineering societies was needed, and that federation should come about through such amendment of the rules of Engineering Council that it could admit local societies. J. Parke Channing, chairman of the council, announced that such an amendment was pending, and both he and Dr. Ira N. Hollis, past chairman of the council, expressed the view that it would soon pass and receive the approval of the founder societies.

Veto Power Discussed

Mr. Channing, in opening the discussion, pointed out that even after the passage and approval by the four founder societies the amendment above referred to would still leave it in the power of any one of the founders to veto a measure. He asked whether that should be permitted to stand or whether, if locals are admitted, there should be a change whereby proportionate voting power is established. A number of delegates said they felt it would be unfair to new societies taken in, to allow the veto to repose in any one society.

Dr. Hollis expressed the view that the purpose of all worth-while engineering societies is to teach their members to serve the public. He urged that we learn to use what we have in the way of engineering societies rather than establish new ones, and that thought was heartily indorsed by C. F. Loweth, of Chicago. Gardiner Williams, of Detroit, while admitting that the national societies had done good work, believed that they should confine themselves to technical activities, letting Engineering Council organize the locals for civic work, since civic influence must be exercised locally. He advanced the view, seconded by others, that engineering practice is so complex and local conditions such that there is warrant for the existence of a large number of engineering societies, and that the new ones, so long as they had a good reason for being, would not harm the existing organizations. All should be tied to-

gether, however, by some coördinating agency.

Replying to a query whether the American Association of Engineers would consider affiliation with Engineering Council, C. E. Drayer, secretary of the association, said that he could not speak for his board. He did feel certain, though, that Engineering Council could neither absorb nor take the place of the association. He urged that the two organizations should not duplicate work.

The question of the attitude toward the union movement being raised, a number of speakers expressed the view that union methods were not consonant with professional ideals. One chief engineer of a railroad was cited who believed that his young men could get fair compensation only by organizing. Reference was also made to a prominent engineer who deplored the movement, but felt that no antagonism should be developed against the men who joined unions, so that when they have learned that the unions cannot satisfy their needs in a professional way they will not feel that the older societies have turned from them because of their earlier union affiliations.

Two-Way Flat-Slab Patent Invalid

Another flat-slab reinforced-concrete floor patent has been declared invalid in a district court. This one is the Sinks patent, U. S. No. 1,005,756, on a two-way construction. The decision was rendered Apr. 16, 1919, by Judge A. L. Sanborn in the United States District Court, northern district of Illinois, eastern division. Suit was brought by the Condron Co., present holders of the patent, against the Corrugated Bar Co. for infringement in the construction of buildings at Fort Wayne and Chicago.

Judge Sanborn concluded his decision as follows: "The patentee may have made a better flat-slab or shallow-beam construction than prior inventors, but the patent itself, apart from simplifying computation, simply proceeded along lines suggested by engineering skill. I think the patent is invalid and that the bill should be dismissed."

Pending a decision on this case in the United States Court of Appeals, the Condron Co. announces that it will make no royalty charges to its patent licensees, or to those who accept licenses from them for the use of the Sinks invention in flat-slab buildings erected or contracted for between Apr. 30, 1919, and the date of such decision, regardless of whether the decision, on appeal, sustains the Sinks patent or not. Under the Condron Company's agreement with the owners of the Norcross patent, which expired Apr. 29, 1919, all licenses granted by the Condron Co. for the Akme System have protected the company's patrons from claims of infringement of the Norcross as well as the Sinks patent.

Registration Law in Michigan Passes Legislature

Architects, Engineers and Surveyors Included Under Bill as Amended

The act for the registration of architects, engineers and surveyors has been passed by the Michigan legislature as an amended form of one of the alternate bills introduced into the legislature, and discussed in *Engineering News-Record* of Feb. 27, 1919, p. 423. It provides as follows:

All persons desiring to practice or to be be known as architects, engineers or surveyors, as principals or in responsible charge of work, must be registered by a board, to be appointed by the Governor and to consist of three architects and five engineers. All persons who have been engaged in practice as engineers or surveyors as principals or in responsible charge of work for a period of two years preceding the adoption of the act shall be registered without examination in the branch in which they show themselves to be qualified.

Registrants shall be designated as registered architects; or as registered engineers of such class as the work they may have done or for which they may be qualified may determine, particularly as of classes of less general qualification than that indicated by the title civil, mining, mechanical, electrical or chemical engineer; or as registered surveyors. No plat of the subdivision of land shall be received for record by any public official unless it has been prepared by a registered engineer or a registered surveyor and signed by him as such.

Persons desiring hereafter to begin practice as above shall pass an examination in the English language and in such other appropriate subjects as the board shall determine. Engineers and architects of recognized standing as specialists, resident in other states, shall be admitted to practice without examination, and engineers registered under laws of other states and countries providing equivalent requirements, and in good standing thereunder, shall be admitted to practice, provided that similar privileges are extended to the registrants under this act.

After the end of the construction season of 1919 no public work of an architectural or engineering character shall be undertaken by the state or any county, township, municipality or village thereof, the estimated completed cost of which shall exceed $2000, unless the plans therefor shall have been prepared by a registered architect or a registered engineer, and the work shall be supervised by a registered architect or registered engineer.

No time limit is set within which registration must take place for those now qualified to register under the act. No restriction is put upon the performance of architectural or engineering work for private parties by persons who do not call themselves architects or engineers. The act repeals the preëxisting act for the registration of architects, and provides that all registrants under that act shall be considered as registered under the new act.

The act requires an examination fee of $5 and a registration fee of $15 from those taking examinations, and a registration fee of $20 for those registered without examination, and a fee of $5 for renewal of certificates which are renewable, upon not less than 30 days' notice on Jan. 1, 1925, and on the first day of January every fifth year thereafter. The members of the board are appointed to hold office for eight years, one member to be appointed each year.

Executive Secretary for American Chamber of Commerce, London

Appointment of George P. Toby as executive secretary of the American Chamber of Commerce in London has been announced by its president, G. M. Cassatt. The membership of the London organization contains representatives in England of American manufacturing and exporting interests and also prominent British manufacturers, exporters and importers. It is equipped to handle inquiries expeditiously, and desires American business men to utilize the service.

Mr. Toby, the new executive secretary, has been long connected with banking and industrial corporations in this country and is well known as an investment banker. In this capacity he has made a careful study of the operation of American industries and public utilities. For over a year during the war he was connected with the Treasury Department at Washington on the preparation of plans for coöperation between the various Government departments and the business world, including studies of the markets for products, methods of distribution, etc. His visits to Europe in this connection and other extensive travels in Europe and Canada have given him a broad view of the field.

Consulting Engineers Honor French High Commissioner

The American Institute of Consulting Engineers gave a dinner in honor of M. de Billy, deputy high commissioner of France, on Apr. 24 in New York City.

The dinner was held immediately before the departure of M. de Billy. It was felt that the good will of the engineering profession should be evidenced, as the commissioner himself is an engineer. In speaking of his experiences in this country, M. de Billy dwelt upon the aid that American engineers had extended to the commission in the work it has been doing during the war.

The following guests were present: M. de Billy, deputy high commissioner, French Republic; Controleur H. Johannet, Colonel Dulauroy, Colonel Duvaux, Captain Vaneufville, Lieutenant Mittaine, all of the French mission; S. M. Felton, formerly director general of military railways, United States Army;

Consul General Romolo Tritoni of Italy; Consul General Pierre Mali of Belgium; E. G. Spilsbury, M.E.; Nelson P. Lewis, C.E.

Civil Service Examinations

New York.—Junior assistant engineer, State Engineer and Highway Department, $1200-$1440 per year, May 24. Apply to State Civil Service Commission, Albany, N. Y. File applications before May 24.

New York.—Bridge designer, Public Service Commission, First District, $1501 to $2100 per year. Apply to State Civil Service Commission, Albany, N. Y. File applications before May 24.

Philippines.—Wireless engineer, Bureau of Posts, Philippine Government, $3000 per year, June 10. Apply for form B. I. A. 2, to be filed before June 10, filled in by medical officer in the service of the United States.

Tennessee.—Assistant highway engineer, $1800 to $2100 per year, May 7, at Nashville. File applications as soon as possible.

For United States Civil Service examinations listed below, apply to United States Civil Service Commission, Washington, D. C., or to any local office of the commission, for form 1312.

United States.—Expert patent investigator, $1800 to $2400 per year, and technical patent expert, $2400 to $3600 per year, May 20.

United States.—Highway bridge engineer, $1800 to $2100 per year, junior highway bridge engineer, $1200 to $1600 per year, Bureau of Public Roads and Rural Engineering, May 21. File applications in time to arrange for examination at place selected by applicant.

United States.—Engineer in forest products, $1860-$3000 per year; assistant engineer in forest products, $1200-$1800 per year, Forest Products Laboratory, Madison, Wis., May 27. File applications before May 27.

United States.—Chief of road survey party, $1800 to $2100 per year, transitman for road surveys, $1200 to $1800 per year, highway draftsman, $1200 to $1800 per year, Bureau of Public Roads and Rural Engineering, May 29. File applications before May 29.

United States.—Scientific assistant in public health work, Public Health Service, $1500-$2500 per year, June 3. Apply for form 2118, to be filed before June 3.

United States.—Senior engineer and senior architect, Interstate Commerce Commission, $1800-$2700 per year, June 10. File applications before June 10.

United States.—Assistant material engineer, Bureau of Construction and Repair, from $4.48 to $6.40 and upwards per diem. No date specified. Applications should be filed without delay.

United States.—Junior recreational engineer, Forest Service, Denver, Colo., $1800 to $2400 per year, May 6. Apply for Form 2118.

United States.—Statistician, Department of Interior, $1800 per year, May 13. Apply for Form 2118.

Engineering Societies

Calendar

Annual Meetings

NATIONAL FIRE PROTECTION ASSOCIATION; 87 Milk St., Boston, Mass.; May 6-8, Ottawa, Can.

AMERICAN ASSOCIATION OF ENGINEERS, 29 S. LaSalle St., Chicago; May 12-13, Chicago.

NATIONAL CONFERENCE ON CITY PLANNING; 19 Congress St., Boston; May 26-28, Niagara Falls and Buffalo.

AMERICAN WATER-WORKS ASSOCIATION; 47 State St., Troy, N. Y.; June 9-13, Buffalo, N. Y.

AMERICAN SOCIETY OF CIVIL ENGINEERS; 29 W. 39th St., New York; June 17-20, St. Paul-Minneapolis.

AMERICAN SOCIETY FOR TESTING MATERIALS; University of Pennsylvania, Philadelphia; June 24-27, Atlantic City, N. J.

AMERICAN CONCRETE INSTITUTE; 6 Beacon St., Boston; June 27-28, Atlantic City, N. J.

The San Francisco Association of Members of the American Society of Civil Engineers was addressed Apr. 15 by W. Lewis Clark, an engineer of the California Highway Commission, who spoke on experience in that state in highway construction. Mr. Clark spoke for A. B. Fletcher, chief engineer of the commission. Among the subjects discussed were engineers' licensing laws, the trend toward union organization of draftsmen and engineers, the Development Committee program, and means of strengthening the influence of the parent society.

The Engineers' Society of Milwaukee held its regular monthly meeting Apr. 29 under the auspices of the Milwaukee section of the American Institute of Electrical Engineers. The meeting was addressed by A. A. Oswald, of the Western Electric Co., who read an illustrated paper on "Wireless Telephony and Telegraphy in War."

The Montana Society of Engineers voted to make eligible for membership all members of the national engineering societies, without restriction to any single branch of engineering. This action, in the form of an amendment to the constitution of the society, was taken at the annual meeting held in Great Falls Apr. 11-12. The following officers were elected for the coming year: President, Samuel Barker, Jr., Butte; vice-presidents, Charles A. Lemmon, Anaconda, and George T. McGee, Helena; secretary and librarian, Clinton H. Moore, Butte.

The Pittsburgh Chapter of the American Association of Engineers will hold an open meeting for railroad technical engineers May 3. Among the speakers will be **D. A. Tomlinson**, assistant secretary of the national association.

The Engineers' Club of Minneapolis was addressed Apr. 21 by B. S. Moodey, of the Minneapolis Steel & Machinery Co., who spoke on the heat treatment of steel.

The Engineers' Club of Trenton was addressed Apr. 24 by J. F. Lincoln, vice-president of the Lincoln Electric Co., Cleveland, who spoke on "Electric Arc Welding as Applied to Present-Day Commercial Manufacturing and Repairs."

The Oregon Society of Engineers was addressed Apr. 25 by G. C. Wells, who spoke on "Engineering and Exploration Experiences on the Malay Peninsula."

The New York Chapter of the American Association of Engineers held a meeting Apr. 23, at which Robert M. MacBride spoke on his experiences while in Europe with the party of journalists who accompanied President Wilson in the inspection of the devastated districts. The next meeting of the chapter will be held May 14.

Personal Notes

H. ELTINGE BREED, who has resigned as first deputy commissioner, New York State Highway Department, as mentioned in *Engineering News-Record* of Apr. 24, 1919, p. 840, has opened offices in New York City at 507 Fifth Ave., for the private practice of engineering, specializing in highway work and organization. Mr. Breed was graduated from Colgate University in 1900 and soon afterward entered the service of the Newport News Shipbuilding & Dry Dock Co. A year later he entered the department of the State Engineer and Surveyor of New York State, passing through various civil-service grades to the rank of assistant engineer. In 1911 he was with the State Highway Commission engaged in design work, and in the following year he had charge of the Coleman du Pont road in Delaware as assistant chief engineer. After visiting Europe to study

highway conditions he engaged in private practice until 1915, when he was appointed first deputy commissioner of the New York State Highway Department. He served in that capacity until his recent resignation.

COL. JAMES SCRUGHAM, who resigned the position of state engineer of Nevada, to enter Government service, has been reappointed to his former position by Governor Boyle. SEYMOUR CASE, who filled the position of state engineer in Colonel Scrugham's absence, has been appointed assistant state engineer.

PROF. CHARLES A. HOLDEN, who for the past year has served as acting director of the Thayer School of Civil Engineering, Dartmouth College, has been appointed director. He was born in 1872 and was graduated from Dartmouth College in 1895, and six years later from the Thayer School of Civil Engineering. He afterward entered the engineering department of the Boston & Albany R.R. In 1900 he became instructor of civil engineering in the Thayer School and was later appointed assistant professor of civil engineering and assistant professor of mathematics. From 1900 to 1904 he acted as resident hydrographer for the United States Geological Survey, at Hanover, N. H.

CAPT. R. S. MOORE, Engineers, U. S. A., who was with the 209th Engineers when demobilized at Camp Sheridan, Montgomery, Ala., has entered the service of the Shipyard Plants Division, Emergency Fleet Corporation, Gulf district, with headquarters at Houston, Tex.

H. G. COUTTS, general superintendent of the housing division, United States Shipping Board, Emergency Fleet Corporation, has resigned to become associated with the Free-Luce Land & Building Co., Cleveland.

HERMAN ROEMER, Baltimore, who has recently been engaged in Government work, has been appointed superintendent of the paving division, highway engineer's department of that city.

W. C. HARTMAN, Construction Division, U. S. A., has received his discharge from the service and has returned to his former work as designer of reinforced-concrete structures, Widmer Engineering Co., St. Louis.

A. L. DABNEY, consulting engineer, Memphis, Tenn., who has been engaged in Government work at Muscle Shoals, Alabama, has returned to his office in Memphis to resume private practice. In 1917 he was commissioned as a major of engineers and attended an officers' training camp, later resigning his commission, being physically disqualified. He was then stationed at the Air Nitrates Plant No. 2, Muscle Shoals, for more than a year, in charge of the construction of water-works, sewers and drainage, and later in charge of operation.

ERNEST G. EAGLESON, consulting engineer, Boise, Idaho, has been elected mayor of that city. He is a graduate of Nebraska University and for many years has been engaged in irrigation and other engineering work in the West. In 1911 he was elected city engineer of Boise and has more recently been engaged in private practice.

CAPT. E. V. GUYTHER, Construction Division, U. S. A., who recently received his discharge from the service, has returned to his former position in charge of municipal engineering work with the Widmer Engineering Co., St. Louis.

JOHN F. VAUGHAN has resigned as district manager, Emergency Fleet Corporation, New England district, and has resumed his engineering practice at 185 Devonshire St., Boston, which has been in charge of his principal assistant, E. A. EKERN, during his service with the Government.

NICHOLAS S. HILL, JR., and S. F. FERGUSON, consulting engineers, announce the removal of their offices and laboratory from 100 William St. to 112 E. 19th St., New York City.

COL. JAMES B. CAVANAUGH, Corps of Engineers, U. S. A., has been appointed United States district engineer of the Nashville, Chattanooga and Florence, Ala., districts, with headquarters at Nashville.

R. C. STARR, superintendent of construction, Stone & Webster Corporation, with headquarters in Seattle, has resigned to become construction engineer, San Joaquin Light & Power Corporation, at Fresno, Calif. Mr. Starr has charge of work on the hydro-electric project now being rushed to meet the demand for additional power. Previous to his association with Stone & Webster he had charge of raising the height of three dams at Huntington Lake in Southern California for the Pacific Light & Power Company.

CAPT. GEORGE R. CAMPBELL, Engineers, U. S. A., has received his discharge from the service and has been appointed United States cadastral engineer, Department of the Interior, with headquarters at Olympia, Wash.

EARL WHEELER, O. A. MECHLIN and FRANK RHEA have become associated under the firm name of WHEELER, MECHLIN & RHEA, advisory and purchasing engineers, with offices in the West St. Building, New York City. The work of the firm will consist of furnishing service to foreign and domestic clients, purchasing machinery and engineering materials in the United States to be used to construct, maintain and operate property.

CAPT. EDWARD M. BURD, Coast Artillery, U. S. A., who recently received his discharge from the service, has become associated with the Blaw-Knox Co. of Pittsburgh as designer and salesman in transmission tower and structural work.

PROF. JAMES E. SMITH, Department of Civil Engineering, University of Illinois, has been elected mayor of Urbana. He has been a member of the city council for four years.

E. L. WAGNER, formerly of the firm of ROBINSON & WAGNER, sewage-disposal engineers, New York City, has opened an office at 320 Fifth Ave., for the practice of sanitary engineering.

LEIGH HUNT, consulting engineer, Kansas City, Mo., announces the formation of the Leigh Hunt Co., successor to the Hunt Engineering Co. The new company will engage in general engineering and contracting.

IRA G. HEDRICK and W. W. HUFF have become associated under the firm name of HEDRICK & HUFF, consulting engineers, Kansas City, Mo.

J. C. RALSTON, formerly city engineer of Spokane, Wash., has been appointed consulting engineer of the Columbia Basin Commission.

PHILIP PETRI, district engineer, Baltimore & Ohio R.R. Lines East, with headquarters in Pittsburgh, has been appointed division engineer, with headquarters at Cumberland, Md.

OBITUARY

CHARLES H. JACOBI, assistant engineer, Division of Capital Expenditures, United States Railroad Administration, died in Salt Lake City Apr. 20. He was born in 1883 and was employed for a number of years as assistant engineer, Lehigh Valley R.R., and more recently as construction engineer, Westinghouse Church Kerr & Co. He entered the service of the United States Railroad Administration in July, 1918.

S. SANNE-JACOBSEN, of the firm of Gannestad & Jacobsen, consulting engineers, Pittsburgh, died in Beaver, Penn., Apr. 11. He was a graduate of the technical school of Horten, Norway, and had been engaged in engineering work in the Pittsburgh district for the past 25 years.

Manufacturers' Association Annual Convention in New York

The National Association of Manufacturers has announced its annual convention, to be held at the Waldorf-Astoria Hotel, New York City, from May 10 to 21, inclusive. Topics to be discussed are: Governmental ownership of railroads, Government supervision and stabilizing of trade prices, Federal revenue and tax legislation, employment relations, employers' duty to provide jobs for sailors and soldiers, approaching revision of the patent laws, the industrial legislative outlook, and vocational training.

Among the speakers will be Walker D. Hines, director general of railroads; Daniel Willard, president of the Baltimore & Ohio R.R.; Prof. William Starr Myers, Princeton University; Frank A. Halsey, commissioner of the American Institute of Weights and Measures, and Edward J. Prindle, member of the committee on patent law revision of the Council of National Defense.

Many committee reports will be made; among them will be one by the committee on readjustment after the war, which will make recommendations, having made an exhaustive survey of the present situation.

Motor-Truck Company To Make Large Increase in Plant

Expenditures involving $37,398,000 in new plant will be made during 1919 by the General Motors Corporation, as outlined by W. C. Durant, president and general manager. The additions will be made in office and sales buildings and new equipment in Detroit, Flint, Pontiac, Lansing, Saginaw, Mich., Toledo, Ohio, St. Louis, Mo., Janesville, Wis., Bristol, Conn., and Muncie, Ind. About $12,650,000 will be spent in Detroit, including $5,000,000 for a fifteen-story general office building, with a four-story research laboratory in the rear. The next largest expenditure will be at Flint, where $6,715,000 will be expended. In the latter appropriation a thousand homes for employees, with water mains, sewer systems, paved streets, etc., are provided for.

Unemployment Decreases, Says Federal Employment Service

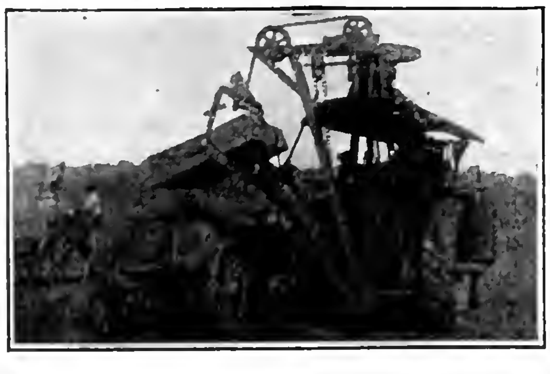
Employment conditions throughout the United States are steadily improving, according to reports received by the United States Employment Service, from 3417 representative concerns in 58 cities. While there is still a surplus in many cities, some report a shortage of skilled and unskilled labor.

Among the cities replying, 27 report a surplus of labor of 59,957 as compared with 73,576 during the previous week. Six of the cities show a combined shortage of 3600 skilled and unskilled laborers. The other 15 report an approximate equality of supply and demand.

The labor surplus has disappeared in New York, and conditions in the New England States show a marked improvement. Several cities which last week reported heavy surpluses reported this week an apparent equality of supply and demand. Of the six cities reporting a shortage of labor all are in the South except Seattle. They are Louisville, Ky., Wilmington, N. C., Charleston and Columbia, S. C., and Memphis, Tenn.

Shoveling Attachment for Road Rollers and Tractors

An attachment for shoveling earth, which may be used upon steam, gas or electric tractors and upon steam rollers, is shown in the accompanying photographs of work at Myers Park, Charlotte, N. C. The device was invented by C. H. Wolfe, of Charlotte, and has been used by the Mecklenburg



CYCLE OF OPERATION OF SHOVEL ATTACHMENT

County government, on road work. With the shovel removed, the attachment makes a useful portable derrick.

Operating in practically a horizontal position, it is said to have proved particularly adaptable to road work in skimming off shallow cutting. The derrick portion allows the shovel to swing through an angle of 180° for dumping, so that the wagons do not have to be placed accurately. It can handle old macadam, gravel, shale, crushed stone, coal, sand and snow. Only a few minutes are required to remove the shovel in order to use the attachment as a derrick. The method of operation is readily seen from the three photographs.

The shovel-pan is 7 ft. wide, 4½ ft. from cutting edge to back, and 1 ft. deep. When level full it holds about 30 cu.ft. and will handle 1½ cu.yd. when heaped. In the two machines which have been manufactured and are in use, the shovel is made the same width out to out as the traction engines to which they are attached, so that the wheels of the engine are always running upon a smooth surface. The weight of the entire outfit, including engine, is 22,000 lb., and it can be operated in all locations and over soil conditions which will support a traction engine of this load.

Under favorable conditions, the machine is reported to have loaded a maximum of 680 loads in a 10-hour day, and the average performance is said to be 450 loads for this period. It is operated by one man who handles all the levers and also fires the engine.

It is understood that Mr. Wolfe holds a patent on the attachment, which is to be manufactured by the Moffatt Machinery Manufacturing Co., of Charlotte, N. C.

BUSINESS NOTES

The Ferro-Concrete Products Co. is the name of a new concern organized by A. M. Fisher, formerly with the Concrete Steel Products Co. of Chicago, and recently discharged as captain from the Fifth Division, American Expeditionary Forces. The offices of the company will be in the Harris Trust Co. Building, Chicago, where it will represent the Witherow Steel Co. and the Electric Welding Co., both of Pittsburgh.

The Chain Belt Co., of Milwaukee, Wis., announces that the J. J. Wernette Engineering Co., of Grand Rapids, Mich., will handle the former company's "Rex" line of concrete mixers and pavers.

The Sullivan Machinery Co. announces the organization of a foreign-trade department, with S. W. Copeland, formerly attached to the St. Louis office, as manager, with headquarters in Chicago. The company has branch offices in London, Salisbury House; Paris, 18 Ave. Parmentier; Santiago, Chili, Casilla No. 27, and at Sydney, N. S. W., Chambers, Martin Place. Agencies are established in various other foreign countries.

The Chicago Pneumatic Tool Co., Chicago, Ill., announces the appointment of T. J. Hudson as acting manager of the pneumatic tool sales division. He succeeds S. H. Waldron, who will return to Minneapolis, Minn., as district manager of sales for that territory. The company also announces the election of Allan E. Goodhue as managing director of its English subsidiary, the Consolidated Pneumatic Tool Co., Ltd., with offices at 170 Piccadilly, Lon-

don, and with plant at Fraserburgh, Scotland. He will also have charge of European sales for the Chicago Pneumatic Tool Co. Mr. Goodhue was for a number of years connected with the sales department of the Midvale Steel Co. and the Midvale Steel and Ordnance Co. of Philadelphia, Chicago and Boston, leaving to enter the Government service in March, 1918, as manager of the steel and raw material section, reduction division, of the Emergency Fleet Corporation, which position he held until Jan. 1, 1919.

The Daly Meter Co. will move its main office and works from Boston, Mass., to Cleveland, Ohio, effective May 1. The Boston office will be retained with H. D. Fisher as manager, to handle sales and engineering service in the New England district. For the present the New York and Philadelphia districts will also be covered from the Boston office. All other districts will be covered from Cleveland.

Trade Publications

The Lakewood Engineering Co., of Cleveland, Ohio, has issued a new bulletin, No. 29-A, describing Lakewood road-construction plants. The first half of the bulletin describes the methods employed in the construction of roads in large contracts, the remainder is devoted to a description of the equipment used.

The Yale & Towne Manufacturing Co., of 9 E. 40th St., New York City, has issued a semi-centennial souvenir in the form of a 76-page booklet, containing a history of the corporation and industrial biographies of various men prominent in the company. The booklet is 5½ x 8 in. and is illustrated.

"Heavy Duty Oil Engines" is the title of bulletin O. E. 20 of the Pittsburgh Filter & Engineering Co., Pittsburgh, Penn. The booklet contains eighteen 6½ x 9-in. pages and deals with the subject of large internal-combustion engines.

"Banking Service for Foreign Trade" and "Trading With China" are the Titles of two pamphlets issued by the Guaranty Trust Co., of New York. The former describes banking connections in foreign countries and the various methods of exchange. The latter is a general booklet dealing particularly with China, and describes the methods found successful in dealing with the Chinese.

The Solar Metal Products Co., Inc., of Columbus, announces the following changes in its organization: G. R. Le Sauvage, who was elected president Jan. 2, 1919, has assumed the duties of general manager, succeeding H. R. Gogay, formerly vice-president, treasurer and general manager, who has resigned; E. C. Camp has been elected assistant treasurer, and assistant to the president, and continues his work as sales manager.

"Highways and Railways for the Defense of Our Nation" is the subject of a 6 x 9-in. 20-page booklet just issued by Sauerman Bros., manufacturers of cableway excavators, car scrapers, etc., Monadnock Block, Chicago, Ill. This booklet deals with a general plan of defense for the United States and lays stress upon the necessity of good highways in time of war. It contains illustrations of various methods of defense, and of heavy artillery apparatus.

The Wallace & Tiernan Co., Inc., 349 Broadway, New York City, has just issued an 8½ x 11-in., 64-page pamphlet entitled "Chlorine Control Apparatus." The book is illustrated with half tones and line cuts showing apparatus, layouts and charts pertaining to the control of chlorination.

Construction Costs Carry On

Changes for Most Part Unimportant—Steel Deadlock Continues—Better Feeling Throughout Country Than Reported Last Month

By Alden W. Welch

In considering present prices of construction materials, one must not see only his little vicinity to the exclusion of the rest of the world. Prices are higher everywhere. They have advanced in sections where the influence of the war was not directly felt. Inflation is general. So much money and its equivalent in the form of bonds has been issued that its buying power has depreciated.

There is one safe highway, but it can be traveled by means of only one conveyance—confidence. What prices were last month, they are the same today. Here and there one material or another has cheapened, just as here and there other materials have advanced.

A general decline is almost as inconceivable as a general rise—though the latter is possible. This is a period when, as never before, the much criticised British slogan, "Business as usual," applies. And by "business as usual" not present business is meant, but the lively business that the needs of the country warrant.

It Is Time To Start Building—Prices Cannot Drop

Probably never in the history of the world was the housing situation more acute. In this, the richest nation, there are insufficient dwellings. Houses are being sold over the heads of people who have nowhere else to go. This serious tension is not being relieved by private initiative. It is a crisis beyond which is some unknown climax, which will be reached unless something is done. The thing to do is to build.

Everybody ought to know that prices cannot return to the pre-war level. Is there any man who will voluntarily submit to a reduction of his income? Organized labor is receiving more than ever it did, but it is demanding still more. The establishment maintained by a salary would collapse if the salary were appreciably reduced. And the same thing is true with those who receive dividends. Pre-war prices should be forgotten, because the world is upon the threshold of a new era.

Inasmuch as steel is the chief material element in the foundation of industry, any uncertainty regarding the future price of this product renders the entire structure uncertain. Last month the only general price movement was in steel, which declined $7 a ton. The new schedule was fixed by the Government's Industrial Board and the manufacturers, in joint session. It was expected that the new prices would be accepted by Government and public alike, but the Railroad Administration refused to do business under these revisions. A month has been consumed in controversy, which ought to be settled forthwith. Until it is settled, the national construction program will remain "in the air."

The latest word at this writing is from George N. Peek, chairman of the Industrial Board. In a letter to Director General Hines he says:

"The prices arrived at were the lowest which the members of the board believed that they could recommend and which would at the same time permit the producers to maintain the existing scale of wages and preserve the average independent producer. . . . If, however, you have any facts, figures or information showing that, on any ground whatsoever, the price recommended was too high, we shall be glad to approach the representatives of the steel producers again, and attempt to secure a modification of their offer in accordance therewith."

It would seem that the logical step would be for the Railroad Administration, the Industrial Board and the producers to get together and remain in session until a satisfactory agreement was reached. The existing uncertainty in the steel situation has a sinister influence upon the whole construction field.

Throughout the Country

New York—There are few price changes to report. The most important is in cement, which is now $2.30 net in cargo lots, alongside dock to contractors, against $2.45 net last month. As elsewhere, the charge for sacks has been reduced to 60c. per barrel instead of $1. The fluctuations on all the materials in the New York market are clearly shown

in the three-page price section that follows this article.

An encouraging sign is the two large building projects about to be got under way at Times Square. In this one neighborhood, it is reported, ground will be broken this week for a 20-story office building to cost $2,500,000, and soon after for a million-dollar structure to house two educational and civic-improvement organizations. The latter building is to be ready for occupancy by January.

Probably nowhere else than in New York is the incentive to build greater. This is not only because of high rents and the fact that the demand for apartments continually increases, but extensive transit improvements that have been under way for a number of years have just been completed, thus giving access to large, open areas, now made convenient to the several business districts of the metropolis. In past times apartment houses were erected largely in the hope that they would eventually be filled. Today they may be built on the certainty of immediate occupation. Just as soon as it is recognized that prices higher than in 1914 are a healthy reflection of the prosperity of the country, capital will become active. It is a very difficult task, however, to convince capital of the fact that today's prices will be tomorrow's.

Chicago—The building situation is improving slowly, as indicated by the accompanying tabulation of permits, which compares the activities of the middle weeks of March and April. From Apr. 5 to Apr. 19 permits issued numbered 127 more than in the corresponding period of March, the improvement amounting to 70 per cent.

Baltimore—Optimism appears to prevail, it being predicted that, beginning July 1, the building trades will be busier than in many years. As Baltimore prices are not included in the monthly price section of *Engineering News-Record*, it may be stated that common brick is quoted at $18 delivered; front-face brick averages $24; sand 50c. and 60c., respectively, for two grades, at railway loading points; gravel, two grades, $1.10 and $1.30 per ton; crushed stone, $1.25 for 2½-in.; fabricated steel, $115 a ton; lumber, common, including pine, fir, hemlock and spruce, $45 to $47.50 delivered from local yards in city; heavier timber, up to $55 delivered.

St. Paul—The most notable feature was the drop in cement, from $2.40 to $2.20 net. Natural cement followed from $1.63 to $1.55, as did also hydrated and lump lime. Lumber is at present the same as last month, but an increase is expected in fir, the principal timber in this market. At a meeting of the West Coast Lumber Manufacturers' Association, Apr. 6 in Tacoma, Wash., costs were analyzed, with the result that there was an apparent loss of $2.80 per 1000 ft. The revised price of fir in St. Paul will likely approach closely the present price of pine in this territory. Sandstone paving blocks are out of the market, owing largely to the shutdown and dismantling, during the war, of the plant at Sandstone, Minn. Bids were recently requested by the City of St. Paul but no response was received from Wisconsin quarries. Building activities are slow, but the general feeling is much more optimistic. Engineers and architects are doing considerably more estimating than a month ago.

Detroit—Several large buildings are planned or are under construction. These include banks, office buildings and mercantile blocks. Several large industrial works are contemplated. For some of these the sites are being purchased and the preliminary arrangements are being made.

St. Louis—Prices carry on in St. Louis. The reductions in triangle mesh and nails are a belated reflection of last month's general decline in steel. The lower price of brick is apparently a further effort to stimulate construction. The increase in the price of 3½-in. wood block is not important, being merely an attempt to establish a current price. It would probably fall if large orders were in prospect. Grading and paving work have started, as have also some sewer work and a small amount of home building. The general situation, however, is what is was in March.

Kansas City—Paving work has just opened up in a large way. Many important contracts are under way and others have yet to be awarded. The Real Estate Board, backed by other organizations, has inaugurated a "Build-a-Home" campaign. Large yellow-pine industries announce a contemplated increase within the next two weeks of from 50c. to $1 per 1000 ft. They report that the supply from the Southern fields is only 60% of normal, while the capacity for output is but 70% efficient. It is asserted that labor, though sufficient, is less efficient than it was before the war. Foreign demand for yellow pine has increased incalculably since the armistice was signed, and shipping facilities have improved to such an extent that heavy export is possible. Previous to the war, lumber shipped to Europe had to be of certain grades and sawed according to specifications. Now, the yellow-pine men say, Europe wants just lumber, and it does not ask the price, taking all sizes and grades standard in this country. Portland cement has been reduced from $2.30 to $2.26 net in carload lots, Eastern lime from $22.80 to $22 per ton. Fir lumber has been increased $2 per thousand. Dynamite is also less in cost.

San Francisco—Price changes in this city are for the most part reflections of the general decline in steel last month. The reduction in the price of Douglas fir is most interesting, in view of the threatened increase elsewhere, and is said to be an effort to stimulate construction.

COMPARISON OF BUILDING PERMITS ISSUED IN CHICAGO IN MIDDLE TWO WEEKS OF MARCH AND APRIL

	Residences	Stores	Factories	Warehouses	Miscellaneous Buildings	Total
March 15	73	4	4	2	4	87
March 22	80	1	3	5	4	93
April 12	160	5	3	2	18	188
April 19	93	2	5	4	17	121

	No. Over $100,000	No. Over $50,000	No. Over $5000	No. Less Than $5000	Total Amount
March 15	None	2	19	28	$521,000
March 22	2	3	19	34	1,370,500
April 12	6	2	54	57	2,509,950
April 19	3	1	41	48	1,261,400

As the greater portion of the present building activity is in small homes, the materials feeling the greatest effects are brick, lumber, etc. Other materials in excellent demand are paints, oils, turpentine and glass, owing to the large amount of building-repair work now going forward.

Boston—Generally the prices are much the same as last month. The principal interest appears to be in lumber. In one week 4,000,000 ft. b.m. were used to construct reviewing stands. This special demand exhausted the stocks of the smaller yards, with a consequent brisk demand, but the situation is only temporary. Two lumber dealers, the Blanchard Lumber Co. and Waldo Bros., profess to see a slight change in favor of opening up work, asserting that conditions in the smaller towns justify their optimism. In Boston, however, there is very little construction, though more than $50,000,000 worth is estimated to be on the drafting board.

General Situation

On the whole, the industrial voice of the country contains a cheerful note. It is frankly admitted that there is not enough construction work under way, but the present quiet seems to be a natural calm immediately preceding unusual activity. Not only is there a vast amount of private building which must be done, but there is an almost incalculable public program that will have to be carried out. Consider just one item—school houses. The Department of Labor estimates that contracts for nearly a thousand public school houses aggregating $100,000,000 have been held up because of the war. Educational demands are superior to material prices, and just as these schools will have to be built, so will sewerage plants and water-works, public improvements generally, and an unnumbered host of residence buildings.

Catching Up With Deferred Maintenance

DURING the war maintenance was quite generally deferred in every branch of activity, including not merely the industries and the railroads but our homes as well. If the views commonly entertained in the business world are correct, the time is not far distant when we shall face a labor shortage. With the tide of emigration that is expected to set outward when peace is concluded, and with the reawakening of business, it would not be surprising to find this shortage as early as next autumn. Now, however, there is an oversupply of men. Of that we have testimony from the industries as well as from the Government. This, then, is the time for catching up on our deferred maintenance. Prices are high, without a doubt, but there is general agreement that marked retrogression is not to be expected. Moreover, the damage done by lack of maintenance proceeds in a ratio that is geometrical rather than arithmetical. In other words, maintenance that is kept up from time to time proves less expensive than when it accumulates. While, therefore, the cost of catching up on our maintenance now is much above what it would have been if done when first required, it is less now than it will be at a subsequent time. The crucial factor, too, is men, and they are available now.

Departing from Beaten Paths

AS IN every art there are problems and expedients that go beyond the scope of the instruction books, so in engineering by no means all planning and building follow the methods taught as standard. Even in structural practice, which on account of its precision and elaborate literature might appear to be an exception, this truth holds. It is demonstrated in a picturesque way by a piece of bridge reinforcement described on another page of this issue. A fundamental principle requires the members of articulated structures to meet centrally; yet in the present case gross and deliberate violation of this principle was found to be good engineering. A tension chord that should be straight or smoothly polygonal was arranged in zigzagged alignment in order to satisfy most effectively the special stress requirements of the case. Obviously, the engineer's skill and resource are put to a very different test when he creates such a precedent-ignoring construction than when he applies normal methods, no matter how precisely or how efficiently. And it may fairly be said that a command of standard methods alone, without the ability to strike out a new path when occasion demands, is but high-grade mediocrity. Where, however, is the student of engineering to acquire the necessary boldness and constructive power of thought? Do the methods of teaching bring it into being and develop it? Progressive educators, we believe, are keenly mindful of this desideratum and endeavor to provide for it. But unquestionably the study of original work on the part of others, as described in current literature, will prove a powerful aid.

Two Elements of Originality

IN THE remarkable roof-erection work described in this issue, two particular elements of originality are brought into view. One of these lies in the fact that the general method was borrowed from bridge practice. Most minds tend to erect fixed partitions between different fields of activity, preventing them from seeing similarities and analogies; yet those who are readiest to see analogies will surely be most fertile in original expedients. No doubt, it is proper to make separate mental pockets for building erection, bridge erection, and ship erection; there are essential differences between these subjects, to ignore which would breed confusion of thought. But the man who, while appreciating these differences, is able to borrow wisely from the one subject in order to benefit another is the successful originator. Developing their working method by this very procedure, the erectors of the Crucible Steel building have done—or rather, are doing, for the work is still in progress as we write—a remarkably successful piece of work. Yet their method is exceedingly simple, especially so when it is considered that the problem was set by unusually severe demands on the part of the owners. This leads up to the second element of originality which the present case brings out: No matter how well the methods of doing a thing are standardized, the spur of an abnormal demand sets the mind to work finding other ways of doing it. Necessity is the mother, etc.

Eliminating the Side Ditch from the Highway

IT IS generally admitted, as contended in an article by W. P. Blair on p. 914, that the highway side ditch is a nuisance. Evidently, a comprehensive system such as that advocated by Mr. Blair would no doubt satisfactorily take the place of the ditch and solve the drainage problem in many soils and under many conditions. But a large number of engineers still regard a clean ditch as the surest and quickest way of removing water from the highway. It has the advantage, at least, of being open to inspection. Indeed, the problem of inaccessibility is one of the chief arguments used against tile by those who do not favor underdrainage. How to keep the tile from filling up with roots, and how to arrange them to drain subsoils which are practically waterproof, such as clay, appear to some engineers to be

unsolvable problems. If with impervious soil conditions the system proposed will not function, it would be well to consider the plan of covering the entire subgrade with a 3- to 4-in. blanket of gravel or crushed stone. This would carry the water to the longitudinal drain and would make unnecessary the lateral tiling and the consequent trenching of the subgrade, always an undesirable procedure. Obviously, such a design is expensive, but, with the high cost of permanent pavements, would not the additional expenditure be a profitable investment? The growing importance of better drainage, on account of the increased first cost of road surfacings, will warrant the engineer in giving to this problem, upon which the permanence of the improvement most largely depends, his best attention.

Army's Own Construction Is Not Public Works

INCLUDING the Construction Division of the Army in the proposed Department of Public Works was apparently inconsistent on the part of the engineering societies' conference held in Chicago last week. It may prove to be injudicious. The second paragraph of the code of principles set forth by the conference stated that the Department of Public Works should "comprise those works which are built and operated for the use of the public." This distinctly eliminates the Construction Division, which is a war creation charged solely with the construction, maintenance and operation of structures in this country used by the Army itself. Although the war emergency forced this division into most elaborate projects and provided it with an admirable personnel, its essential purpose is the same as was that of the peace-time construction branch of the Quartermaster Corps. So far as the Public Works Department is concerned, it differs in no way from the Bureau of Yards and Docks of the Navy, which was apparently not even considered as a possibility in such a department. Such a distinction will only give a weapon to opponents of the proposed department. The defense of the inclusion seems to be that the great warehouses and port terminals are foreign to the field of the Army engineer. That is true, but that which we propose to create is a peace-time organization. In time of war the War Department might call on it to aid in building construction, but to take out of the Army the doing of its normal building work not only violates the principle that only work for the use of the public is to be included in the proposed department, but opens the proposed bill to unnecessary attack.

Educating the Public On Engineering Matters

DISTRIBUTION of technical information for the instruction of the public is a useful activity of the engineering department of the Kansas State Agricultural College. Technical articles are prepared on subjects of local interest, such as irrigation and drainage, in language easily comprehended, and are sent on request to the local press and to farm journals. This development of the college-extension system may be classed with the well known short courses in highway and drainage work, in their influence on the community. The press is merely a different vehicle. By its means, information may be supplied on matters of local interest, such as good roads, land reclamation, street paving or the water-supply and sewerage facilities of small towns. Articles of that sort do not displace the engineer. Rather, they educate the public concerning the purpose and importance of the engineer's work and its bearing on the welfare of the community. While many universities have publicity agencies, in most cases the bulletins and news sheets inform the public about the work and activities of the institution. The Kansas idea differs in supplying the public with data about engineering matters in which it is directly interested.

Appreciation of the Place of the Local Society

TEN years ago the local engineering society was scarcely a factor in the organization of the profession; five years ago it was just beginning to function well. Today it is one of the chief elements of strength in professional organization. The national societies as such have recognized this, through their support of the local-section movement, but it has remained for the secretary of the American Society of Mechanical Engineers to go full length in support of the local societies. In the March *Journal* of the society Mr. Rice says: "I am unreservedly for developing and supporting the local society first of all. After one has done his full duty locally then he may join that national society which best serves his specialty." That is good doctrine. The profession will become strong nationally by becoming strong locally.

Latin and Greek for the Engineer

DEAN Cooley's views on the place of Latin and Greek in the training of the engineer, reported elsewhere in this issue, will come, we are sure, as a surprise to most members of the profession. Engineering, as it is taught today, has little or no relation to the world that preceded the eighteenth century. If there is no sympathy with the Elizabethan period, why should there be any thought in the minds of the men of science for a world that seems hopelessly ancient? All the more reason, therefore, for the shock that will come to engineers when it is proposed that Latin and Greek be part of the pre-engineering curriculum.

Dean Cooley sees the need for men broadly educated, and, seeing that, he takes the very logical position of pleading for a type of education that confessedly turns out broad men. He does not contend that purely scientific education cannot produce breadth. We take it, however, that he feels very decidedly that such education has not produced breadth. We should like to see the proponents of a purely scientific education cross swords with Dean Cooley on this matter. It would tend, at the very least, to bring home to us some of the fundamentals of education.

For our own part, we must confess that we have seen more breadth come out of the colleges of literature and arts than out of the engineering schools, and we have hoped that in the development of our engineering colleges such methods or such thoroughness might be introduced that would produce the desired result in breadth and culture. So far, however, the literary schools have the better of the argument. Obviously, the problem is a complicated one, and the length of time available for education must be considered.

Dean Cooley has thrown down a gage which, if taken up, should produce a valuable as well as interesting discussion.

Uniform Slab Strength for Heavy-Traffic Roads

WITH the tendency toward heavy, concentrated loads in highway transportation, the problem of design has ceased to be limited to the questions of smoothness of surfacing and of enough mass to resist wear for a reasonable length of time. Sufficient load-bearing and beam strength to resist immediate destruction is now essential. The desirability of determining the maximum loads to be expected, in order to design all types of road subject thereto for equal strength, can hardly be questioned. This principle has been recognized in drafting the new specifications for main highways in Illinois, as discussed by Clifford Older, chief state highway engineer, on p. 905. A standard concrete road has been designed, and all other types have been proportioned to have the same beam strength.

While most engineers will indorse the principle, there is likely to be disagreement as to the correctness of the assumptions made in arriving at designs of other types to approximate the concrete standard. The changes in many, if not most, of the pavements are radical, raising materially the relative cost of some types with respect to others. Questions are bound to arise: Have proper values been assigned to the components of combination slabs? Has sufficient allowance been made for the cushioning effect of certain surfacings? Why are such revolutionary changes necessary in pavements which have given satisfactory service on heavy-traffic city pavements heretofore? Frank discussion of these and allied questions should bring out points of view and data, based on experience, which should be of material assistance to highway engineers. We are certain that Mr. Older will welcome discussion on the technical merits of his method of procedure.

We shall without doubt all agree on one conclusion, as the result of the discussion: That there is sad lack of data on the beam or slab strength of different types of pavement. One other factor has been repeatedly stated —the lack of agreement as to assumed conditions of support which should be accepted as standard in investigating the load-carrying strength of a pavement slab.

Manifestly, we have been injected into a new set of problems by the advent of heavy highway loads. There is need for the sort of inquiries which Mr. Older's procedure stimulates.

Advance in Subaqueous Tunneling

TWENTY years ago the construction of a soft-ground tunnel under a river ranked among the most formidable and hazardous tasks of engineering construction. Interruptions, delays and fatalities were normal accompaniments of such enterprises. The art has advanced greatly within the past generation. Difficulty and hazard have been so reduced that today a subaqueous tunnel is hardly a much more serious undertaking than any open-excavation contract.

With the completion of the fourth pair of rapid-transit tunnels under the East River at New York—a fifth pair is nearing completion—and the opening to traffic of the second pair, the progress of the art has recently received significant emphasis. Three pairs of these tunnels have been begun and completed within the past five years, substantially without incident; high rates of progress have been attained, the finished structures are of excellent character and precise in grade and alignment, and the casualty list has been kept remarkably low. Yet the East River subsoil, comprising rock, sand, gravel and mud, presents all the classic complications of the most difficult problems of tunneling. Compared with the tunnels built a dozen years earlier from the Battery to Joralemon St., the four new pairs, at South Ferry, Old Slip, 14th St. and 60th St., have a history of remarkably greater success. Their completion marks the end of a long development period of cast-iron-lined shield tunnel construction.

Refinements in the application of well known methods, rather than the introduction of new methods, are to be credited for this result. The shield-and-compressed-air method has been known for many decades past, and the shields in use today differ only in minor constructional features from those of prior tunneling operations. Cast-iron tunnel lining and the methods of putting it in place and making it secure also contain nothing new. Nor is the practice of dumping a temporary fill into the water overlying the tunnel in any respect new. But rigid control of the work, and systematic care and vigilance throughout, in the regulation of exposure of men to the compressed air, as well as in the guarding of the face and in the grouting, have permitted the utilization of these elements with increased efficiency.

Thus, it is now recognized that the blanketing of the river bottom with clay has such an important bearing on success as to justify large expenditure for this item. Formerly, tunnel builders were inclined to economize in the first blanketing, and they usually had to reinforce and repair the blanket subsequently, when heavy leaks or blowouts showed it to be weak. The view taken today is that it is cheaper to prevent a blowout than to plug it. To adequate blanketing alone may be given much of the credit for reducing the tunneling hazard as well as for making possible high rates of advance. Consistent care in handling the face work, however, and conscientious survey checking and control of shield movement, are other factors fully as important, influencing the safety and expedition of the work as well as its exactness.

There is a particular satisfaction in contemplating the approximate perfection of tunneling exhibited in the East River work, because it affords a sound basis for the development of future possibilities lying beyond the range of past experience. It is not to be expected that subaqueous tunnel construction will forever be circumscribed by present limits of size and depth. Indeed, the project for a road tunnel under the Hudson River may carry the art quite beyond these limits within very few months, if the project for a tube of 42-ft. diameter, which General Gothals recommended a year ago is adopted for execution. But ordinarily progress is not made by such great leaps into the unknown; it builds up step by step on a foundation of well worked-out experience, constantly venturing ahead but remaining always within reach of the accomplished. In progress of this kind the East River work, together with the pioneer engineering done in the present Hudson Tube tunnels and the Pennsylvania tunnels, will constitute the solid ground of departure.

A record of what was done and learned in the rapid-transit tunneling still remains to be written. In the rush of building, the engineers have not found time to note down their experiences for the use of posterity. As the work approaches its final stages, however, we may hope that the record will be written, and made available, in printed form, to all engineers.

Erecting Long-Span Roof Over Steel Mill By Rolling Trusses to Place

Rebuilding of Crucible Steel Company Mill Involves Remarkable Roof Construction—Erection Method Adapted from Bridge Practice—Trusses Rolled Along Craneway in Groups Weighing 800 Tons

DIFFICULT requirements presented by the reconstruction of a large rolling-mill building at the Crucible Steel Co.'s Harrison, N. J., plant are being met in highly successful manner by methods new to building erection. The well known bridge rolling procedure has been adapted to the case, and by its help a roof of unprecedented proportions is being erected over and around the rolling-mill unit of the plant while furnaces and mills remain in full operation, as indicated by the view, Fig. 1.

Three old buildings, occupying a space about 200 x 380 ft., at present contain the rolling mills and their heating longitudinal trusses; it lacks adequate crane facilities and is not adapted to change or regrouping of the furnaces and mills. Renewal, however, was complicated by the necessity for maintaining the machinery in full operation. Every foot of floor space is in use, and there was no room for placing either columns or falsework inside the building. Moreover, the plans for the future development of the rolling mill, as projected by William H. Taylor, chief engineer, required that the new building be clear of columns, so that it would be possible to rearrange and alter the equipment at all times unhampered by limitations on the use of the floor space.

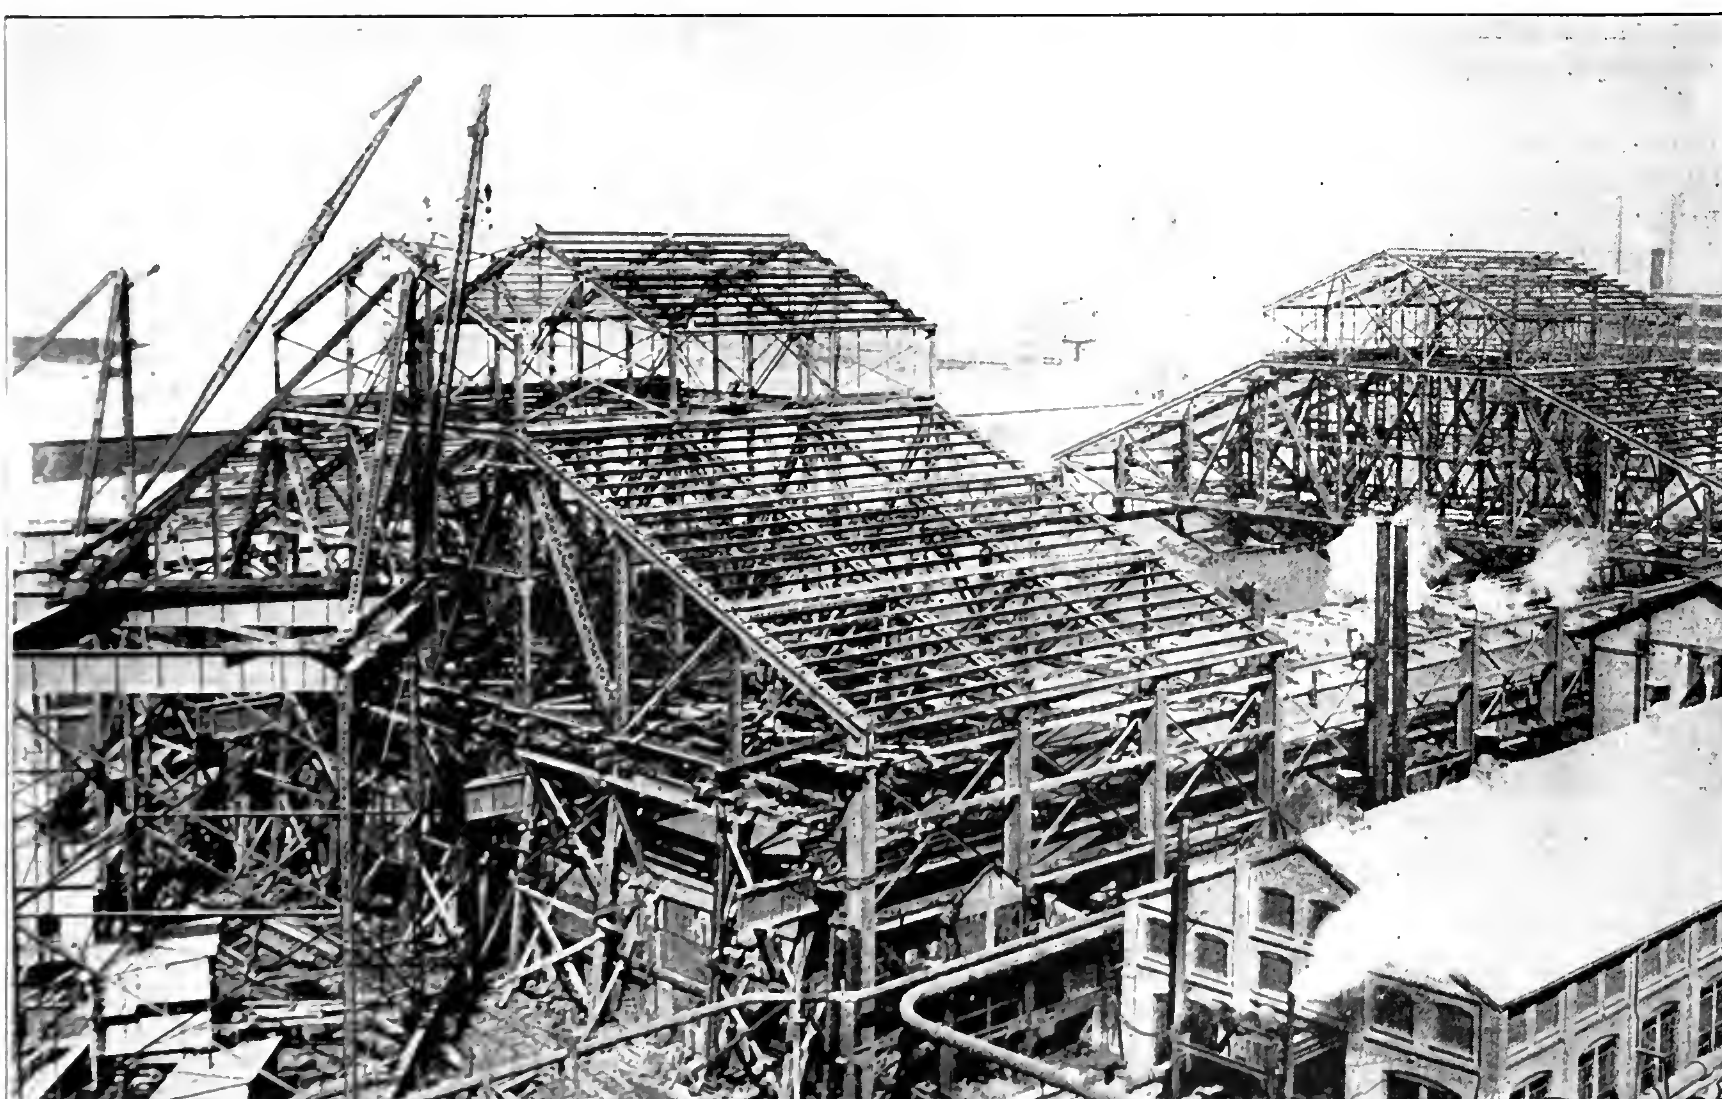

FIG. 1. SECOND GROUP OF FOUR TRUSSES OF CRUCIBLE STEEL COMPANY ROLLING MILL READY TO BE ROLLED TO PLACE—VIEW FROM SOUTHEAST

furnaces. Upon completion of the new building surrounding them, a structure 240 x 390 ft. having no interior columns whatever, they will be taken down with the help of the traveling cranes of the new building. The machinery will remain in service undisturbed throughout the work, and ultimately may be rearranged in the clear floor area as desired to suit the improvement plans.

In the expansion of the plant that has been going on for four years, modernization of the rolling-mill unit formed one of the most difficult items. The old three-bay building which houses it (see sketch Fig. 2) is low, dark and much obstructed by columns and timber

Within the past year a long-span roof of radically novel structural arrangement was designed and built to house a new press and forge shop at the plant. The successful completion of this structure was followed by the design of a long-span structure for the rolling mill. this roof, now being erected, contains the longest simple trusses in any mill-building roof yet built, 235 ft. 9 in. between centers of columns. The trusses carry not only the roof loads but also two pairs of crane-runway girders, which provide three 73-ft. craneways side by side, each running the full length of the building.

It was impossible to put up falsework for erecting these trusses in place, and their size and their great

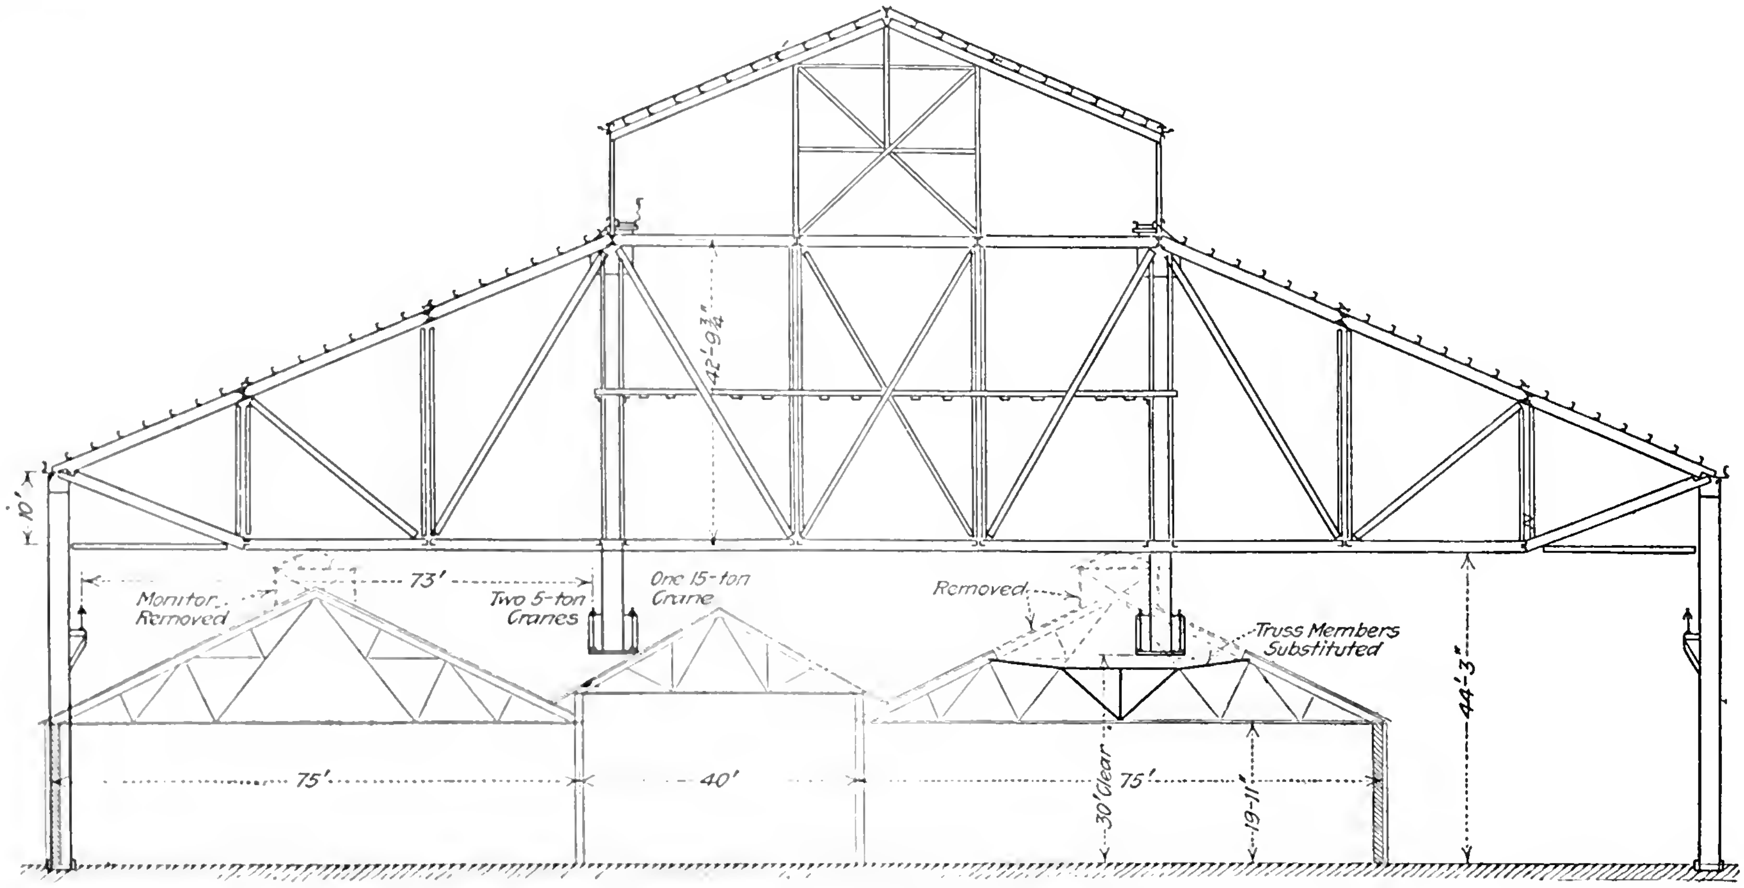

FIG. 2. RELATIVE POSITION OF OLD ROLLING MILL AND NEW LONG-SPAN ROOF; OLD ROOF RECONSTRUCTED TO AVOID INTERFERENCES IN ROLLING

weight—100 tons per truss—made it impossible to swing them to position from the side. The use of the rolling-to-place process often resorted to in bridge renewal overcame the difficulty; in fact, the design was made on the basis of this method, proposed by the erection department of the American Bridge Co., contractor for the building.

The trusses are being erected on staging at the south end of the building (Figs. 4 and 5) and are then rolled along tracks supported on the outer crane runways, sup-

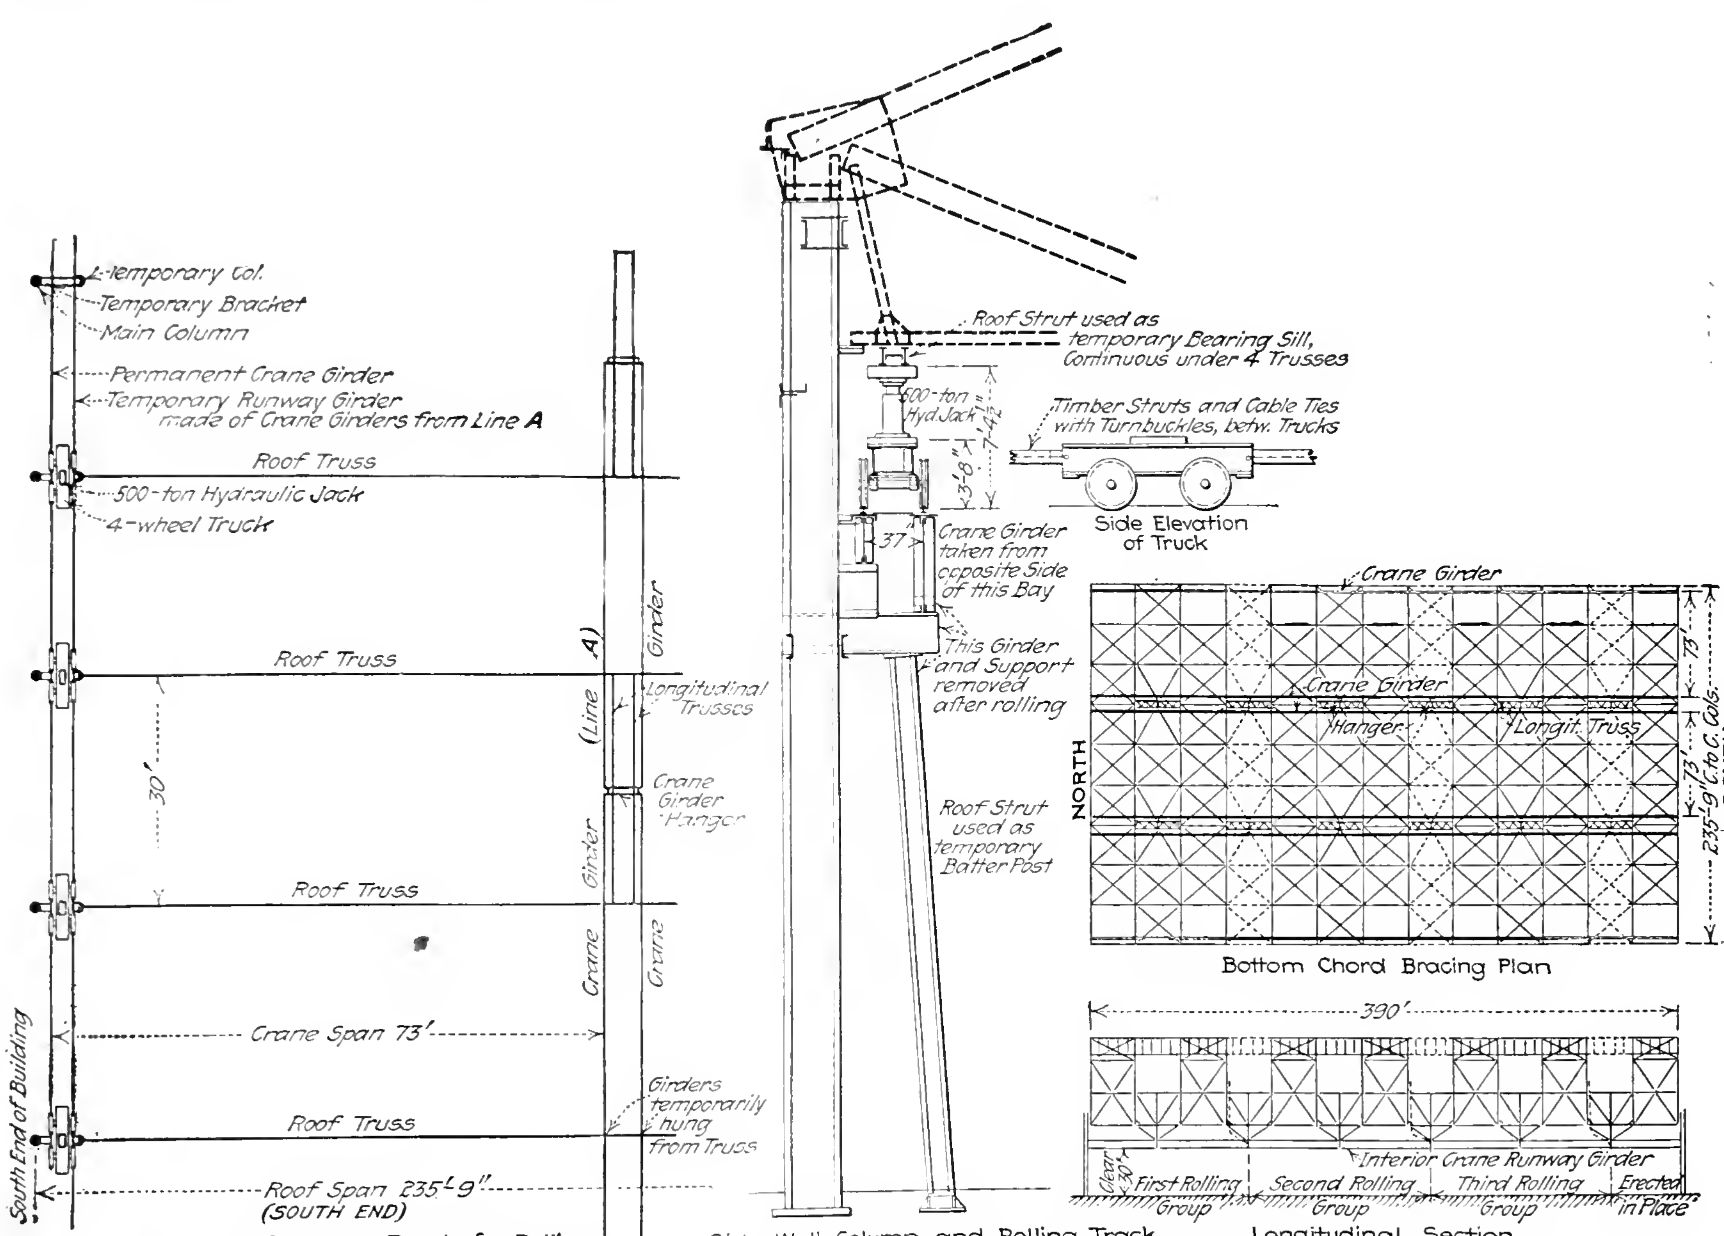

FIG. 3. UTILIZING COLUMNS AND CRANE GIRDERS TO FORM ROLLING TRACK FOR TRUSSES

plemented by additional girders (see sketches in Fig. 3) borrowed from the interior runways. This ingenious expedient of using the side-wall columns and their attached crane girders, supplemented by other girders, for track on which to roll the trusses (see Fig. 4) enables the work to be done very economically and simply. Design and erection procedure being worked out in close coöperation, it was practicable to suit the unusual erection requirements at almost no sacrifice of extra material. J. B. Gemberling, division manager of erection, and J. Sherrard, district erection superintendent, are in charge of the work for the contractor.

At the front of the building, over a low transverse bay, it was possible to set up timber horses, partly within the building, to support an erection platform on an area 30 ft. deep across the full width of the building. This affords room for erecting two trusses. When they are swung, and the bracing, purlins, crane-runway drop brackets and crane girders are in place, the pair is jacked up on four-wheel trucks under the ends of the trusses and rolled back. According to the original plan for the work, this group of two trusses was to be moved back to its final place in the roof. But it was later decided that time could be saved by moving in groups of four trusses. The pair is therefore rolled back only 30 ft., giving room for erecting a third truss and its panel of purlins, and again rolled back 30 ft. for the erection of the fourth truss. The group of four, shown in the view, Fig. 5, is finally rolled back to its intended position in the building, this move proceeding in the same way as the shorter move, but requiring special rigging of the derrick hoist lines to do the hauling. When the group of four trusses is landed it is complete and self-contained, requiring only connection to the columns and attachment of the intermediate crane girders to their truss hangers.

No material could be erected in the final position of the roof trusses except a few light parts such as the purlins of the intermediate panels. It was necessary, therefore, to design the interior crane-runway system in such a way that the 4½-ton panels of girder between successive groups of trusses would be carried by these groups, as they could not be put in place afterward. Reference to the plan in Fig. 3 will show how the design meets this difficulty. Except at extreme front and rear of the building, the crane girders are made in two-panel lengths, 60 ft., joining half way between trusses and here supported by hangers attached to longitudinal trusses between the transverse roof trusses. The hangers occur only in the bays between the braced pairs of roof trusses. This structural arrangement permits the rolling of two panels of crane girder with each pair of trusses, and so avoids the difficulty of intermediate girder panels.

In the erection of a pair of roof trusses on the staging on the front of the building the crane girders are set first, resting on cross sills of the staging bents. The ends of these girders project 15 ft. to rear and front of the respective trusses. The forward longitudinal truss is also erected, cantilevering out from the front roof truss, and its hanger supports the front ends of the girders. The rear ends of the girders are hung to the rear truss by rods. When the two-truss group is swung and moved back, for the erection of the third and fourth trusses, the second 60-ft. girder lengths are put in place similarly, the hangers and longitudinal trusses erected between the pairs to support the junction point

FIG. 4. SIDE COLUMNS AND CRANE GIRDERS FORMING TRACK FOR ROLLING TRUSSES

of the girders, and the rear ends again supported by temporary rods hung from the rear truss. The rear longitudinal truss cannot be erected at this stage because of interference with the erection equipment. In this condition the group of four trusses is rolled; the rear ends of the crane girders do not receive their final support until the next group is rolled forward, carrying the longitudinal truss and hanger of the intermediate panel. The purlins of this panel are placed by a jinnywink set on the roof.

Trucks and Rolling Track—Utilizing the outer crane girders as part of the track on which to roll the trusses made the equipment needed for the operation quite simple. The view, Fig. 4, and the drawing, Fig. 3, in conjunction explain the arrangement.

For steady guiding it was desired to use four-wheel trucks running on a track of two rails at each end of the trusses. One rail is laid on the permanent outer line of crane girders, and the other on a temporary line of girders set 37 in. inside of this and resting on steel shelf-beams and batter posts attached to the main columns. The temporary line is made up of 60-ft. lengths of girder borrowed from the interior runways. The batter posts are top-chord bracing struts of the roof, while the shelf-beams are extra material; the addition of the temporary construction increases the stability of the side columns, reducing the chance of lateral sway during the moving.

The permanent outer crane girders, 36 in. deep, span one panel, or 30 ft., while the interior girders are designed for the 60-ft. span between hangers and there-

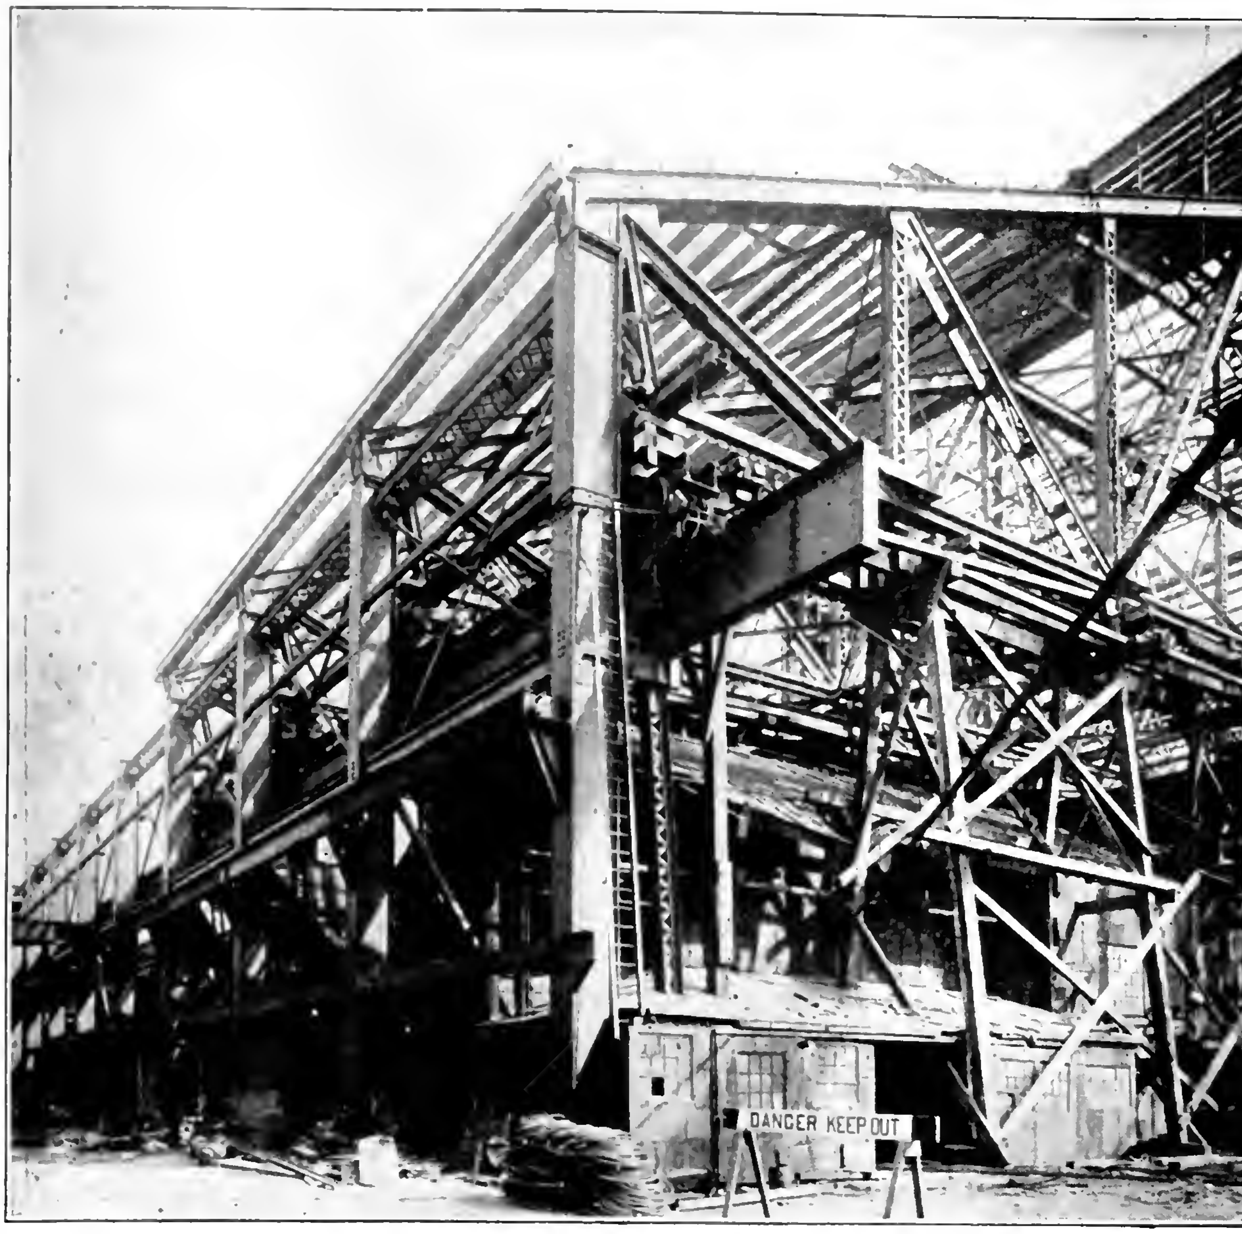

FIG. 5. FOUR-TRUSS GROUP ERECTED AT SOUTH END OF BUILDING, ON FOUR-WHEEL TRUCKS READY FOR ROLLING BACK

fore are made 60 in. deep. When used as part of the rolling track, however, the 60-in. girders are blocked up to bear at the middle as well as at the end supports.

With a truck under each end of each truss, eight four-wheel trucks support one of the 800-ton moving groups (comprising four trusses of about 100 tons weight each, and 400 tons of crane girders, purlins and bracing). Each truck carries a 500-ton hydraulic jack (it happened that smaller jacks were not available), by which the truss end is raised 3 or 4 in. from its seat on the top of the main column and blocked up at this height upon the truck sill, to free it for moving. After the move the jacks similarly lower the group to a seat on the columns at its final location.

Moving the truss groups has turned out to be exceedingly simple and rapid, with this equipment. The hauling line at either end of the truss group is reeved from the hoisting engine through a snatchblock at the front end of the building, thence back to a two-sheave block at the rear end and forward through another two-sheave block attached to the sill of the second truck from the back of the group. This gives a five-part tackle. The four trucks on either side are strutted and tied together by timbers and turnbuckle cables, so that the pull of the line distributes to the four trucks. The two derrick engines at the front of the building handle the east and west lines, and the operators are able to keep the two ends of the group abreast without travel indicators or other special devices.

On Mar. 25, when the first group of four trusses was rolled to place, the move was made in 15 min. The second group was rolled Apr. 15, taking about the same time. The third group of four is to be moved about May 8. This will complete the rolling, as the two southerly trusses will be erected at once in their final position.

Layout for Erection—An unusually convenient erection plant was set up for building the Crucible Steel rolling mill. Fig. 7 sketches the layout. Two derrick towers, built of crane girders and roof-bracing struts in part borrowed from the main structure and in part belonging to a building under contract elsewhere, support two stiffleg derricks fitted with 90-ft. booms. These derricks, regular equipment, are rated at 30 tons capacity, though the extreme lift in this work is 18 tons (end section of top chord) at about 80-ft. reach. The 60-ft. crane girders weigh only nine tons. Because of track interference, these towers had to be set diagonal to the building, but this position worked out very satisfactorily. Material is supplied as needed, coming on cars from a storage space elsewhere in the yard, and is at once hoisted to place. The working space at the front of the building is thus left unencumbered.

A gang of 75 men is employed in the erection work, under Foreman D. McQuarrie and H. Adams.

The side columns, each weighing nine tons, were set

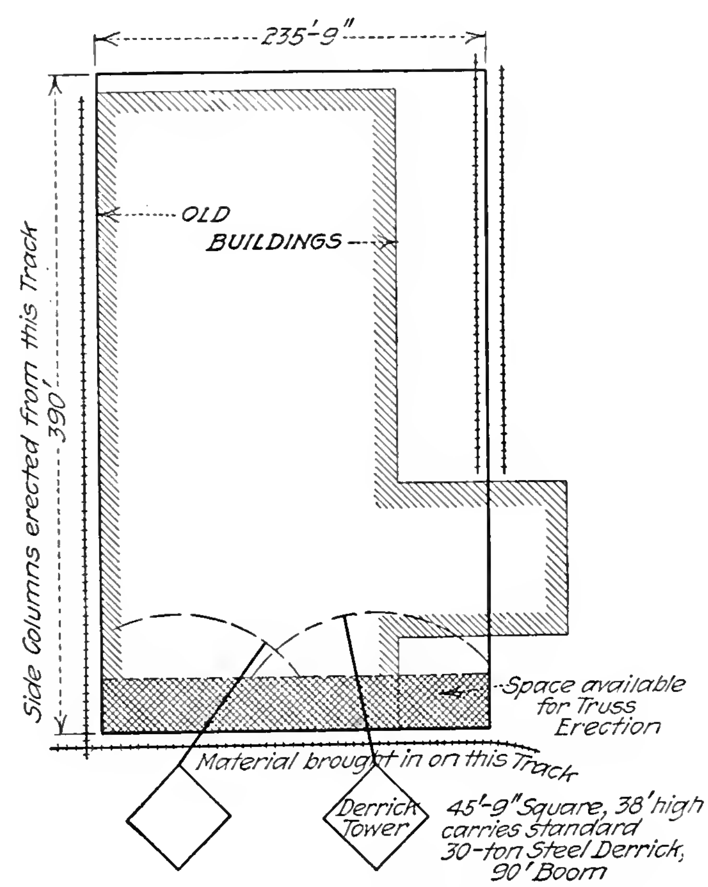

FIG. 6. TRACK AND DERRICK LAYOUT

by locomotive cranes running on tracks along the sides of the building. To give room for preparing the foundations and setting the columns, the building wall was replaced by a temporary shelter partition 6 ft. in, and the old side wall was torn out. In the front bay of the building, staging bents as sketched in Fig. 7 were dropped through the roof of the front part of the building and capped with pairs of 24-in. I-beams.

Camber was provided for in the trusses to the amount of 2½ in., of which 1 in. was designed to be permanent dead-load camber, to allow for deflection under crane loads. The blocking wedges indicated in Fig. 7 were set a trifle high, however, to permit of entering the middle section of the top chord easily, and were then slacked off to let the parts adjust themselves to the natural camber determined by the shop fabrication.

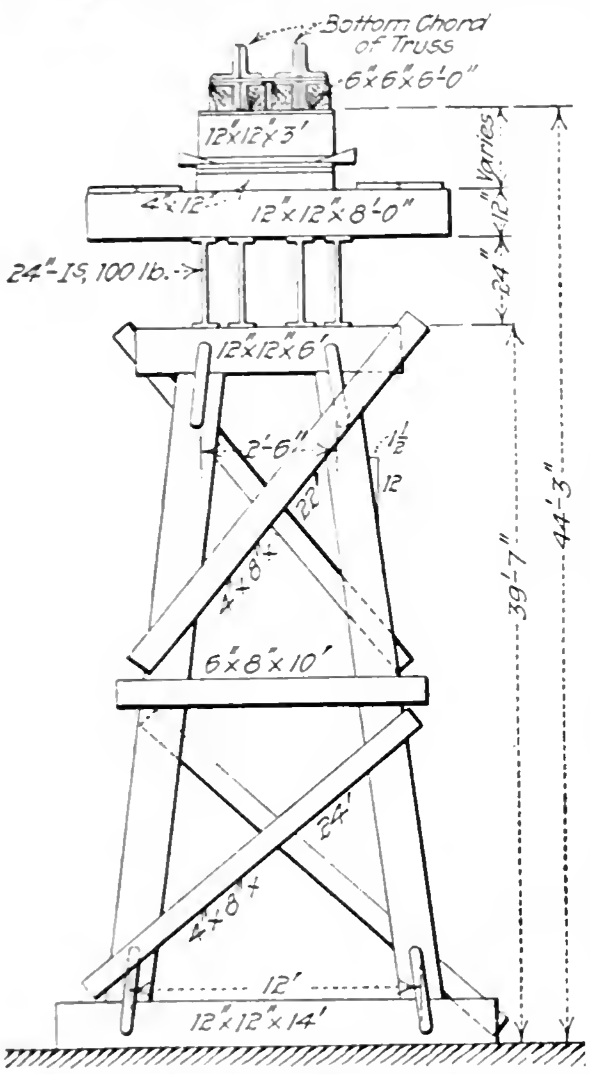

FIG. 7. TYPICAL BENT OF ERECTION FALSEWORK

Returning Crane-Runway Girders—When a group of trusses has reached its final position, the track directly under it is no longer needed. The track girders taken from the interior crane runways must then be moved to the front of the building for erection in a succeeding truss group, since, as already stated, there is no opportunity to set them in position from within.

In part, these girders are dismounted from their seats, lowered, and removed from the building by a locomotive crane running along outside the building. On the larger part of the east wall this is not practicable, however, due to the location of the track and various interferences, and it has been necessary to hang the girders from the roof trusses and telegraph them forward, a rather tedious process in this instance.

As each length of rolling track is removed, short extension brackets originally attached at the rear of the building are bolted to the rear end of the remaining section of track. These brackets are necessary to extend the track beyond the columns at which the rear truss of the next group will be landed, since the rolling truck has an overhang of several feet. Similar brackets are in service at the front end of the building for the outer or permanent line of girders, whereas the inner or temporary line overhangs forward a full 30-ft. panel, since it is made up throughout of two-panel lengths and the building contains an odd number of panels (13).

Reconstructing Old Roof to Clear the New Work—As will be seen from the sketch drawing, Fig. 2, the new trusses foul the monitors of the old roof, and the easterly hangers and crane girders cut into the main trusses of one bay. These conditions made a certain amount of roof reconstruction necessary before the new work could proceed. In the design of the new structure the height was determined by requirements independent of the old building. The monitor interference, amounting to only a foot or so, was easily taken care of by removing the monitor frames and transferring the corrugated-iron roof sheeting of the monitors to the main roof planes.

FIG. 8. ENDS OF TRUSSES CARRIED ON FOUR-WHEEL TRUCKS FOR ROLLING

At the point of interference between the easterly crane girder hangers and the old roof trusses, however, other procedure was necessary. An ingenious reconstruction plan was adopted, involving the substitution of a horizontal chord central section of truss for the peak of the roof truss. The design was such as to permit carrying out the reconstruction operations without shoring. As indicated by the broken lines in Fig. 2, the new chord and web members inserted in the old trusses are so located as to connect to existing gusset plates. Thus they could be attached before the old trusses were disturbed. After they were completed, and capable of taking the load, the ridge members above the new top chord were burned away and removed, and plank sheathing was laid.

Express Trucks—Gasoline and Electric

The American Railway Express Co. employs, in addition to horse-drawn trucks, 1828 gasoline motor trucks, and 1058 electric trucks. The 1828 gasoline trucks are operated in 197 cities—an average of slightly more than nine per city. The 1058 electrics are operated in 23 cities—an average of 46 per city. The ratio is 63% gasoline and 37% electric.

Limestone Rock Asphalt Produces Good Mortar

Tests Show That It Has High Strength, Light Weight and Marked Impermeability—Concrete Results Unsatisfactory

By James R. Nash
Office Engineer, State Highway Department, Austin, Texas

MORTAR made from a natural limestone rock asphalt found in Texas is strong, light and impermeable, according to tests recently made in studying the subject of concretes for ship work. The same aggregate was also used for concrete, but the tests were not very satisfactory, due probably to insufficient mixing and working of materials of this nature. The tests were made with the idea of developing a mortar in which, if incipient cracks should develop due to stresses in the steel, the asphalt in the aggregate would have a tendency to repel water to such an extent that it would prevent sea water reaching the steel.

The aggregate used was a limestone rock asphalt found in Texas, containing approximately 10% of asphalt, the remaining 90% being a comparatively soft limestone. The asphalt is a hard, natural asphalt with a high melting point not unlike the Bermudez natural lake asphalt, but a little harder under ordinary temperatures. The quantity of the asphalt varies from a few per cent. to approximately 14%. The high asphalt content material is called "rich," while that with less than 6% is considered "lean." That which contains about 9 or 10% asphalt is considered "medium."

When heat is applied to a mortar made with this aggregate after it has set and allowed to dry, the asphalt in the stone contiguous to the surface of the mortar becomes soft and is drawn to the surface. A thin covering of a hard asphalt is the result. It is superior to a paint coat of asphalt on the concrete, because the asphalt is part of the aggregate and has therefore a much stronger adherence, and because the heating of the surface tends to melt the asphalt within the mortar, thereby filling up all minute air or water voids in the mortar.

A test made on a mortar disk one inch thick showed it to be impermeable to water under 60-lb. pressure for 48 hours. Three tests were made, and the specimens weighed less after the test than before. The loss was accounted for by the evaporation of water from the specimens; the latter were stored in water until tested.

The strength tests given here are the results of laboratory methods, so it would be necessary to make a field test in a mixer before a definite recommendation could be made. Longer mixing and less water than ordinarily applied to mortar are desirable.

This material is produced commercially by the Uvalde Rock Asphalt Co., of San Antonio, for street construction, by the addition of a flux and heat. For road construction the material is used without heating. The tests were made in the laboratory of the Engineering Division, Bureau of Economic Geology, of the University of Texas.

TESTS OF ROCK ASPHALT MORTAR AND CONCRETE

	Proportions by Volume	Character of Rock Asphalt Screenings	Consistency	Tensile Strength Lb. per Square Inch 7 Days	Tensile 28 Days	Tensile 2 Mos.	Compressive Strength Lb. per Square Inch 7 Days	Compressive 28 Days	Compressive 3 Mos.	Remarks

Comparison of Short-Haul Truck and Rail Shipments

Trucks Reported to Be Efficient for 125-Mile Hauls—Freight Delays, Extra Boxing, Clerical Work Prove Expensive Items

MOTOR-truck transportation on short hauls up to 125 miles, when all the factors, such as delays, extra boxing, weight of boxing, etc., incident to rail shipment are considered, will reduce manufacturers' shipping costs for less-than-carload lots considerably. It will also eliminate a number of transportation evils which are both costly and annoying. These opinions were expressed by W. J. L. Banham, general traffic manager of the Otis Elevator Co., in an address delivered before the National Truck Owners' Conference in New York. The Otis company has effected large savings in this manner, according to the speaker. An abstract of Mr. Banham's remarks follows:

Users of motor trucks should consider to what extent they can operate them in competition with rail movements for short hauls. The principles involved are service and cost. In order to make a fair comparison between the two means of transportation, it is important that the manufacturer shall be in a position to know the cost of moving freight by each method to short-haul points. Some manufacturers figure that when a freight rate is 50c. per hundredweight by rail and 75c. by motor truck, that this means a saving of 25c. per hundredweight.

However, this is not a fair comparison of the total transportation cost, which starts with the boxing of the freight and includes all expenses that are incurred until delivery of the goods in good order is made to the receiver.

While some of these charges are hard to separate from general expense, every effort should be made to do so,

as such separation is important in determining the best method of transportation. The accompanying table shows the variation between rail and truck shipments in the neighborhood of New York.

In computing the cost by rail the following items were included: The first-class freight rate, plus 15c. per hundredweight teaming charges from the shipper's warehouse to the freight house, plus 15c. per hundredweight teaming charges from the freight house to the receiver's warehouse, plus 24c. per hundredweight for increased cost of boxing, plus 17% on account of increased weight due to boxing. There is considerable additional expense, which is not included, but will be referred to later. The rate by way of motor truck covers delivery from shipper's warehouse to the receiver's warehouse. It was averaged, and is believed to be a fair tabulation to be compared with the cost of rail movement.

Factors Making Up Shipping Cost

Taking up the various items responsible for additional expense, the cost of extra boxing may be considered the most important. The amount of this saving, however, will be controlled largely by the amount of material to be boxed or packed, and how much less protection can be used when moving by motor truck as against a less-than-carload movement by rail. In practically every instance it is necessary to prepare material for freight shipment in an entirely different way from that used if it is moved by trucks. This additional packing expense is necessary on account of the number of handlings the less-than-carload shipments received by the railroads and by transfers at both ends. This boxing is generally very much less where truck transportation is used.

Important in connection with this boxing is its weight. This is often increased by moisture from 10 to 25% over the dry lumber weight, where the material is stored out of doors. Also, the extra space required for packing shipments, storing lumber, etc., could generally be utilized to greater advantage for other manufacturing purposes which would produce a profit. Mr. Banham estimated that the Otis Elevator Co. saves $100,000 per year in the cost of boxing, by using motor-truck shipments.

Increased clerical work, delays in transit and, often, loss of shipments are other items which produce extra expense in rail shipment. After the shipment has been properly prepared and the necessary shipping documents have been made out, the shipping department is burdened with an additional expense covering transfer of freight from the shipping floor to the carrier's freight house by truck or other means. If the freight is to be prepaid, the freight bill when rendered must be checked by the shipping department and passed for payment to the interested department. Where thousands are to be handled this checking is expensive. With the use of trucks, this check is made as the merchandise is loaded on the trucks.

It would seem now that the transportation cost has been completed, but in many instances this is not the case. Delays occur in transit, often from six days to six weeks. Where such delays occur it is necessary for the shipper and receiver to locate the freight, and a tracer must be sent out, involving additional expense. Inasmuch as the consignee does not consider that payment is due until the shipment is received, these delays occasion a large loss in capital which might be used for greater manufacturing activities. Where shipments or portions of shipments are lost, as is not uncommon, replacements must be made at further expense.

COMPARISON OF COST OF RAIL AND MOTOR TRUCK TRANSPORTATION FOR SHORT HAULS

Haul	Cost per Cwt. Via Rail	Cost per Cwt. Via Motor Truck
From Yonkers to—		
Newark	$1.04	$0.20
From New York to—		
Newark, N. J.	.91	.15
Passaic, N. J.	.91	.18
Paterson, N. J.	.91	.20
Elizabeth, N. J.	.91	.20
New Brunswick, N. J.	.91	.40
Trenton, N. J.	.98	.60
Philadelphia, Penn.	1.02	.80
Chester, Penn.	1.05	1.00
Wilmington, Del.	1.13	1.20
Coatesville, Penn.	1.15	1.05
Portchester, N. Y.	1.02	.63
Greenwich, Conn.	1.02	.63
Stamford, Conn.	1.03	.65
Norwalk, Conn.	1.06	.68
Bridgeport, Conn.	1.10	.70
New Haven, Conn.	1.13	.73
Derby, Conn.	1.13	.73
Ansonia, Conn.	1.13	.73
Shelton, Conn.	1.13	.73
Naugatuck, Conn.	1.15	.74
Waterbury, Conn.	1.16	.75
Meriden, Conn.	1.16	.75
Hartford, Conn.	1.21	.90
Springfield, Mass.	1.25	1.00
Holyoke, Mass.	1.25	1.10
Worcester, Mass.	1.31	1.50
Boston, Mass.	1.36	1.50
Providence, R. I.	1.32	1.10

Contrast this with movement by truck where delivery from shipper to receiver is made within a 24-hour period, with less than half the handling and greatly decreased packing charges. Practically none of the additional expense incurred by rail shipment is necessary when movement is made by truck. If a fixed rate is agreed upon, the shipper is in a position to know at once what his shipping charges will be.

Is it not to the advantage of the manufacturer to make delivery to his customer within the shortest possible time? If a freight shipment takes 30 days by rail, as against one day by truck, the capital tied up might have been used 29 days for manufacturing. It is the best advertising feature of Marshall Field & Co. of Chicago that they agree to make delivery within 50 miles of their store within 24 hours. Prompt delivery gets the business, and slow delivery would lose it.

Broader Commercial Education for Engineers

As a result of a meeting of a committee composed of administrative professors of engineering and commerce at representative higher institutions of learning, and delegates from the four national engineering societies, called to meet in Washington, D. C., by the Commissioner of Education, the following recommendations were made, to be considered by a general conference proposed for the near future: (1) That from 12 to 18 semester hours be required of all engineering students covering the following subjects: General economics, cost accounting, business organization and business law; (2) that for engineering schools desiring to extend further the commercial or industrial aspects of engineering, the following subjects are recommended as electives: Labor and employment, corporation management and finance, statistics, marketing, scientific management, psychology, transportation, and political science; (3) that the economic phases of engineering be emphasized in engineering instruction wherever possible.

Illinois Adopts a Uniform Basis of Design for All Types of Rigid Pavement

Concrete Standardized, Other Types Designed to Equal It in Load-Carrying Capacity—Flexural Strength To Govern—Brick and Bituminous Concrete on Concrete Base Only Other Types Considered for Main Road

By Clifford Older
Chief Highway Engineer, Department of Public Works and Buildings, Illinois

In view of the rapid development of interurban truck transportation, load-carrying capacity is the logical basis for the design of rigid pavements of different types. In rigid pavements flexural strength is the governing feature, and, having established a standard design for one type, it is sound engineering practice to make all other types conform to it in strength, as nearly as possible. A standard concrete slab, 7 in. at the side and 8 in. at the center for 16- to 18-ft. widths, has recently been developed by a conference of the northern Mississippi Valley states, and this has been adopted by the State of Illinois as the basis for all its rigid surfacings. The only other types considered suitable for the primary road system of Illinois are monolithic brick and bituminous concrete on a concrete base.

Illinois is facing the problem of expending judiciously for road building a state bond issue of $60,000,000, together with about $24,000,000 of Federal-aid appropriation. Practically all of these funds will be used on the main road system of the state, constituting approximately 5% of the total road mileage, and estimated to carry about 60% of the entire state traffic. The design of the pavements to be used on these roads is therefore a matter of the greatest importance.

Rigid Types To Be Used on Main Roads

In this discussion, the rigid types considered are portland-cement concrete, brick on a concrete base and bituminous concrete on a concrete base. Other types of rigid pavement, such as wood-block or granite-block are not considered because they are not available for country road work in Illinois on account of cost. Gravel, water-bound macadam, and the various forms of bituminous macadam are considered to be nonrigid types.

In Illinois, perfect drainage is difficult to obtain in subgrade building. The nonrigid pavements depend almost entirely upon the solidity of the subgrade for their stability. While every reasonable effort will be made to secure good subgrade drainage, yet experience in this state has shown that nonrigid pavements require an excessive expenditure for underdrainage, if serious rutting under heavy traffic is to be avoided.

This condition also necessitates the use of thicker nonrigid pavements than commonly used, and more thorough rolling with heavy rollers to secure the required density of pavement. The stone available for macadam road building in Illinois is a comparatively soft limestone which crushes under heavy rolling. Internal wear under heavy traffic is also a serious matter. These considerations lead to the conclusion that macadam or bituminous-macadam roads, as they may be built practically under Illinois conditions, are essentially light-traffic roads, and cannot be made to bear even moderately heavy truck traffic, except at a first cost which is practically equal to that of the rigid pavements. Gravel roads are subject to the same criticism. The high cost of maintaining nonrigid types under heavy traffic is well understood. These conclusions have led to the adoption of rigid pavements for the main roads.

Any of the three types of rigid pavement considered —namely, concrete, brick and bituminous concrete on a concrete base—has sufficient wear-resisting qualities to make this factor comparatively unimportant. Disintegration due to weather or other natural causes may also, as far as we know, be disregarded in the case of any of the three types mentioned. Available data on maintenance cost do not indicate that this element would be a controlling factor. It therefore follows that the main factor to be considered in the design of such pavements is load-carrying capacity.

It is not the primary function of rigid pavements to span soft spots in the subgrade. The subgrade should be as uniform and unyielding as can be obtained at reasonable cost; but, regardless of the care used, all subgrades are more or less yielding. The function of rigid pavements, therefore, is to provide means for the transmission of traffic loads to the subgrade without exceeding the capacity of either the pavement or the subgrade.

It is fundamental that the load-supporting capacity of a rigid pavement is dependent upon its transverse strength, and its transverse strength is measured by its thickness and the modulus of rupture of the material of which the surface in tension is composed.

Pavement Design Not Subject to Exact Mathematical Analysis

It is generally admitted that with our present knowledge the design of a rigid pavement is not subject to exact mathematical analysis. The forces of traffic, character and moisture content of the subsoil, frost action and other factors are so variable and complex as to defy exact analysis, and any computations must be used merely as a guide to the judgment. *It is reasonable to assume, however, that all types of rigid pavement, provided they are to be used interchangeably under the same soil and traffic conditions, should have equal flexural or transverse strength.*

Under the abnormal motor-truck traffic of last year, failures were observed in practically every type of rural road. In view of these condtions and the increasing use of concrete as a paving material, a conference of the engineers of the highway departments of the northern Mississippi Valley states was recently held for the purpose of standardizing the design of concrete pavements. The aim of this conference was to provide a concrete pavement which, under average soil and drainage conditions, would have sufficient strength to withstand the expected increase in volume and weight of traffic.

For 16- and 18-ft. pavements the design adopted calls for a thickness of 8 in. at the center and of 7 in. at the sides. The concrete to be mixed in the proportion of 1 part of cement, 2 parts of fine aggregate, 4 parts of coarse aggregate, and only sufficient mixing water to give maximum strength. Illinois has adopted this stand-

ard except that a 1:2:3½ mix will be used at least for 1919 construction. This design has also been adopted by Illinois as a standard of strength or traffic-supporting capacity on which to base the design of all other types to be used under the same conditions.

Comparison of Other Pavements With Standard

A standard of strength having been adopted, it is relatively simple to compare it with other rigid pavements. Assuming traffic loads to be equal, the moments producing flexure of the slab will be equal. Also, the results will be relatively correct whether the pavement is considered as a slab or simple beam. For convenience the latter assumption is made.

The modulus of rupture of the pavement may then be expressed by the common flexure formula $S = Mc/I = K/d^2$, where K is a constant which is equal to $6M/b$, and is equal for all slabs of equal strength and proportionate for all slabs of unequal strength, S is the modulus of rupture and d is the thickness of the slab. Then

$$K = Sd^2 \qquad (1)$$

$$\text{or } d = \sqrt{\frac{K}{S}} \qquad (2)$$

For the standard road $K = 459 \times 8 \times 8 = 29{,}400$, using a modulus of rupture for 1:2:3½ concrete of 459 lb. per square inch. Substituting this value of K and the modulus of rupture for any given concrete in formula (2), the thickness at the center line of a pavement of equal strength may be determined. Or, determining K for any pavement by formula (1) will enable a comparison of transverse strength to be made.

The accompanying table gives a comparison of some of the properties of common concrete mixes:

Proportions of Concrete	Modulus of Rupture * Lb. per Square Inch	K for Pavement 8 in. Thick at Center	Per Cent. of Strength of 1:2:3½ Mix. (8-in. Slabs)	Thickness at Center Line (d) for Strength Equal to 1:2:3½ Concrete
1:2:3½	459	29,400	100.0	8.0
1:2:4	439	28,100	95.6	8.2
1:3:5	285	18,200	61.9	10.1
1:3:6	226	14,500	49.3	11.4
1:1:2	710	45,400	154.5	6.4
1:1:1½	709	45,300	154.0	6.4
1:2½:4	375	24,000	81.7	8.9

* Obtained from "Concrete, Plain and Reinforced," Taylor and Thompson p. 258.

The results given are independent of the exact values of modulus of rupture, providing these values are relatively correct.

Brick Pavements

Brick pavements have been constructed in many different ways. For several years the Illinois department has favored the monolithic type, as it seems to be giving excellent results. In a report of tests of monolithic brick slabs made at the University of Illinois (see *Engineering News-Record*, of Nov. 1, 1917, p. 820), Prof. C. C. Wiley states, in effect, that the modulus of rupture of the concrete base of monolithic brick slabs is approximately the same as that of plain concrete of the same quality, and that such slabs are fully equal in strength to concrete slabs of the same thickness. The tabulated results of these tests would seem to indicate that a higher modulus of rupture might be expected for the base of a brick slab than for the base of a concrete slab of the same thickness and quality of concrete. However, in the few tests recorded where the brick surface was in tension and with transverse courses (a condition which applies near transverse joints or cracks), a very low modulus of rupture was noted. Although this fact would seem to indicate an element of weakness, yet the number of tests made was so low that the tests could hardly be considered conclusive. The Illinois department has assumed that, in the light of our present knowledge, it is reasonable to consider the combined concrete and brick slab to be equivalent, from a flexural standpoint, to a homogeneous concrete slab having the same quality of concrete. Under this assumption a monolithic brick road may be considered in exactly the same class as a concrete road, in so far as traffic-supporting capacity is concerned.

Since the transverse strength of a concrete slab is measured by the modulus of rupture of the concrete, it is evident that, under the above assumption, a monolithic brick pavement should have a base of the same quality of concrete as would be used in a homogeneous concrete slab of equal thickness, in order to have equivalent strength. It is also evident that, if we should make the total thickness of a brick road 8 in. and use a lean mixture in the base, its traffic-supporting capacity would be reduced in proportion to the modulus of rupture of the base. Illinois has, therefore, adopted as one standard a 3-in. brick laid on a concrete base 5 in. thick, and having the proportions 1:2:3½.

This will result in a pavement having practically the same carrying capacity as the standard concrete pavement heretofore described. The problem is somewhat different if 4-in. brick are used, because if the same total thickness is maintained the base would be so thin as to require a finer aggregate and more care in construction. It has therefore been considered advisable to use a base of 1:2½:4 concrete, 4 in. thick at the sides and 5 in. thick at the center, making a total thickness at the center of 9 in. An examination of the table will show that this pavement should also have a load-supporting capacity equal to that of the standard concrete road.

If asphaltic or sand fillers are used instead of cement grout, it is evident that the pavement can no longer be considered to act the same as the homogeneous concrete slab. It is probable that brick surfacing with a soft filler has some strengthening effect which may be added to the carrying capacity of the base, but the amount of such effect cannot be determined definitely. In the absence of definite data, we have assumed that the strength of the combined concrete and brick slab would be equal to a homogeneous concrete slab having a thickness equal to the thickness of the base plus one-half the thickness of the brick wearing surface. For example, if 4-in. brick are used with a soft filler, the concrete is to be 2 in. less in thickness than if no surfacing were used.

Bituminous Concrete on a Concrete Base

It seems logical that the bituminous-concrete type of pavement on a concrete base should be considered in somewhat the same class as the brick with the soft fillers, so far as traffic-carrying capacity is concerned. Two designs for bituminous-concrete surfacing have been adopted by the Illinois department: (1) A 2-in. Topeka type of bituminous concrete laid directly on a concrete base; (2) A 1½-in. binder course of bituminous concrete on which is laid a 1½-in. Topeka-type wearing surface, making a total thickness of 3 in. of wearing surface on a concrete base.

Since it is wholly a matter of opinion as to how much weight can be given to the transverse strength and

and cushioning effect of the bituminous wearing surface, it has been decided, for the sake of simplicity, to allow the equivalent of 1 in. of concrete for both the 2-in. and 3-in. wearing surface. This means that a 2-in. Topeka-type wearing surface should be laid on a 7-in. concrete base, if a proportion of 1:2:3½ is used; on a 9-in. base if a 1:3:5 mix is used, or on a 10-in. base if a 1:3:6 mix is used. (See the table.)

A study of cost, taking into consideration the ordinary range in cost of delivered materials, indicates that this type of pavement will be cheaper if laid on the thinner and richer base, rather than on the thicker and leaner base. Any possible saving in cement is more than offset by the cost of delivering the larger volumes of aggregate.

The 7-in. base of 1:2:3½ mix has therefore been adopted.

Objections have been raised to the so-called unprecedented richness of the base for both brick and bituminous-concrete surfaces. The chief reasons for these objections are undoubtedly the prevailing idea that the selection of type will be dependent upon cost, and because leaner bases of about the same thickness have given reasonable service in city streets. Bituminous concrete on a concrete base has seldom been used for rural roads, and the conditions of traffic are so different that previous experience in city streets should not receive undue weight. Practically all types of properly constructed pavement have been a success or failure in city streets, dependent upon the character of traffic on the particular street. Again, all city streets are more or less satisfactorily drained by a sewerage system, whereas on country roads an equally uniform subgrade cannot be obtained at reasonable cost.

A careful analysis of the country road problem indicates that in the future there will be unprecedented conditions to meet. Heavy motor-truck traffic will prevail on all the main improved roads, and this traffic will be confined day after day to the same wheel tracks, because of the limited widths of pavement which can be built with available funds. With these considerations in mind, it seems absolutely justifiable to take this rather drastic stand in the design of pavements for a comprehensive system of roads.

Starting with one well established design of rigid pavement, it is not only feasible but sound engineering practice to design all other principal types of rigid pavement in such manner that, within reasonable limits, each will have the same carrying capacity or transverse strength, under equal subgrade and traffic conditions.

New Classification Proposed for Rock To Be Excavated

Geologist Bases Grading Rules on Ease of Excavation and True Geological Composition

ROCK classification, as used by engineers in excavation work, is not as accurate as a geologist would wish, nor does it serve to prevent many disputes in actual practice. With a view to providing a classification which will better serve, Warren D. Smith, professor of geology at the University of Oregon, has recently submitted to *Economic Geology* for March-April, 1919, the following discussion, which he hopes will receive the consideration of engineers:

The classification of rocks given in geology handbooks is too technical and too clumsy, as now arranged, for the use of the field engineer, and we find in the literature nothing very adequate which the engineer can use. In some cases he has fallen back on a classification something like this, which all geologists will recognize as being a very loose and unsatisfactory classification. For instance, I found the following classification in use by the engineers of a railroad company in Oregon: (1) Solid rock; (2) sandstone; (3) cement; (4) shale; (5) earth.

Now, all geologists know that there are many different kinds of solid rocks and many different kinds of sandstones, and so on. No regard is paid in this classification to the differences in cementing materials in the sandstones; there is nothing in here about structure, or texture, which determine the ease or difficulty in excavating the material. No attention is paid to whether the material is weathered or to the degree of alteration. For instance, the word cement may include many different kinds of cementing substances, silica, calcium carbonate or iron oxide, and it makes a great difference which one of these is the binding substance.

A good classification will probably have to include terms generally used by geologists, but these must be so grouped that we get in any one group materials which can be excavated with about the same degree of ease or difficulty, as the case may be. In the following proposed classification very heterogeneous substances are grouped together, but, taking into consideration texture, structure and composition, we think there are included those materials which, from our experience, we judge ought to be classed together for similar rating in regard to excavation.

We realize that this classification is open to criticism, but criticism is what is invited, for an excellent way to develop a good classification is to propose one, have it criticized, and then make a new one, or, if necessary, several new ones.

In the case of a small job, involving little financial outlay, where not very much can be either made or lost by the contractor, the old, loose classification as now used might be retained; but with a big piece of work, where thousands of cubic yards of rock have to be moved, it will pay both the company and the contractor to have a geologist. If the company retains no geologist on its staff then let it secure the temporary services of one, and have him classify the material to be excavated. In this particular case I know that several hundred dollars could have been saved.

For use in connection with this classification we think that Pirsson's "Rocks and Rock Minerals," with the tables there included for rock determination, should be used. There is no escaping the fact that the engineer must know the common rocks and minerals. If he does not know them now, he must either take a course where he can learn these, or a geologist must be retained.

The following classification has four main groups, and is as follows:

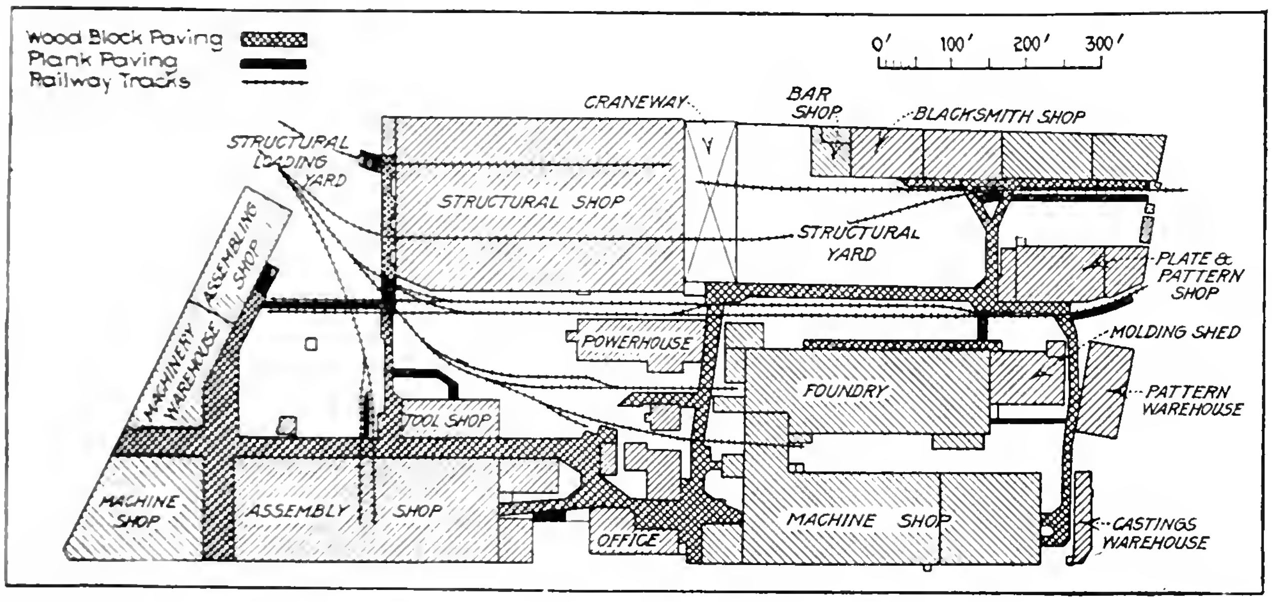
Name	
All granitic rocks, granites, diorites, etc. Sandstones (siliceous cement) Quartzites and quartz masses Traps (basalt) porphyries and volcanic glasses Conglomerates and agglomerates Gneisses, breccias	GROUP I. Solid and unweathered rocks.
All rocks of Group I. badly weathered Sandstones (lime or iron cement) Limestones and marbles Serpentines, schists, slates and argillites Hardpan (glacial, etc.)	GROUP II. Intermediate rocks.
Shales Rubble limestone Loose sandstone Coquina Marls Travertine Tuff Glacial till	GROUP III. Soft rocks.
Silt Mud Sand Gravel Volcanic ash (loose)	GROUP IV. Unconsolidated (earth)

Tractors Reduce Service Cost at Machinery Plant

Dispatcher System with Truck Trains on Paved Roadways Handles More Material with Fewer Men Than Old Teams

NEARLY 80% reduction in cost of intershop distribution of material has been effected by the Minneapolis Steel & Machinery Co. by means of electric tractors and trucks operated on paved roadways under the control of a dispatcher system.

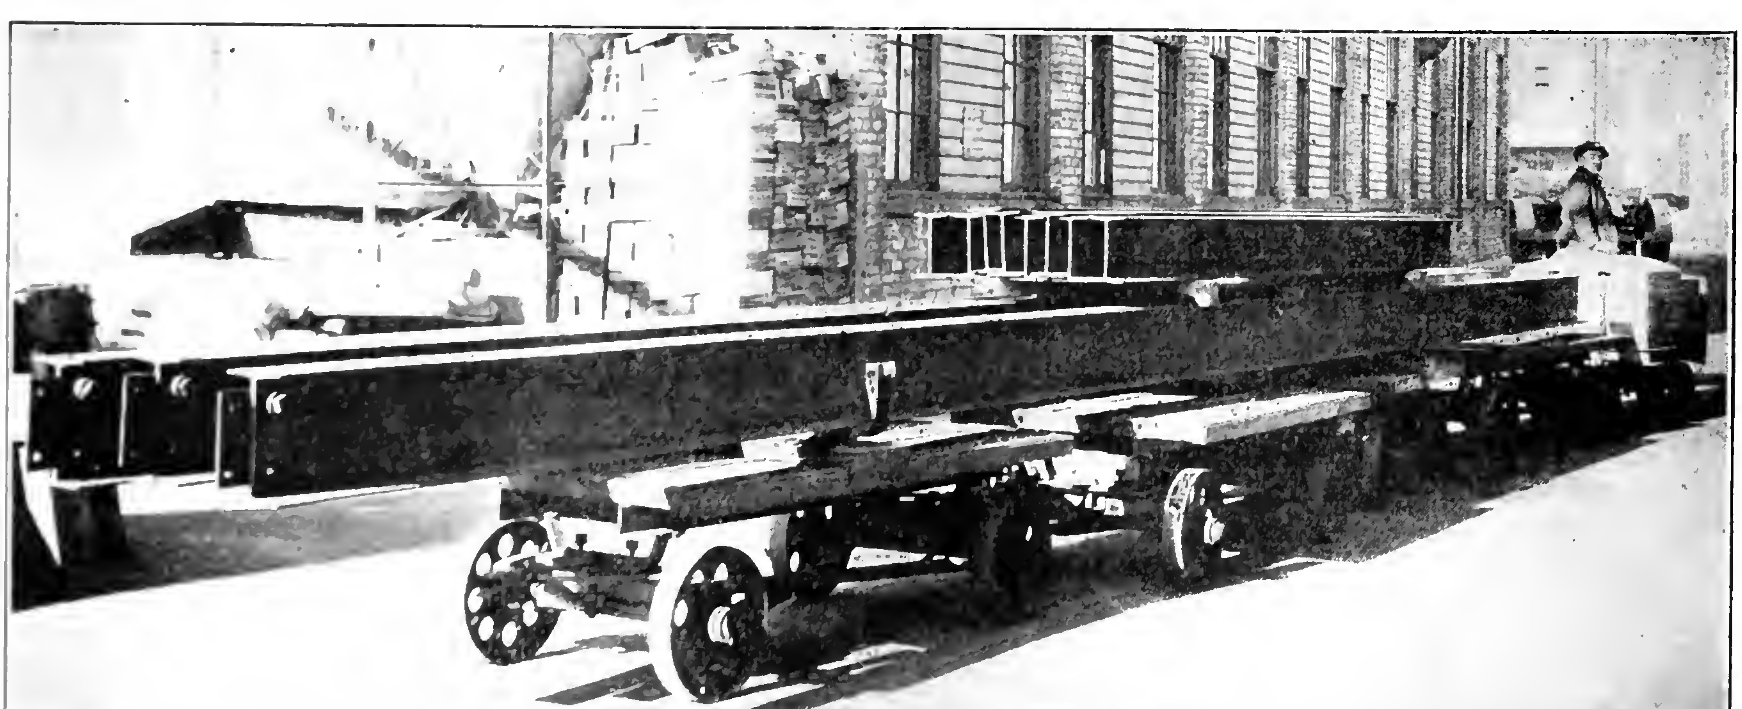
The old intershop service was operated by 14 hired wagons and teams, each with a driver and two helpers, under the direction of a foreman and four assistants, making a total of 47 men. For 100 tons moved daily the cost averaged $1.50 per ton. By paving the roadways and organizing a dispatcher system to control the movements, the cost was reduced to about $1 per ton. With the introduction of tractors hauling trains of trailer trucks, accompanied by further development of the dispatcher system, the cost was reduced to 31 to 35c. per ton for a daily business of 200 tons and with a force of 14 instead of 47 men. The average daily mileage has not been determined yet.



PAVED ROADWAYS FACILITATE DISTRIBUTION OF MATERIALS BY TRACTORS

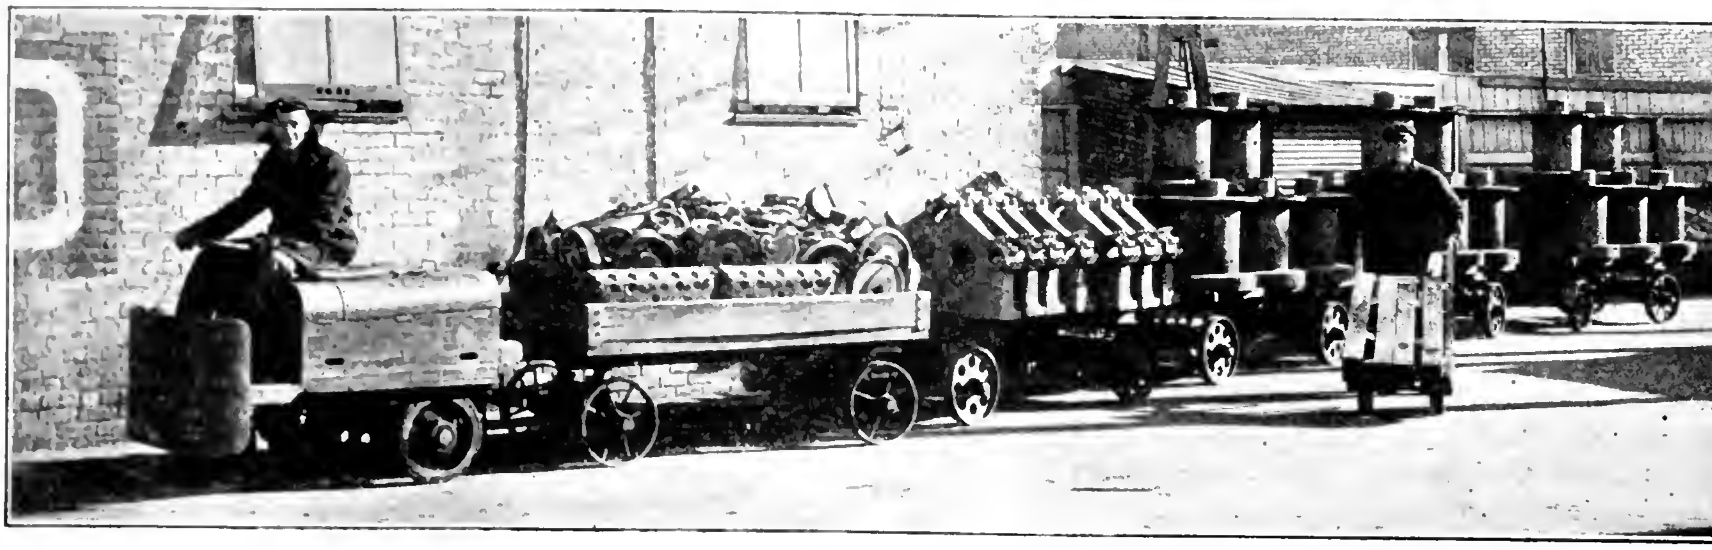
It is expected that by equipping the tractors with recording speedometers the charts will permit close analysis of the situation and still further reduction of the cost by 5 to 8c. per ton, through the elimination of weak points in the service. The system is similar to that at the Topeka shops of the Atchison, Topeka & Santa Fé Ry., described in *Engineering News-Record* of May 30, 1918, p. 1038. The intershop transfer system is headed by a superintendent, who has a chief dispatcher, assistant chief dispatcher, five sectional dispatchers, four tractor operators, one truck driver and one helper, a total of 14 men. There are three electric tractors, 53 trailers, one electric lifting truck and one motor truck with trailer.

All movements of material are recorded by the chief dispatcher, while his assistant looks after the field or outdoor service. The sectional dispatchers are in charge of five designated portions of the plant and see that all incoming material is delivered promptly to the departments in their respective sections, and that finished material is removed promptly and dispatched to its destination. With each movement there is a delivery slip showing the weight, pattern number, description, order number, by whom shipped and to whom and to which department the material is shipped. One copy is kept by the shipper, while the receiver keeps the second copy and signs the third copy, which is returned to the shipper. The last named in turn sends the original slip to the chief dispatcher. From these slips a record is made at the end of each day, showing the material moved and the operating cost. Material is now handled more rapidly, while delays and losses in transit, formerly encountered, are eliminated.



TRACTOR-TRAILER TRAIN HANDLES STRUCTURAL STEEL AT MACHINERY PLANT

Creosoted-block paving is used for the greater part of the paved roadways, which aggregate about a mile in length. The balance is of 3-in. plank. The width is from 16 to 27 ft. for the block-paved portion and 5



MACHINERY SUPPLIES HAULED BY TRACTOR-TRAILER TRAIN

to 10 ft. for the plank paving. The only concrete paving is that inside the buildings. Two electric tractors weigh about 2400 lb. each and have a hauling capacity of 8 to 15 tons. The third tractor weighs about 2275 lb. and hauls from 6 to 12 tons. The plant investment of $30,200 includes $17,000 for paving, $9100 for trucks and $4100 for trailers. The only overhead figured in the cost is that which is sufficient for the operation of the trucks to cover repairs, renewals and depreciation, as the whole interplant delivery system is an overhead on productive labor at the plant. No comparison can be made between the present investment cost and that under the old system, as the company did not own the teams formerly used.

The new system was devised and developed by George H. Anson, superintendent of the intershop transfer and warehousing department, and James B. Gilman, chief engineer of the company.

Low Labor Output in War Work Not Due to Cost-Plus Contract

Interviews With Contractors Prominent in War Work Indicate Low Efficiency of Labor Resulted From Long Hours and Excessive Demand

(*Editorial Interview*)

WAR construction was extravagant in the expenditure of labor. Workmen of all classes were inefficient. Did the cost-plus contract encourage this inefficiency? The word is being passed among construction men that it did. It is being repeated that cost-plus contracting reduced the productiveness of labor and did away with the incentive for close management. A sentiment which was keen for the extension of cost-plus methods is therefore growing indifferent and to some extent turning reactionary.

Inquiry made of a contractor who ranks high because of his successful work of many years, and who carried out important war contracts, elicited the astonishing response that cost-plus contracting was unqualifiedly detrimental to efficiency in construction. The question was then divided into two:

"Is it your experience that labor is less efficient in cost-plus construction?

The answer was "Yes."

"Is the fact due to the form of contract or to some other cause?" was then asked.

The reply was, "The cost-plus contract takes away the incentive to good work and good management."

Merely as personal opinions, these statements were impressive because of their source. They prompted the extension of the inquiry. Interviews were obtained from six contractors, of large experience in peace-time construction, who had been prominent in war work. All freely admitted that the output of labor had been below normal in war construction. All strenuously denied that cost-plus contracting was the cause. Responsibility was placed on overtime work, long hours, scarcity of labor, unwise publicity and the disposition of labor to profiteer. Promise of anonymous publication elicited candid expressions of opinion, on various features of cost-plus contracting, which are deserving of the most serious consideration by contractors who are uncertain of their attitude toward the movement to extend the practice to public-works construction generally.

Causes Affecting Efficiency—Indulgence in excessive overtime was a prolific cause of inefficiency of labor in war construction. It reduced the output of the workman and it lowered his morale and excited his greed for "big money." Undoubtedly, knowledge that overtime must be employed decreased in many instances the output of the workman during straight-time hours. This, coupled with the anticipated and realized decrease of 25 to 50% in efficiency in the overtime hours, amounted to a serious reduction in output per man per hour. Also without doubt, the emergency of war warranted the employment of overtime work even at the sacrifice indicated, but its detrimental results should not be held to be a normal effect of cost-plus contracting.

In much war construction the management worked long hours under great pressure. Opinion differs as to effects. Some assert that supervision was just as efficient and painstaking as it is under normal conditions. Others assert that superintendence and foremanship were less keen; long hours depleted the energy of the men, and the constant demand for quick decision prevented the consideration which some questions needed for wise decision. The success of cost-plus contracting hinges very largely upon the spirit imparted to workmen through their executive superiors. With its energy sapped by long hours, supervision was less inspiring. A portion of labor's inefficiency was traceable to this cause.

Scarcity of labor, and constant newspaper publication of the fact that contractors were borrowing, begging

and even stealing workmen wherever they could be found, gave labor a feeling of independence which often expressed itself in "loafing on the job." Independence was further increased by a weekly wage greater than many workmen required to meet their normal living expenses. The effect of this unusual affluence was in some cases to encourage dissipation and a disposition to lay off, while in other cases it aroused a greed for accumulation which led the men to dole out their energy so that credits for overtime would mount up.

Inefficiency was not peculiar to cost-plus work. Contractors who during the war were doing work for the Construction Division of the Army under cost-plus-limited-fee contracts, and at the same time had work for private concerns on a unit-price basis, were unable to see that there was any greater inefficiency in one case than in the other. Labor was very inefficient in both cases.

War Results Not Criteria—There is no reason to believe that conditions which contributed to inefficiency of labor during the war will continue a controlling influence after the war and particularly after the lapse of a period of readjustment in living standards. The labor market will approach normal conditions, and haste in construction will cease to be the supreme requirement. As stated by one contractor, "It would be manifestly unfair to consider the cost of emergency war contracts or the efficiency of labor on these contracts as a criterion of what might ordinarily be expected in peace work when efficient labor can be obtained or a laborer who is not efficient can be replaced by one who is."

C. S. H.

Poor Plumbing and Unruly Temper Cause Institutional Water Waste

HIGH consumption of water at the Illinois State Reformatory is attributed largely to poor plumbing and the unruly character of the inmates, according to a recent report made to F. J. Postel, supervising engineer of the State Department of Public Works and Buildings by H. G. Thomas, assistant engineer, following an exhaustive water-waste survey.

No underground leakage from the mains was found that would register on a ¾- or 1-in. meter. Meters were then installed on leads to the various buildings or groups of buildings, seven in all. In the past three years the consumption has varied from 91 to 235 gal. per capita. The average since February, 1916, has been 170 gallons.

Quoting Mr. Thomas: "I attribute this solely to the condition of the plumbing and the temper of the inmates. The north cell-house is the older, and the cocks on the cell fixtures are of poorer construction than in the south cell-house. Incoming inmates are also first assigned to the north cell-house as well as all third grade or most unruly inmates.

"The cocks being of poorer construction, are more easily put out of commission, and the per capita consumption in the north cell-house runs about 140 gal.. as against 72 gal. in the south cell-house. Most of the inmates are in the shops or on the farm or grounds for about eight hours of the day, and wash up for their noon and night meals in the shops and make use of the shop fixtures for toilet purposes during that period."

Some of the groups gave the following daily per capita rates: Chain shops, store, machine shop, blacksmith shop, carpenter shops, foundry, print shop, inside barn, south cell-house, bathroom, south towers and all of the farm, 30 gal.; superintendent's houses and offices, 99 gal.; north cell-house, 140 gal.; school, receiving and discharging department, tailor, shoe and paint shops, yard gang, toilets and showers, captain's office, library and most of the offices and inmates' kitchen demand, 10 gal. per capita of the whole population; peeling room of inmates' kitchen, officers' quarters, and bakery, 4 gal.; south cell-house, 72 gallons.

A favorite habit of the inmates is to balance the self-closing cocks open so as to wash in running water. Temporary relief is being tried by putting on a stop to prevent opening the valve wide. It is estimated that all the present outlet cocks in the cells can be replaced by positive self-closing cocks at a cost of $4800 and reduce the use of water to 40 or 50 gal. per capita, also largely reducing the annual water bill.

Education for Intelligent Industrial Production

Addressing a body of students and professors at the State University of Iowa recently, Prof. J. H. Dunlap stated that the primary purpose of all education in applied science was more intelligent industrial production.

The state is furnishing educational facilities to the end that there may be in this country and in the world trained engineers who will make a return of a thousandfold in terms of intelligence. He said that the two fundamental elements of production are materials and men, yet the engineering school of the past has been largely concerned with materials, their physical properties and the laws by which they can be utilized in the service of mankind. The second factor of production—namely, the human factor—cannot be neglected longer.

The war has brought mankind to the firm determination that the square deal shall be given it, or else no deal at all. The world today is divided into two camps. One camp is seeking the upbuilding of mankind through the destruction, root and branch, of our capitalistic society. The other camp is seeking the upbuilding of mankind through the beneficent operation of an applied science which will make surveys, determine causes, design and build in human society an immortal structure which shall be forever founded on those elementary principles of justice to all men, for which we have been fighting in time of war, and for which we must continue to struggle in time of peace. The problem, in its final analysis, is an engineering problem.

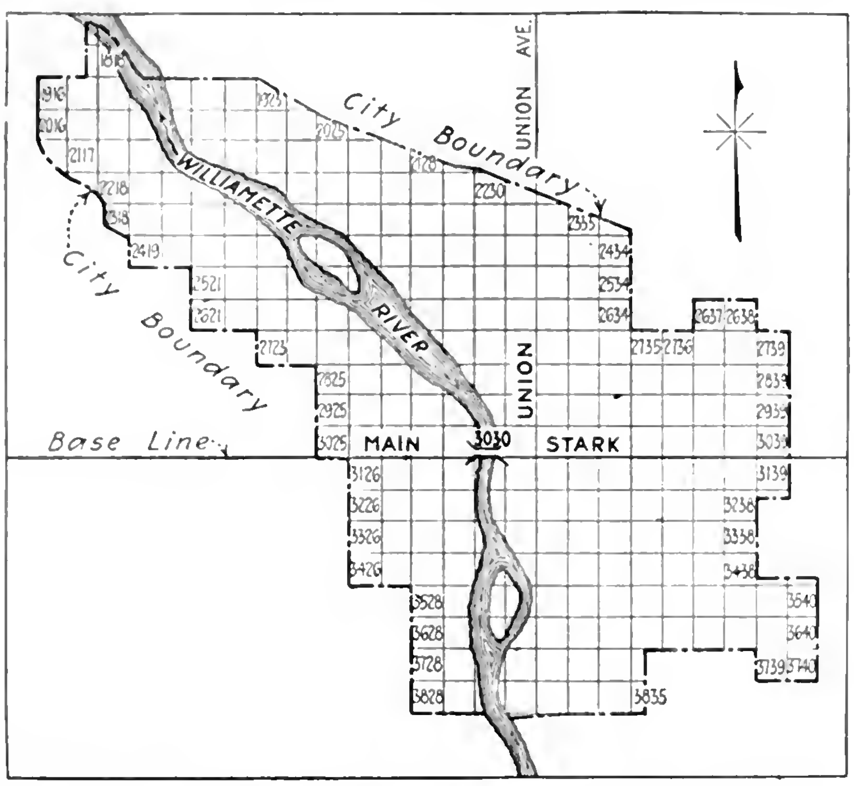
Its solution rests with men trained in methods of scientific investigation and in the application of law to every problem of life. Such men are to be the engineers of the future, the builders of a new world.

Reference Maps More Accessible With New Numbering

Quarter Section Sheets of City Map of Portland Oregon, Numbered with Reference to Base Line and Meridian

By Orrin E. Stanley
Sewer Engineer, Portland, Ore.

PORTLAND has recently substituted a logical system of numbering the "quarter-section sheets" used as reference maps in the city offices, in place of the old and cumbersome manner of designating them, which apparently "just happened." By the new system, the city is divided into half-mile zones extending east and west, and the half-mile squares in these zones are numbered consecutively from west to east, a hundred numbers being assigned to each zone. The zones themselves are



NUMBERING ARRANGED IN ZONES WITH REFERENCE TO A MERIDIAN AND BASE LINE

numbered from north to south, their numbers being the first two figures of the sheet numbers, while the last two figures indicate the position of the quarter section with reference to a meridian.

By the old, discarded method a map of the city was divided into half-mile squares. Those of the top row were numbered from west to east, beginning with No. 6; the second row started at the east with No. 7; while the third row began at the west with 15, each row ending at the city boundary. In this manner sheet No. 172 was reached at the south edge of the city. Additional territory was annexed to the city from time to time, and the sheets showing these annexations received consecutive numbers, from 173 to 244, these higher numbers appearing at most unexpected places around the edge of the guide map. No copy of a law limiting the numbers used for this purpose to 244 can be found, but for some reason (or lack of reason) the use of figures stopped there, and additional sheets were designated by letters. The entire alphabet was used for this purpose, and by means of primes was used as far as T″ a second time through. Fortunately, the expedient of using Greek or Chinese characters does not seem to have occurred to the draftsman.

These sheets are arranged by consecutive numbers in book form for use in the various offices, and under the old arrangement much annoyance was experienced in trying to follow a street beyond the limits of one sheet. Several draftsmen in the city engineer's office felt that a reform was desirable and set about bringing order from chaos by giving the sheets numbers from which their relative position in the city might be readily determined.

The first plan suggested was to have 50 zones of 50 squares each; another proposed zones of 40 numbers each, a third plan called for the use of letters to designate the zones and numbers of one or two figures to indicate the position of the sheets with reference to a meridian. Each of these plans was fully discussed in the drafting room and finally got to the city engineer, but they were all rejected in favor of "hundred-number" zones.

For purposes of computing the haul of heavy materials such as sand, gravel, etc., the "official" center of the city is assumed to be the center of the drawspan of the Burnside St. bridge. The quarter-section sheet which shows this point near its center received the number 3030. This allows for the growth of the city to a point 15 miles to the north and the same distance to the west of this place without getting beyond the limits of the numbering scheme, and it was thought by those who discussed the matter that topographical conditions are such that a greater extension of the city in those directions is very improbable. The arrangement of numbering is shown on the accompanying map, with the intermediate numbers omitted. Sheets having 30 as the first two figures lie along the north side of the Willamette base line, and those having 30 for the last two figures lie along the west side of Union Avenue.

The entire city is mapped on these quarter-section sheets, the original scale being 100 ft. to 1 in. Blueprints or white prints on cloth are used in many of the city offices, and additional information—such as the location of houses, the house-numbering outline, the sewer system showing house branches, the water system with all connections, survey monuments with corrected measurements between them, street-grade elevations, curb distances, etc.—is drawn on them for use in the offices where such information is desirable.

Rectograph prints of the tracings, reduced to a smaller scale, are used in several of the offices where only such information as is shown on the original tracings is required.

This numbering scheme was worked out in the city engineer's drafting room some time ago by L. F. Schuele and the writer, but it was not made effective until the present city engineer, O. Laurgaard, ordered the necessary changes made on the drawings.

Engineers' Registration Act for Oregon Amended

The engineers' registration act for Oregon, discussed in *Engineering News-Record* of Mar. 27, 1919, p. 616, has been amended to include the insertion of a sentence which makes the Board of Engineering Examiners consist of two civil engineers, two mechanical engineers, one electrical engineer, two hydraulic engineers and two mining engineers

Reinforcement of Bridge by Means of an Eccentric Chord

Floor Span Over Railway Tracks Weakened by Corrosion — War Conditions Delay Renewal — Erection Conditions Necessitate Placing New Chord Above Floor—Panels Offset to Balance Eccentricity

A DIFFICULT problem was presented recently by the necessity of strengthening a steel bridge span in Chicago without infringing on the underclearance and without using falsework. It was solved by the ingenious expedient of adding a second bottom chord above the floor of the bridge, and, as this chord was far off center of the web connections, neutralizing the eccentricity moments at the connections by irregular alignment of the chord. At the same time the floor of the bridge was strengthened in effective manner by placing new hangers and by supplementing the steel stringers by wooden stringers.

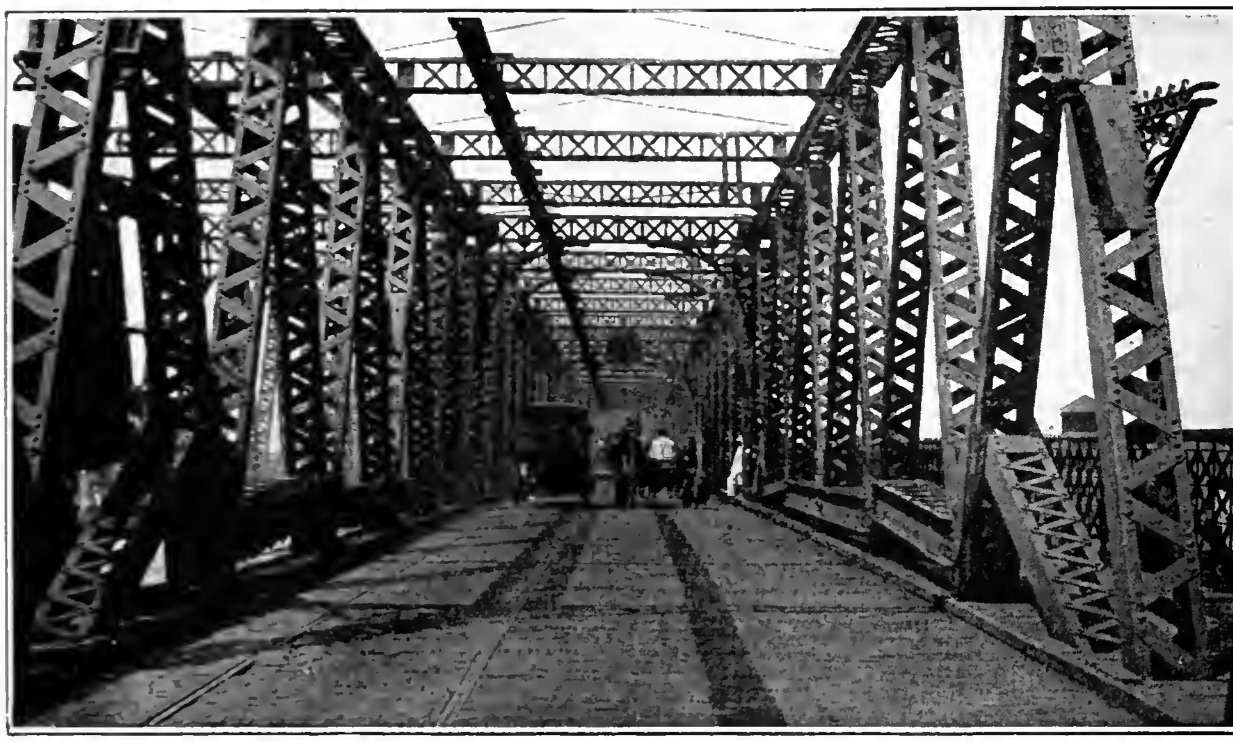


FIG. 1. SPAN OF TWELFTH STREET VIADUCT, CHICAGO, REINFORCED BY ADDING BOTTOM CHORDS ABOVE THE FLOOR

Twelfth St. crosses a group of important railway tracks by a viaduct 810 ft. long, composed chiefly of wrought-iron truss spans, built in 1886. In the course of time corrosion had destroyed large parts of the floor and bottom chord members exposed below the floor, and within the past four or five years replacement or repair had become an urgent matter. Designs for a larger and more substantial viaduct were prepared three years ago, and the expectation was that construction could be undertaken in 1917 or 1918. The state of the steel market, however, made it impossible to obtain material, and the work was postponed indefinitely.

On account of the great importance of the crossing with respect to street traffic, some method of reconstruction had to be devised to keep the structure in service, and the plan had to be such that the work could be done under traffic. Twelfth St. is the only thoroughfare across the tracks in a distance north and south of nearly a mile. It carries important vehicle traffic and a street-car line, so that closing the street during the repairs could not be considered. The railway traffic is equally important, and could not be interrupted.

The chief difficulty was presented by a through-truss span of 110 ft. 9 in., crossing a group of New York Central R.R. and Rock Island R.R. tracks, including the four main tracks of the New York Central R.R. The span has three trusses, the middle one separating eastbound and westbound roadways. The underclearance here is only 17 ft., so that no space was available for either staging or supports under the bridge. On account of the low clearance the blast action of the engine exhaust had been of particularly severe effect. The stringers and bottom chord for the entire length except the panel at either end were seriously weakened; the bottom chord, for example, had been reduced in section nearly one-half. Furthermore, some of the bars of the pin-connected lateral system had been cut in two. Corrosion had also been active, and the top flanges of the stringers were materially reduced in section. It was necessary to replace all these parts entire. The floor-beams, on the other hand, had not suffered greatly. In these circumstances the main problem was how to replace the bottom chord under the hampering space and traffic conditions. Replacement of the stringers offered less difficulty.

It was decided to leave the old bottom chord undisturbed and add a new chord just above the floor, 30 in. above the old one, carrying it down in the end panels to connect centrally at the end pins. As the web members intersect on the center line of the old chord they would be several feet apart at the level of the new chord, and thereby would develop very large rotational moments. To neutralize these moments the chord was offset in successive panels, as shown in the diagram elevation, Fig. 2.

Below the truss diagram in Fig. 2 is given the graphical stress polygon for full live load, from which it will be seen that the chord and web stresses are in equilibrium under this load condition. The inclination of the short chord sections between adjacent web members was worked out by analytical computation to produce this result, and the stress polygon is merely a check. The rotational tendency of the web stresses at each eccentric panel point is just balanced by the opposite rotational tendency of the tensile stresses in the bottom chord.

As detailed, the short sections of chord at the panel points are formed by large gusset plates, which make

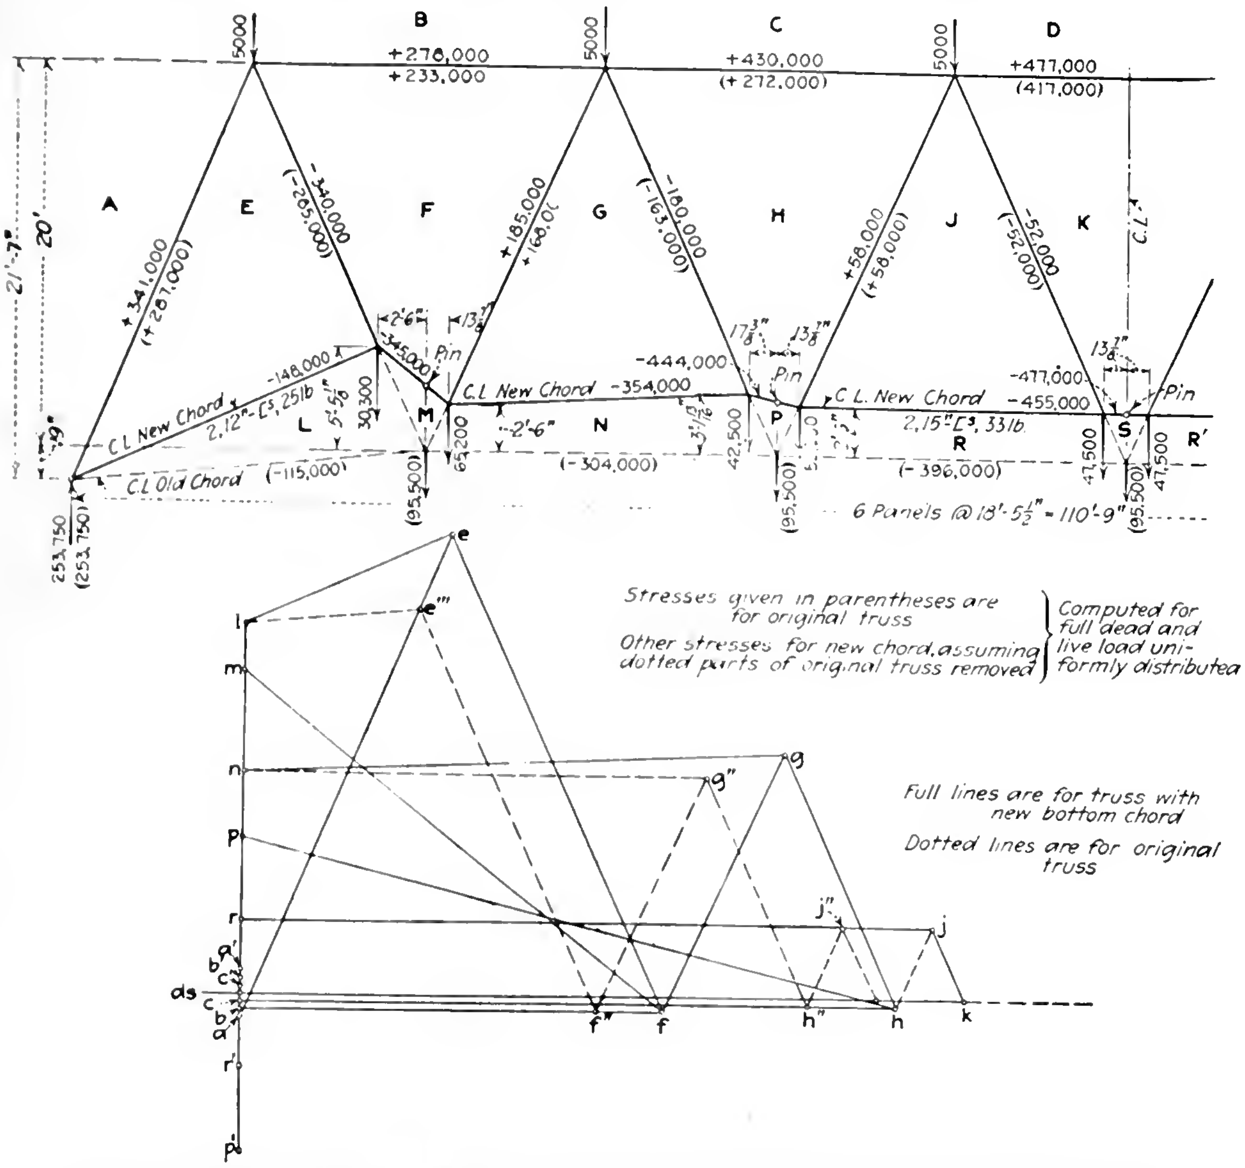

FIG. 2. TRUSS DIAGRAM AND FORCE POLYGON FOR REINFORCED TRUSS—CHORD ALIGNED SO AS TO NEUTRALIZE ECCENTRICITY MOMENT

the connection between the new chord and the old web members. The panel point, therefore, is a stiff assemblage, and the secondary stress moment occurring under partial live load are distributed equally to the members, without strain in the connection.

As the truss with the new chord (considering the old chord out of action) is shallower than before, the primary stresses in most of the truss members have been increased about 10% by the change; but as these members are in good condition the extra stress is not of serious consequence.

In strengthening the floor the main item was placing 9 x 18 timber stringers between adjacent steel stringers. The timbers were designed to carry the full floor load without assistance from the old stringers. A special stirrup support was designed for carrying them, consisting of two 3 x ½-in. steel bars passing over oak saddles on top of the floor-beam and engaging anchorage angles under the new and old stringers, all as shown by a detail in Fig. 4, which is shown on the following page.

At each truss panel point the gusset plates of the new chord carry a 4-in. pin on which are hung two U-rods (Fig. 4). The lower threaded ends of these rods carry bearing plates on which the old floor-beams are seated; stiffener angles riveted to the ends of the beams engage the rods in such a way as to prevent lateral movement.

In carrying out the work, the first step was to reinforce one of the outer trusses, street traffic being diverted to the other roadway to give working room. The reinforcement of the other outer truss was the second step. The middle truss then had to be reinforced while both roadways were in service. Throughout the whole operation the street-car service on both roadways was maintained.

With the trusses reinforced, it was an easy matter to place the floor-beam hangers, then the new timber stringers and their stirrup connections. This work was done first on one roadway, then on the other, vehicle traffic being diverted to a single roadway. The weakened or severed bottom laterals were not replaced, as the structure was believed to be stiff enough to require no lateral system.

Under the contract with the city, requiring that repairs to the viaduct be made by the railway whose tracks are crossed, the work was paid for by the New York Central Lines West and the Rock Island Lines, at a total cost of about $11,000. The planning and execution of the work, however, were in the hands of the New York Central R.R. B. R. Leffler, bridge engineer, New York Central R.R. West of Buffalo, worked out the scheme of reinforcement, and decided upon the use of a secondary chord. The idea of offsetting

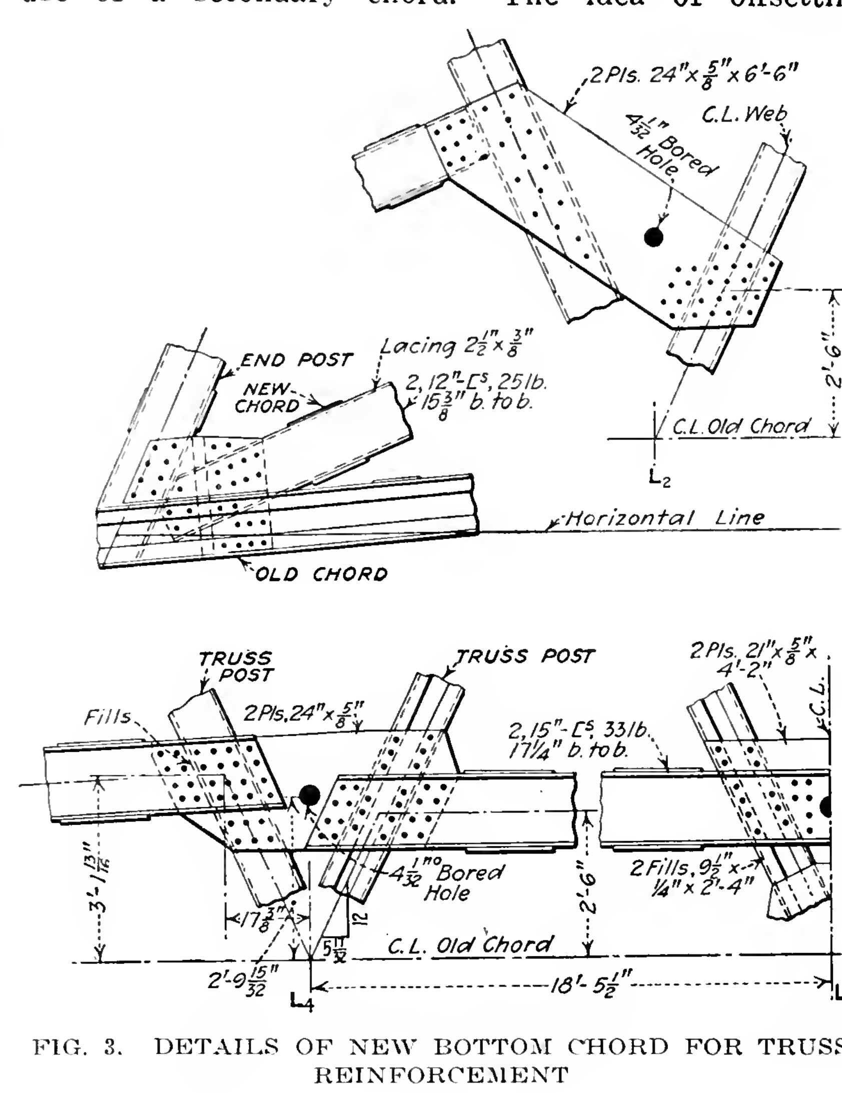

FIG. 3. DETAILS OF NEW BOTTOM CHORD FOR TRUSS REINFORCEMENT

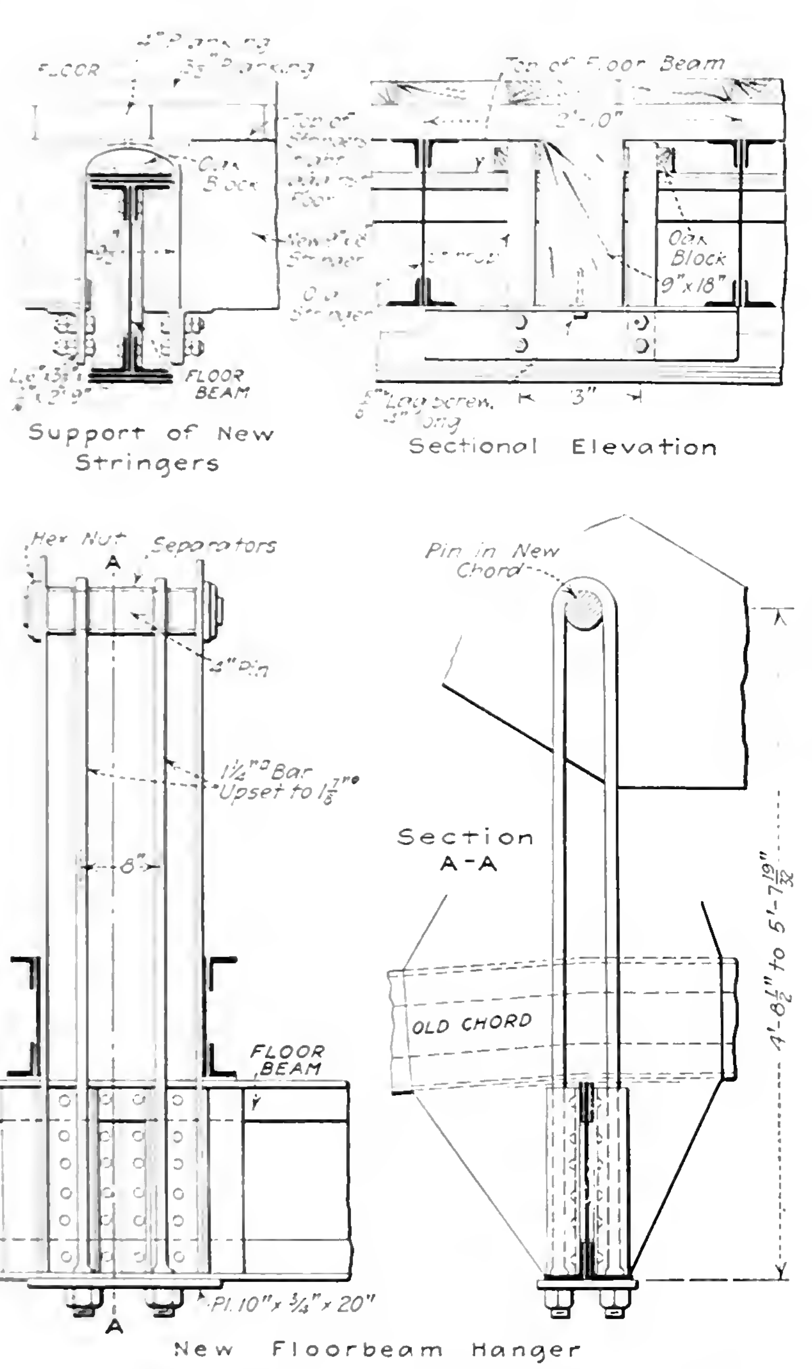

FIG. 4. FLOOR-BEAM HANGER AND STRINGER STIRRUP

the chord in such a way as to neutralize the rotational moments at the joints was developed by H. Grytness, chief draftsman in Mr. Leffler's office. The reinforcement work was carried out by the Strobel Steel Construction Company, of Chicago, on a force-account basis.

Patch Worn Paving with Concrete

Concrete patching for cuts and wornout places in brick, asphalt, concrete and other paving is being used extensively at Terre Haute, Ind. It was adopted on account of low cost, and is said to be entirely satisfactory.

The worn spot of the pavement is first cleaned out to the base of the original pavement, all dirt being removed, and then a thin layer of cement grout is sprinkled on and worked with a brush or broom till it covers the bottom and sides of the hole, which is then filled with concrete.

The most important part of the operation, according to John W. White, secretary of the board of public works, is to have proper concrete. This should be a 1:2:3 mix, using washed material with coarse aggregate ranging from ¼ to ¾ in. The surface is finished with a wood float ½ in. above grade to allow for shrinkage in setting, and traffic is kept off for several days. Large and small patches are made, there being no limit as to size.

Drainage System for Improved Country Highways

Tile Underdrainage Would Protect the Surface, Decrease the Cost of Roadside Maintenance, and Remove Dangerous Ditches

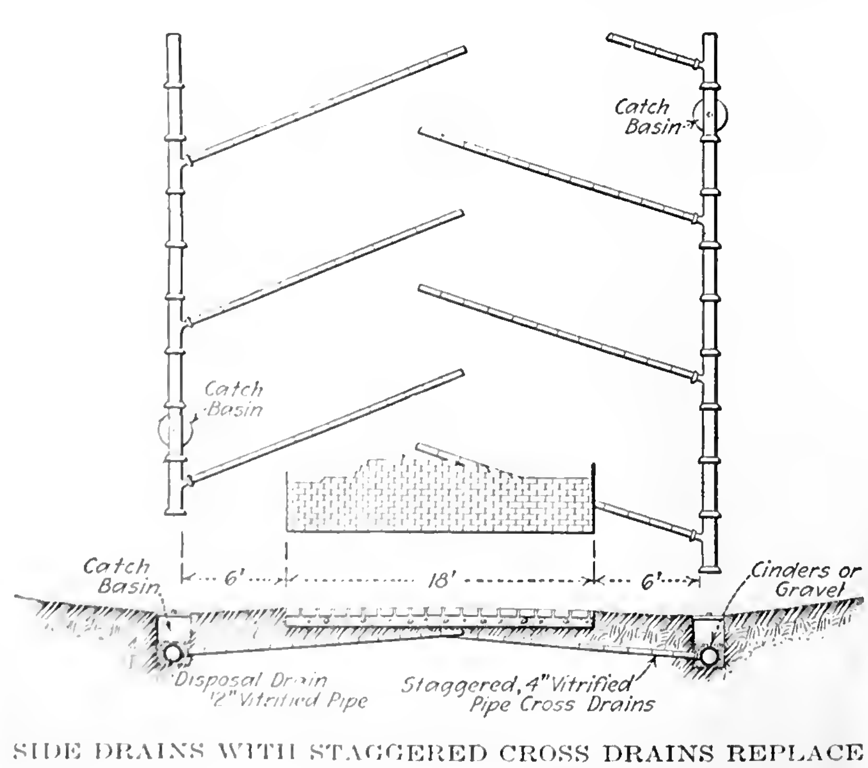
By Will P. Blair
Vice-President, National Paving Brick Manufacturers' Association, Cleveland, Ohio

ADEQUATE drainage systems consisting of tile underdrain should supplant the obsolete ditch for improved country highways. If this were done the road would not only be better drained, but, by the elimination of the unevenness of the right-of-way, keeping it in good condition would be easier, thus saving a large portion of the expense of roadside maintenance, which often costs more than maintenance of the wearing surface. Aside from protection of the wearing course by more effective drainage and greater economy in maintenance, the danger from deep side ditches would be removed—to the great advantage of traffic.

The need for proper drainage continually confronts the engineer when designing and planning a road improvement, but it is as constantly ignored. In fact, drainage neglect is so common a fault that the most illuminating examples fail to impress deeply. We have echoed and preached in meetings and at conferences its necessity. Reference to the subject so often made has put it into a trite class, so that its consideration has merely followed a rut, rather than receiving any really constructive treatment. It has not been made the subject of research or experiment, or of serious thought.

The most common road-drainage design is to provide open gutters or ditches at the roadside. City streets are seldom underdrained at all. The practice has scarcely been called in question. Water-disposal pipes are frequently placed underneath and lengthwise of the roadbed, resulting in injury to the road. The use of open side ditches may almost be regarded as a universal practice. For what reason? They do not drain.

Can the function intended be provided for by a different plan? I believe so. Not that it might be universally employed, but always wherever other means are less efficient. The plan is shown by the sketch diagram and cross-section. The side disposal drains are



SIDE DRAINS WITH STAGGERED CROSS DRAINS REPLACE DEEP SIDE DITCHES

placed below the frost line where water can flow continuously, unhindered by either ice or dirt accumulation. The side drains should also be placed at such depth that the lateral drains will receive sufficient fall, so that the subgrade can be freed promptly from excessive moisture, thus insuring against damage by heaving due to freezing. Where the road surface is impervious an entirely dry base can be maintained. The entire right-of-way can be graded, providing only for a gentle flow of the surface water into occasional catchbasins located at proper intervals. The sides can then be mowed and cleaned at the least possible expense.

Comparing this condition with the open ditches, the latter require constant attention to keep them from clogging up and retarding the flow of water. Instead of real drainage, we usually have a system of frog ponds—reservoirs which feed the moisture by capillary attraction into the roadbed—resulting in more or less but constant injury to and ofttimes destruction of the wearing surface.

While the fact that the cost of maintaining the berms and embankments imposed by the open ditches is often greater than the cost of maintaining the wearing surface has been perfectly apparent to experienced observers, actual data have but recently become available for its confirmation.

In Illinois, 59 miles of improved brick road surface cost $5.36 per mile to maintain. The shoulders of the same road cost $51.20 per mile. Maintaining the surface of other roads was found to cost $30.25 per mile, while their shoulders cost $51.20 per mile.

In Ohio, 302 miles of brick road surface cost $10,351.99 to maintain. The roadsides of the same mileage cost $27,183.53. Other road surfaces covering 381 miles cost $39,825.17 and the roadsides cost $52,522.78.

Underground Drains Easy to Maintain

It is known from experience that underground disposal drains are maintained in constant working order with scarcely any cost whatever for an indefinite number of years. The cost of installation in many instances is less than that of the open ditch. Cost of drainage is often made the reason against its installation, yet a single case, to which Fred R. Williams, paving engineer, of Cleveland, will bear testimony, demonstrates the unsoundness of the excuse.

The case in point came about in the construction of Woodhill Road in Cleveland. The specifications provided the drainage plan herein advocated. In spite of frequent rains, the installation of the drainage system enabled the contractor to proceed with his work of laying the pavement. Other street contracts held by the same contractor, but not calling for such drainage, were held up, awaiting a sun-dried condition. The lesson of economy was so plain that the contractor, without other compensation than that of being able to proceed with his work, installed this very system as a matter of construction economy.

Aside from the economy in construction, durability of the road and the great reduction in maintenance cost due to establishing a drainage system that will drain, we must be alert to the fact that open ditches on the roadside are often a menace to life. In case of fatal accidents there is but little difference in results whether your team or auto goes into the ditch, down the mountainside or over a precipice.

But a greater reason than all else in support of drainage which wiii drain is the increased durability which it adds to the life of the pavement, thereby lessening maintenance cost and increasing efficiency and satisfaction in use.

Kentucky Sump Holes Materially Reduce Flood Flows

By R. W. Spear
Chicago

Underground conditions in Kentucky on the site of the water-supply for Camp Henry Knox, a field-artillery firing center located at Stithton, are such that the flood flows are as much as 40% less than the calculated maximum. This is due to sump hole areas, common in Kentucky, which are connected with caverns in the soluble limestone and afford temporary storage.

Otter Creek empties into the Ohio River about 30 miles downstream from Louisville. The drainage area above a proposed dam is 150 square miles. From 25 to 50% of this area is composed of sump holes, which are so deep that even in prolonged rainy seasons they have no surface outlet. The location of the outlets is generally unknown; but the writer learned during the course of his study that a particular sump hole was the source of Big Springs, outside the Otter Creek drainage basin about five miles from the sump hole. This fact was established in a crude but efficient way by farmers who poured corn cobs in the sump hole and later observed them coming out at the Big Springs.

It is probable that some water is carried into and some outside of the drainage basin, through these channels. By comparing the Otter Creek watershed with others having similar shapes and sizes and having approximately the same character of rainstorms both in intensity and duration, it was found that the probable maximum run-off at the dam would be 19,000 cu.ft. per second. By calculations made from high-water marks, a maximum flood of 11,000 cu.ft. per second was obtained.

Reason for Discrepancy

In the writer's opinion, the entire discrepancy in the above figures cannot be attributed to the mere possibility that more water is carried out of than into the watershed by the outlet of the various sump holes. The major portion of this discrepancy must be attributed to the fact that a very considerable portion of the total rainfall finally reaches the channels of Otter Creek and its feeders through the sump-hole channels—a route that is much slower than the surface drainage routes. The distance from sump hole to creek is often as much as five miles, and the water in passing through the underground channel has such a sluggish flow that the sump holes empty themselves only at a considerable period of time after the cessation of a storm. In many instances this underground flow is so slow that the sump holes become ponds.

Geologically, a sump hole is a tumbled-in cavern formed originally in a porous stratum near the surface. These sump holes and caves hold back that portion of the storm water which would contribute to the peak load stream flow, until after the surface drainage has reached the streams and passed on.

Reorganization of the Engineering Standards Committee

Effect of Engineering Standards Movement on Technical Societies—Reorganization to Give Broader Representation—Association May Be Formed to Elect the Committee—Formulating Safety Codes

BY EDWARD B. ROSA
Chief Physicist, Bureau of Standards, Washington, D. C.

(Concluded from "Engineering News-Record" of May 1, 1919, page 862)

Opening to discussion the vitally important subject of centralized standardization, the first part of Dr. Rosa's article asserted that existing technical societies will not be harmed, that the movement is founded on principles of fair play, and that a coördinating agency is needed in standardization. After telling why reorganization on a democratic basis became necessary, he undertook to sketch one idea of the possible ultimate form of organization. Continuing this subject, Dr. Rosa proceeds to point out why the Bureau of Standards and other Government agencies are concerned in the movement.—EDITOR.

DIVISION 6 would consist of the American Society for Testing Materials and a considerable number of national associations concerned with materials. The American Society for Testing Materials would be the leading society in the division, and would carry on its work substantially as now. It would be in close association with the other societies of its division, with lines of connection with other divisions through members of its coöperating committees. This division would contain representatives of many other societies besides the American Society for Testing Materials, but probably most of them would also be members of the American Society for Testing Materials. Division 6 would, in fact, be an American Society for Testing Materials family, as Division 1 would be an electrical family in which the American Institute of Electrical Engineers would naturally take the lead. Similarly, the American Society of Mechanical Engineers, the American Society of Civil Engineers, the American Institute of Mines and Metallurgy, the American Chemical Society, the Society of Automotive Engineers, the American Railroad Association and other large societies and associations would presumably take a leading position in their respective divisions. The influence of these leading societies and the recognition accorded them would be enhanced by this relation.

SCOPE OF ACTIVITIES

Most of the business of the Standards Committee would probably be done by an executive committee and the paid general secretary and assistant secretaries acting under it. The various sections of the Standards Committee would be advisers to the executive committee on matters pertaining to their respective subjects. The Standards Committee would report annually to the American Engineering Standards Association, which, as a great self-determining national body, would authorize changes of procedure, provide for the selection of the Standards Committee and approve its budget and plans. Such an organization would be businesslike and effective, and as simple as that of any large national organization. The office staff should include some competent editors and draftsmen to assist in putting standards into good form for publication, in as uniform style as possible.

It would be desirable for the association to publish all standards prepared under its supervision in a uniform edition, fully indexed, and thereby make them readily available at small expense to the general public. In connection with such publication, they would be carefully studied to see whether there were conflicts or inconsistencies among them, and useful references would be made from one code or standard to another. Such publication in uniform style, with explanatory footnotes and cross-references, would be of enormous value. It would be the greatest step ever taken toward general acceptance and national uniformity in engineering and industrial standards. This would, of course, not interfere with the publication by each society of its own work in its "Proceedings."

BUDGET OF THE COMMITTEE

The American Engineering Standards Association should have an annual income of not less than $50,000, in addition to the cost of publishing standards, which work would be self-supporting. This income would be derived from a large number of memberships in the association. These memberships would not be personal, but every member would represent some engineering or industrial organization or Government department. If one member were appointed for every 500 members of an engineering society, and a membership fee of $50 were paid, this would amount to 10c. per year per member of such society, and would not be a heavy tax for so important a matter. It would yield $1000 (with 20 members appointed to the association) from a society of 10,000 members, and would give $50,000 per year when the association had 1000 members. As yet, however, no provision has been made for a large membership, and this proposal is only a suggestion for future consideration.

WHY THE BUREAU OF STANDARDS IS INTERESTED

The Bureau of Standards has been greatly interested in the plans of the Engineering Standards Committee from the start, and hoped to see them realized at an early date. The reasons for this were, first, that the committee would be able to render a service of tremendous importance in promoting engineering and industrial standardization, and, second, that it would aid the bureau in getting into closer contact with engineering and industrial organizations and secure a better understanding of the bureau's work. It is impossible for the bureau to explain its work and its plans in detail to every agency that is interested. Although bureau representatives do a large amount of traveling and participate in a large number of conferences and committee meetings, and although the bureau has a large number

of coöperating committees assisting in its work, it is beyond its power to consult everyone who thinks he ought to be consulted in advance of taking up work, or to communicate results from time to time to everyone interested.

We have earnestly wished for years that there was some agency or mechanism that would provide a better connection than has existed between the bureau's research and standardization work and that of the engineering societies and industrial organizations. It appeared that the Engineering Standards Committee, especially if reorganized as proposed so as to be democractic and thoroughly representative and supported by a strong public sentiment, afforded an ideal method of coöperation between the agencies of Federal, state and municipal Government and the technical and commercial organizations concerned with engineering and industrial standards.

Neither the Bureau of Standards nor any other Government department was concerned in the organization of the Engineering Standards Committee, except that the bureau was consulted occasionally, and promised its support when the proper time should come. The bureau has recently been drawn into the discussion in connection with the proposed reorganization of the committee, and believes that the present plans are wisely drawn and deserve general support. The bureau offers its full coöperation in establishing and carrying on the work of the association, and invites the coöperation of the Engineering Standards Committee in return.

Why the Government Is Interested

There has not yet been opportunity for discussion by all departments of the Government of the new plans of the Engineering Standards Committee. It is easy to see, however, why the Federal Government should participate in the formation of an American Engineering Standards Association, within which there is to be an able and representative Standards Committee on which the Government departments will be represented and which will aid in securing the coöperation that is essential in the preparation of standards and specifications. The departments will, of course, be free to act independently of the committee when they see fit, just as any society may do, as there will be no compulsion exercised. But the advantages of coöperation are so great that the committee will without doubt be utilized to the full, and important and far-reaching results in the direction of better and more uniform specifications, leading to economy and simplification in buying, may be expected.

The war has taught many lessons, not the least being the feasibility and advantage of producers coöperating with and helping the Government. Another lesson is that standardization and simplification of sizes and styles are practicable, and go far in the direction of reducing costs and investment in stock. When one thinks of the immense opportunity for improvement in these respects in all the purchases by Federal, state and municipal Governments, and the equally great influence such standardization will have on business generally, it is hard to refrain from extravagant language as to the duty of the hour and the obligation resting upon those in authority to act promptly in this matter.

Some months ago the Bureau of Standards outlined a plan for the preparation of a series of national industrial safety codes. They were intended to meet the needs of a very large number of industries, and to be suitable for adoption by the state accident and industrial commissions. It was planned to secure in the preparation of these codes the active coöperation of engineering and industrial associations, manufacturers, engineers of state and municipal agencies, inspectors, etc. A large and representative committee would be formed to advise the bureau as to the general plans, and many small working committees to assist in the preparation of the various codes, of which there would be fifty or more.

A conference of representatives of all the interests concerned, to discuss the question and to advise with respect to plans for the work, assembled in Washington on Jan. 15. The bureau did not feel warranted in assuming the leadership in so large an undertaking without the strong support and promise of coöperation of the various interests concerned; and it wished to have approval in advance of its plans for securing this coöperation, if the work were to be undertaken. The bureau had frequently been requested to take it up. There was no doubt that the work ought to be done. Industrial accidents to the number of 750,000 each year (not counting the railroads and other industries outside the range of the proposed codes), including perhaps 20,000 fatalities, and millions of dollars paid annually in compensations for accidents, constituted a powerful argument for action.

The questions put to the conference were, "Should the Bureau of Standards take the lead?" and, "Should the work be done under the auspices of the recently created Engineering Standards Committee?" (which, however, was not yet functioning). This brought up the question of whether this committee was sufficiently representative to serve in such capacity, and after a discussion within the committee and between it and a limited number of representatives of other interests, which discussion has continued for three months, the committee has prepared for recommendation to the five founder societies a revision of its constitution which provides for a broadening of its membership and functions and a change of name to the American Engineering Standards Association.

A Referendum on the Question

The Washington conference of Jan. 15 appointed a committee of three (of which the chairman of the Engineering Standards Committee was one) to prepare a report of the conference to be sent to all the engineering, industrial and Governmental bodies represented and to ask for a written reply to the above questions, on which no vote was taken at the conference. This report was held up at the request of the chairman of the Engineering Standards Committee, pending the result of its discussion on the question of reorganization. It has recently been sent out, with a brief statement of the proposed plan of reorganization and a recommendation by the bureau that the work of creating industrial safety codes be carried on under the auspices of the reorganized committee.

No Conflict of Interest

The chairman of the American Engineering Standards Committee, Prof. Comfort A. Adams, now president of the American Institute of Electrical Engineers, with whom I have worked in full accord on the committee

of three, sailed a few days ago for Europe. The third member of the committee, H. W. Forster, representing at the Washington conference the National Fire Protection Association and the National Safety Council, is now in the West. It therefore seems to devolve upon me to give a brief account of the events that led to the proposed reorganization of the American Engineering Standards Committee, in order that the referendum vote of the Bureau of Standards may not be prejudiced by published articles based upon what I believe is a serious misapprehension of the situation.

The matter is of great and far-reaching importance, and there is no need for haste in coming to a conclusion. Full and sympathetic consideration should be given to the question. If anyone doubts the wisdom of the proposed plan, he should attempt to formulate a better one for accomplishing the end in view. Fortunately, there is no conflict of interest to confuse the issue. Everyone desires to see engineering and industrial standardization promoted. Everyone desires to see a large degree of coöperation in such work among the various societies and between such societies and Governmental agencies. Everyone wishes to see fair play, with the recognition of the rights of all, and to discourage the spirit of autocracy either in engineering societies or in Government departments. Since we are in full accord as to all the ends in view, it is only a question of method; and when the circumstances are understood alike by all, it is believed that full agreement will readily be reached.

The American colonies found grave difficulties when they combined as a nation because they had to surrender some of their independence. Engineering societies cannot coöperate systematically without recognizing each other's rights and therefore surrendering some of their own independence. But they cannot exercise their functions independently, in the absence of such coöperation, without frequent conflicts and duplication of effort. We must choose between conflict and coöperation. The members of the American Engineering Standards Committee have recognized the logic of the situation, and have proposed a wise and generous action.

They have outlined a plan, for presentation to the founder societies, whereby the present organization can proceed with business at once but take in new organizations as they apply and qualify (when the constitution is amended), and, when the membership has increased sufficiently to justify it, divide up into divisions and create a smaller Standards Committee with a central executive committee. It will thus gradually become the great national body it should be.

Neurasthenia a Growing Disease in Engineering Work

May Be Caused by Accident, Overwork, Grinding Routine or Outside Worries—Expert Care Imperative

By Chesla C. Sherlock

Des Moines, Iowa; formerly Secretary of the Iowa Industrial Commission, Workmen's Compensation Service

NEURASTHENIA is a disease which is becoming more and more common in the civil engineering field. It is already grounded in contracting work and seems to be gaining a foothold in the structural iron and steel trades. This fact is causing large employers, as well as those engaged in administering the workmen's compensation acts, to demand more of a knowledge of this unusual disorder.

Neurasthenia means "nerve weakness." In medical terms, it is "a condition of nervous debility supposed to be dependent upon impairment in the functions of the spinal cord."

Some think malingering is due to a neurasthenic condition and others consider malingering and neurasthenia as the same thing. Malingering is not necessarily dependent upon the state of the nerves. In fact, the malingerer is generally a fraud. He knows that he is able to do an honest day's work, but he prefers to loaf while making others believe that he is incapacitated. While we have a plain case of deception and fraud in malingering, the sufferer from neurasthenia is so impaired in his nerve forces that he honestly believes that he is incapacitated and unable to resume his employment.

Viewed from the exterior, the two conditions may at times appear to be identical. Without the aid of medical science we probably would have no means of discriminating between the two. A clever malingerer is worse than a neurasthenic; he may prolong his fancied condition for an indefinite period, while the neurasthenic may become himself at any time and return to work.

Neurasthenia may be caused, in an industrial sense, by a number of conditions. I venture the suggestion that "shell shock," as it is known in the trenches, is closely allied to certain conditions arising in industrial employment which might be characterized as "industrial shock." The latter we have called neurasthenia in the past. It may be caused by overwork, too much of a "grind" which exhausts the nerve forces of the worker, rendering him nervous, sensitive, high-strung and an easy prey to mental ills. However, it is accidents and injuries that more often lead the individual of weak nerve force to neurasthenia. Then, again, it may develop from sources entirely outside the employment, such as domestic worries or financial distress. One authority states that it is the result of "misplaced imagination."

Employers should treat the neurasthenic with consideration and not be too ready to class him as a malingerer. Oftentimes the charge that "there is nothing wrong with you" has caused the neurasthenic to suffer greater mental and physical distress than was warranted.

It seems that the neurasthenic condition can arise from all manner of injuries which a workman may commonly receive in normal industrial employment. One man slipped under a heavy load; another lost a hand, still another wrenched his back, and another received a blow on the head which caused him to have ringing sensations in his head for several months. Only experts should be allowed to handle such cases. As neurasthenia is a nerve disorder, it may extend over a period of several years and absolutely incapacitate a man from carrying on his trade. During that time he is subjected to a diseased mind and disordered nerves, rather than to physical disability. He is, none the less, incapable of work.

Neurasthenia is as interesting, as dangerous and as powerful as "shell shock"—and as pitiable. Both cause losses that are unavoidable and both can be corrected if taken in time.

Reinforced-Concrete Culverts Under Irrigation Canal

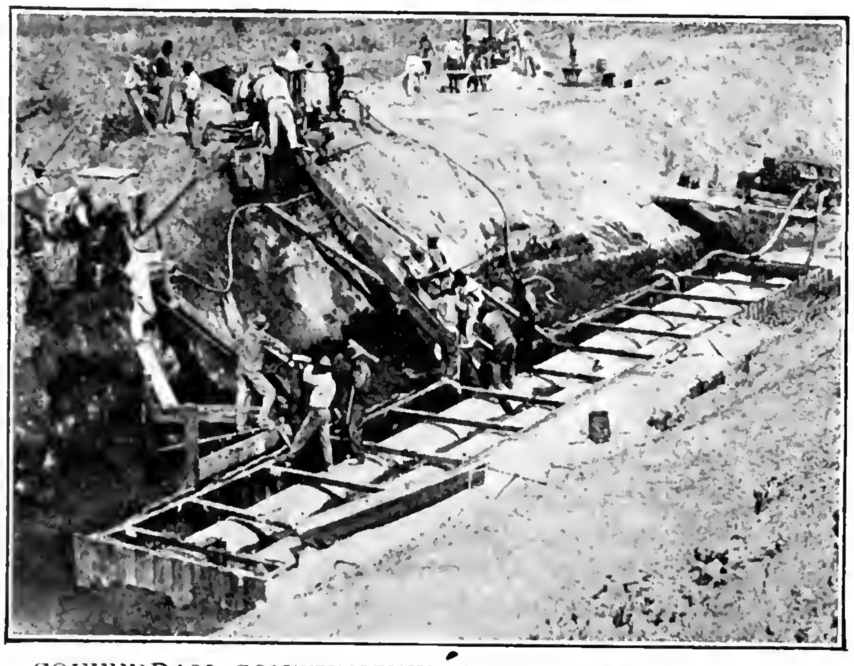
After Many Experiments Engineers on Rio Grande Project Adopt Cradle Construction for Drains in Quicksand

By D. C. Willett
El Paso, Tex.

After much experimentation and many failures in the construction of drains under irrigation canals, there has been developed a type of reinforced-concrete culvert, for use in sandy soil, which is proving satisfactory.

This design has been developed by the engineers of the Rio Grande project in New Mexico and Texas, a special timber cradle being used in connection with the construction of the pipe. A standard drawing has been adopted, as reproduced here, the variable dimensions being lettered and tabulated on each sheet for use in the field.

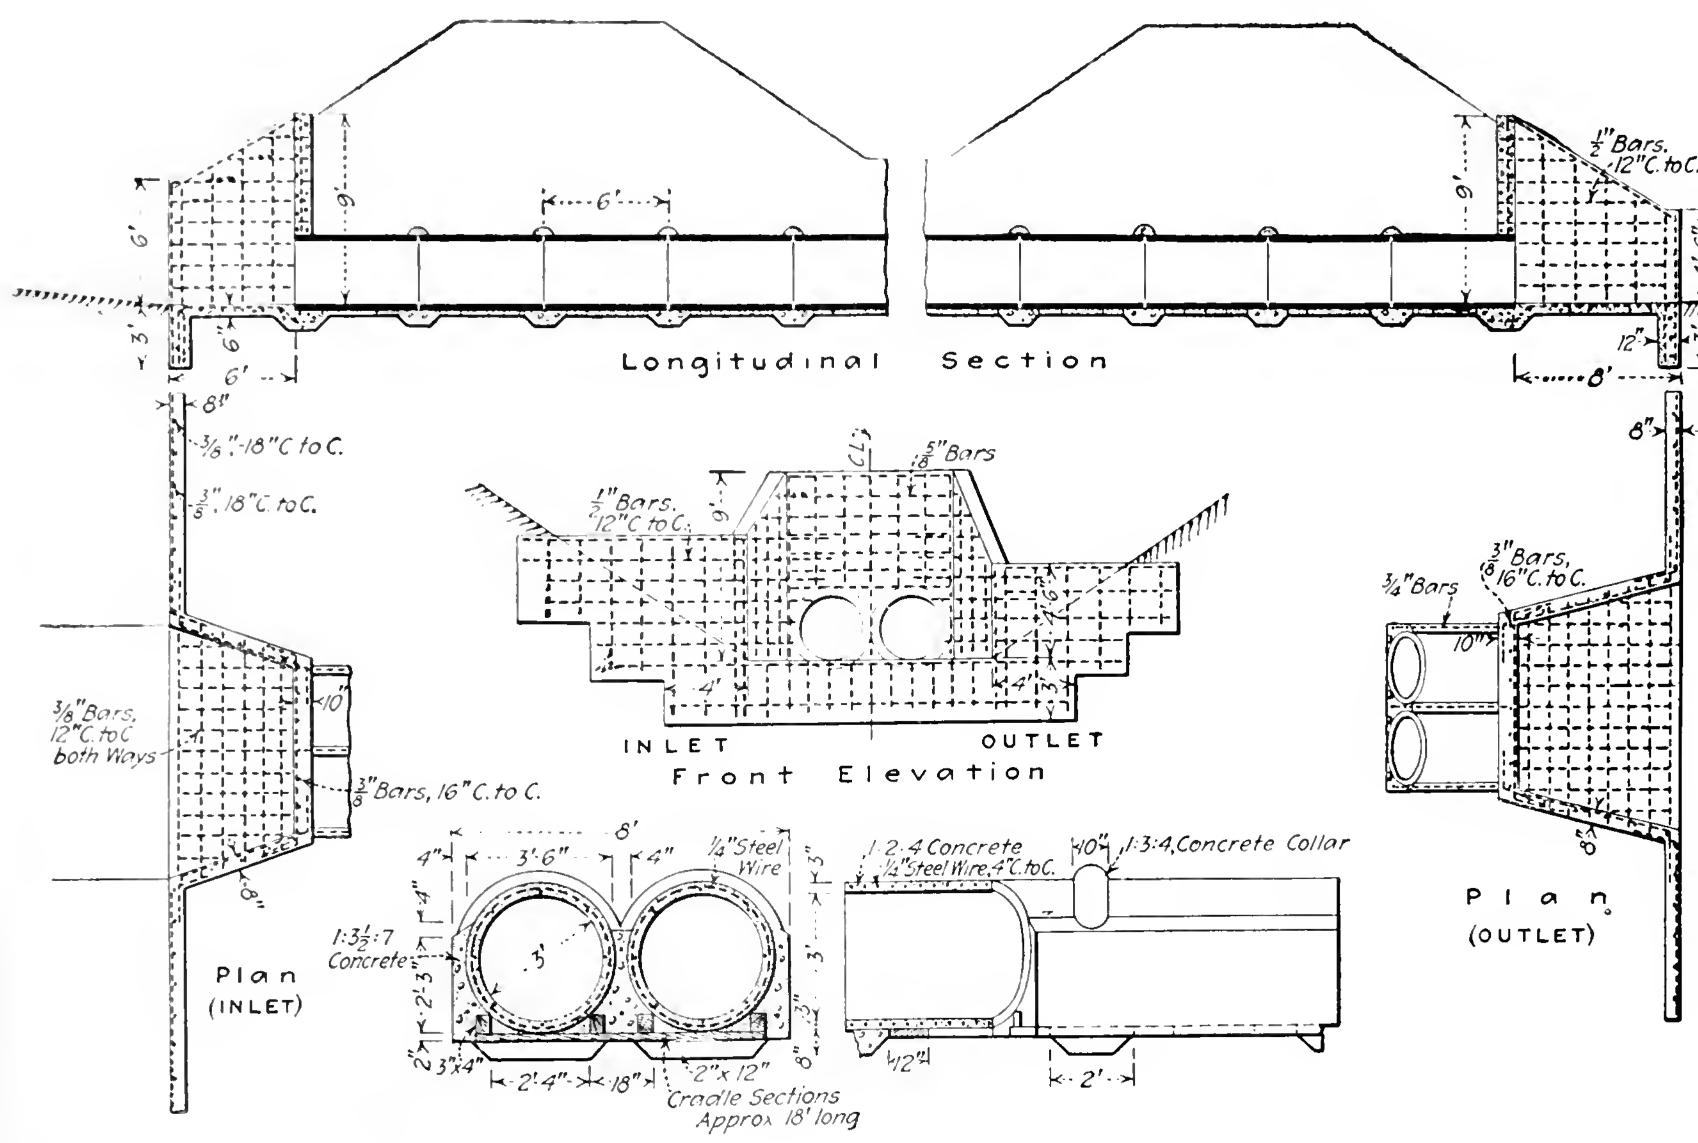
After the timber cradle is laid, to hold the pipe in place, the precast reinforced-concrete pipe are laid by the use of a dragline. A cofferdam is then built, as illustrated in the photograph, with space on one side for the passage of the water from the drain. A small centrifugal pump is set up in a convenient position to pump out the cofferdam and keep it clear of water while the 1 : 3½ : 7 concrete is poured around the pipe. Hand-molded concrete collars, 6 ft. apart, as shown, are added for stiffening the pipe and to prevent leakage of water from the canal above. The concrete used in these collars is a 1 : 3 : 4 mix.



COFFERDAM CONSTRUCTED TO ALLOW PLACEMENT OF SUPPORTING CONCRETE

It will be noted from the dimensions of the inlet and the outlet that the latter is designed 18 in. lower than the former, but the thickness of the walls and the spacing of the reinforcing steel are the same at each end.

The picture shows the Franklin drain at Franklin canal crossing, which was 72 ft. long, with an inlet 6 ft. wide and an outlet 8 ft. wide, the wing walls being 12 ft. long. The total cost was approximately $2800, complete.



DETAILS OF REINFORCED-CONCRETE CULVERTS DESIGNED FOR QUICKSAND FOUNDATION ON RIO GRANDE PROJECT, NEW MEXICO AND TEXAS

Computation of the Time Required To Fill a Graving Dock

Based on the Method of Filling From an Upper Orifice as Well as From Usual Gate Openings at Bottom of Dock

By Eugene E. Halmos
Designing Engineer, Barclay, Parsons & Klapp, 60 Wall St., New York City

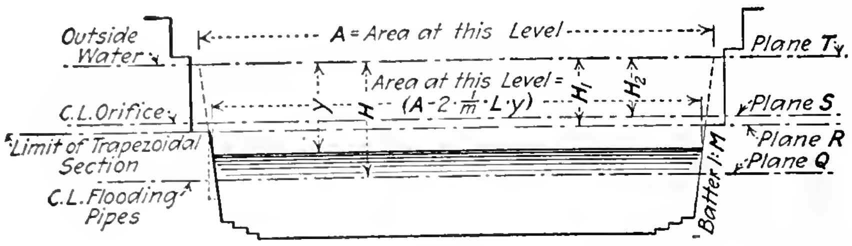
For the purpose of filling a graving dock it is customary to provide a series of flooding pipes located near the bottom of and passing through the caisson gate which closes the entrance of the dock. The pipes are equipped with gate valves which are operated from the deck of the caisson. The number and size of these pipes, however, are limited by stability and structural considerations, and if they are the only means for flooding the dock, the filling of the uppermost few feet, as a rule, takes a very considerable time, due to the constantly decreasing head and the increasing area of the dock.

As time is a very valuable element in the operation of dry docks, it is good practice to install an additional opening in the side wall of the dock, located as high as tidal conditions permit and connected with the outside water by means of a culvert. The top of the orifice should be at least two feet below low tide. The filling of the dock is then performed in the following manner: After the keel blocks are properly placed in the empty dock, first only two or three valves are opened in the gate so as to avoid damage to or displacement of the keel blocks due to the inrush of water. When the water reaches a depth of about 3 ft. on the floor, all pipes are opened in the gate. When the water is up about 5 or 6 ft. above the floor a sufficient cushion is created to dissipate the energy of the water falling from the side orifice, and this is opened and kept open, together with all the pipes, until the dock is filled.

Dock Emptied in Three Stages

Until the water inside the dock has reached the elevation of the pipes, the computation of the time lapsing in filling the dock is a very simple matter, both the pipes and the orifice in the sidewall discharging water under constant head. The discharge per second can be readily determined if the proper coefficients are applied. The volume of the dock at any elevation being known, the quotient of the volume and the rate of discharge will give the number of seconds required to fill the dock to the elevation of the flooding pipes or to any intermediate depth. From this elevation on, however, the determination of the time for filling the dock to any greater depth becomes difficult, because the pipes will discharge under a varying head while the orifice still discharges under a constant head. Moreover, the sides of the dock being, as a rule, carried up on a batter, the horizontal sectional area of the dock is also changing from elevation to elevation. The writer has not found, in textbooks on hydraulics, formulas applicable to these conditions, and therefore believes that his method of computation, hereinafter shown, will be of interest, as this problem is met in practically every case of dry-dock design.

In plan, a graving dock is a long rectangle, finished by a tapering or rounded head. By transformation of areas the equivalent length of a dock of the same volume, possessing the normal cross-section throughout, can be easily found with sufficient accuracy. The accompanying figure shows a cross-section typical of masonry graving docks. It can be seen that the determination of the time necessary to fill the dock, from the elevation of the pipes (Plane Q) to the level of the outside water, will have to be done in three steps. Between planes Q and R the pipes discharge under variable head, the discharge of the orifice is constant, and



CROSS-SECTION OF GRAVING DOCK SHOWING DIMENSIONS USED IN FILLING COMPUTATIONS

the horizontal area of the dock is changing. Between planes R and S the conditions of discharge are the same as before, but the horizontal area of the dock is constant. Between planes S and T both the pipes and the orifice are subjected to the same variable head and the horizontal area of the dock remains constant.

Step No. 1. Filling time between planes Q and R. Let

L = The transformed length of the dock with uniform cross-section.

A = The horizontal area of the dock at the level of the outside water, obtained by producing the batter (1 on m) of the sides of this elevation.

Σa = The cross-sectional area of all flooding pipes.

K = The discharge coefficient of the pipes.

b = The area of the orifice in the sidewall.

K_1 = The discharge coefficient of the orifice.

H = The initial head on the pipes.

H_1 = The head on the pipes when the water in the dock is at plane R.

H_2 = The initial head on the orifice and the head on the pipes when the water in the dock is at plane S.

C = The constant discharge of the orifice under head H_2, being $= K_1 b\sqrt{2gH_2}$ volume units per second.

y = The distance of the inside water level from the outside water plane at any instant.

t = The time required to fill the dock between any value of y to any other value (between H and H_1).

The horizontal area of the dock at any depth y below the headwater is expressed by

$$A_y = A - 2Ly/m \tag{1}$$

The discharge of the pipes and the orifice during an infinitely small time element will produce an infinitely small increment in the height of the water inside the dock, the volume of discharge and the volume of the increment being equal.

Thus:

$$(K\Sigma a\sqrt{2g}\,y^{1/2} + C)dt = (A - 2Ly/m)dy \tag{2}$$

$$dt = \frac{Ady}{K\Sigma a\sqrt{2g}\,y^{1/2} + C} - \frac{2Lydy/m}{K\Sigma a\sqrt{2g}\,y^{1/2} + C} \tag{3}$$

Making the following abbreviations:

$$\left.\begin{aligned} \frac{A}{K\Sigma a\sqrt{2g}} &= B \\ \frac{2/m}{K\Sigma a\sqrt{2g}} &= D \\ \frac{C}{K\Sigma a\sqrt{2g}} &= C_1 \end{aligned}\right\} \qquad (4)$$

Equation (3) may be written:

$$dt = B\frac{dy}{y^{\frac{1}{2}} + C_1} - D\frac{ydy}{y^{\frac{1}{2}} + C_1} \qquad (5)$$

The integration of equation (5) between the limits H and H_1 will give the time required to fill the dock between planes Q and R.

$$t^{H}_{H_1} = B\int_{H_1}^{H}\frac{dy}{y^{\frac{1}{2}} + C_1} - D\int_{H_1}^{H}\frac{ydy}{y^{\frac{1}{2}} + C_1} = I - J \qquad (6)$$

Put $y^{\frac{1}{2}} + C_1 = z$, then

$$y^{\frac{1}{2}} = z - C_1$$

$$y = z^2 - 2C_1 z + C_1^2$$

$$dy = (2z - 2C_1)dz$$

$$\frac{dy}{y^{\frac{1}{2}} + C_1} = \frac{2z - 2C_1}{z}dz = \left(2 - \frac{2C_1}{z}\right)dz$$

$$\int\frac{dy}{y^{\frac{1}{2}} + C_1} = 2\int dz - 2C_1\int\frac{1}{z}dz = 2z - 2C_1 \log z + const$$

$$= 2[y^{\frac{1}{2}} + C_1 - C_1 \log (y^{\frac{1}{2}} + C_1)] + const$$

The first member on the right-hand side of Equation (6) will then become

$$I = B\int_{H_1}^{H}\frac{dy}{y^{\frac{1}{2}} + C_1} = 2B[H^{\frac{1}{2}} - H_1^{\frac{1}{2}} - C_1\{\log (H^{\frac{1}{2}} + C_1) - \log (H_1^{\frac{1}{2}} + C_1)\}] \qquad (7)$$

And

$$\frac{y\,dy}{y^{\frac{1}{2}} + C_1} = \frac{(z^2 - 2C_1 z + C_1^2)(2z - 2C_1)}{z}dz$$

$$= \left(2z^2 - 6C_1 z + 6C_1^2 - \frac{2C_1^3}{z}\right)dz$$

$$\int\frac{y\,dy}{y^{\frac{1}{2}} + C_1} = 2\int z^2dz - 6C_1\int z\,dz + 6C_1^2\int dz - 2C_1^3\int\frac{1}{z}dz = \frac{2}{3}z^3 - 3C_1z^2 + 6C_1^2z - 2C_1^3 \log z + const$$

$$= \frac{2}{3}y^{\frac{3}{2}} - C_1y + 2C_1^2y^{\frac{1}{2}} + \frac{11}{3}C_1^3 - 2C_1^3 \log (y^{\frac{1}{2}} + C_1) + const$$

The second member on the right-hand side of Equation (6) will become

$$J = D\int_{H_1}^{H}\frac{y\,dy}{y^{\frac{1}{2}} + C_1} = D[\tfrac{2}{3}(H^{\frac{3}{2}} - H_1^{\frac{3}{2}}) - C_1(H - H_1) + 2C_1^2(H^{\frac{1}{2}} - H_1^{\frac{1}{2}}) - 2C_1^3\{\log(H^{\frac{1}{2}} + C_1) - \log(H_1^{\frac{1}{2}} + C_1)\}] \qquad (8)$$

The value of (8) subtracted from (7) will furnish the solution, i. e.,

$$t^{H}_{H_1} = I - J \qquad (9)$$

Step No. 2—Between planes R and S the horizontal section of the dock is constant. The second term of the right side of Equation (6) therefore vanishes and formula (7) will represent the time of filling if in $B = \frac{A}{K\Sigma a\sqrt{2g}}$, A is taken as the horizontal area of the dock above the level of plane R, and if H_1 and H_2 are put for H and H_1, respectively.

Step No. 3—Between planes S and T both the pipes and the orifice are subjected to the same variable head ranging from H_2 to zero.

Let

A = the constant horizontal area of the dock,

f = the sum of cross-sectional areas of the pipes and the orifice $= \Sigma a + b$

K' = the combined discharge coefficient of the pipes and orifice =

$$\frac{K\Sigma a + K_1 b}{\Sigma a + b}$$

then the formula

$$t^{H_2}_{o} = \frac{2A}{K'b\sqrt{2g}}H_2^{\frac{1}{2}}$$

well known from the textbooks, will apply.

It will be noted that in the above discussion the distance from the outside water plane to the center of the pipes and the orifice was used as the pressure head. With the dimensions actually given to these openings, this assumption is entirely justified and introduces a negligible error only. Attention is called also to the fact that the pipe openings become "large orifices" when the head is reduced below perhaps four times the diameter of the pipes, resulting in a corresponding change of the discharge coefficient. It may become necessary, to account for this change, that the steps above shown be subdivided, which, however, can be done without difficulty.

Conservation in the Drafting Room by Simple Methods

Women Without Technical Training Are Readily Adapted to Railroad Work—Economies Effected in Lettering and Blueprinting

By James G. Wishart

Office Engineer, Chicago, Rock Island & Pacific Railway, Chicago

While the world war has affected all lines of business more or less, probably no line or profession in civil life has been crippled to a greater extent than railroad engineering, from whose ranks have been drawn the engineering forces required for operating the many miles of American-run lines in France. The selective service acts affected the forces employed in drafting rooms to a considerable extent, taking large numbers of draftsmen. Therefore, the drafting room of the average railroad engineering department afforded a first-class field for the practice of conservation. To offset the loss of men, steps were taken to increase the efficiency of those left on the work, employ and train inexperienced help not subject to war service, and conserve time and labor by the adoption of labor-saving methods and devices.

In some of the railroad drafting rooms the employment of women for drafting work was inaugurated. As a rule, women engaged in the past in drafting work were employed as artists or in the architectural line, and consequently very few had the technical training required to make competent railroad draftsmen. For this reason women employed in this capacity can be used primarily only as tracers or for copy or coloring work, the original detailing being left to the experienced men in the force. With a competent man in charge of a squad of these women, coaching and instructing them, they can soon be trained to handle practically any class of work which the average draftsman in a railroad drafting room is called on to do.

Specializing the members of the force on different

classes of work also gives good results. For example, estimating, yard design, frog and switch plans, mileage reports, rail and ballast records, recording of completion reports, can each be assigned to certain men. This specialization, however, should not be carried to the extent that but one man in the force is familiar with any class of the work; an understudy should be in training at all times for each one, for the purpose of filling vacancies as they occur. Architectural, bridge and signal work are distinctive classes of work and should be handled by men specially trained in these branches of engineering.

Titles, certificates, specifications, prominent lettering, etc., can be applied to tracings in a very short time and at small cost by the use of a small hand printing press. By the use of a special printing ink which is manufactured for use on tracing cloth, work done by this process can be made permanent and sufficiently opaque for blueprinting. A press of this kind has been in the chief engineer's drafting room of the Rock Island for the past 17 years, and in that time has amply demonstrated its usefulness as a labor-saving device. The one referred to is an ordinary hand press capable of printing sheets up to 8 x 12 in. Standard lead type is used, the assortment of styles of letters having been selected to meet the requirements of the work handled.

The work of setting the type and printing on the drawings is performed by the file clerk, who gets a much lower salary than those paid to the draftsmen. It is, of course, desirable where possible to obtain for this work a young man who has had some experience in a printer's shop. Anyone familiar with the time consumed by a draftsman in lettering a single title by hand where something more elaborate than plain lettering is desired can readily realize the saving in time and money made by the use of the printing press, when he learns that little more than half an hour is required by a boy with a little experience to set up and print the most elaborate title on one sheet, and that it requires only a minute or two to reproduce it on other sheets as often as is desired. In addition to the economy effected, uniform work, neat in appearance, is obtained on all drawings. Electrotypes for commonly used phrases, such as the company name, scale, department name and map headings, effect further savings in the time required for setting the type. Standard blank forms can also be printed from electrotypes at low cost in any spare time which the printer may have.

Making of Blueprints

Blueprints can be made from tracings printed in this way immediately after the printed matter is applied, this being accomplished by sprinkling a light film of fuller's earth over the damp ink and immediately dusting it off lightly with a feather duster. While this may give the ink a grayish appearance it does not detract from its opaqueness. Where possible, however, it is preferable to allow the ink to dry for about 12 hours.

Statements, estimates, specifications and similar matter of which a considerable number of copies are desired can be typewritten on a thin, white transparent paper with a black ribbon and a sheet of fresh black carbon paper reversed on the back. Blueprints or blueline prints of first-class quality can be made in any amount from sheets made up in this way. This method is of particular value where the number of copies desired is not large enough to warrant sending it to a printer. We have accomplished a large saving in our valuation work by writing up all of our land schedules in this way and having them placed on the original right-of-way tracings by the lithographic reproduction process at the time when our reproductions of the maps were made for filing with the Interstate Commerce Commission, thus eliminating lettering of these schedules by hand on the tracings. The money saving by this scheme averaged about 75c. per sheet, which on 2500 sheets, the approximate number we made, amounted to \$1875, or practically the time of one draftsman for 16 months.

Lithographic Reproduction

The lithographic reproduction process of making copies of tracings offers many opportunities for saving time and expense in making duplicate copies. By this process copies can be obtained on tracing cloth or paper which, provided the originals are in good shape, are practically as good as hand-made tracings, and as true to scale as the originals. In this process it is possible to eliminate portions of the original from the copy or to insert additional details. This makes possible the use of a set of plans made up for one purpose for making plans for a similar structure where changes are desired in the details. By the reproduction of the original plans with such features eliminated as are not to be incorporated in the new plans, and making the desired changes and additions on the reproductions, most of the time of retracing can be saved and a great saving in expense accomplished. This is particularly adaptable to the duplicating of floor plans in architectural work, and also to the producing of plans of structures where a standard plan can be used as the basis for the reproduction. Where there is any amount of work on the original, the cost of the reproductions is but a small fraction of the cost of retracing by hand, and the chance of errors in copying is entirely eliminated.

The practice of photographing standard plans effects a large saving in blueprint paper and time of printing, and can be applied to any large drawings of which a large number of copies are required, or copies of which are to be incorporated in reports, attached to contracts or put to other similar uses. On our prints of standard plans we save approximately 90% on blueprint paper by using prints of the photo negatives instead of the large-size tracings for filling all current requests, and in addition make a noticeable decrease in the size and weight of packages of prints for mailing. These photograph negatives are made on a 9 x 14-in. film which can be blueprinted in a continuous blueprinting machine just as tracings are. When properly made they will print at the same speed as tracings, and they can be used to fill up open spaces on the paper, thus utilizing what would otherwise be waste paper. With a first-class camera and lens, a dark room and an illuminating frame, these negatives can be made at comparatively small expense by any one with the average amateur photographer's knowledge of photography, and with ordinary care in handling they will last indefinitely. We have made as many as 2000 prints from a negative at an average cost of 1c. each, the negative costing about 80 cents.

Possibly the blueprinting department affords a greater opportunity for practicing economy than any other department in the office end of the engineering

forces, especially at the present time, when the prices of blueprinting papers, chemicals and other supplies are more than 200% above normal. The continuous electric printing, washing and drying machines speeded up the blueprinting considerably more than 100% over the old method of printing with a sun frame, but at the same time they also increased the possibility of waste in paper, and raised the repair bills on equipment. The preventive for these is the employment of an experienced commercial printer in charge of the blueprinting equipment—one who will watch to see that the tracings are fed to the machine in such positions as will best cover the entire width of the paper, and without spaces between their edges, and who can also take care of the minor repairs necessary from time to time on the equipment. While it is necessary to pay a larger salary to such a man than to a boy or inexperienced man, the saving he will effect in materials and repair bills, to say nothing of the increased life of the equipment, will more than cover the increase or difference in salary. The use of 100-yd. rolls of paper, by decreasing the number of joints, reduces the waste in paper due to joining the ends of succeeding rolls. The attachment to the washer of a device for recovering the bichromate of potash solution after it has been sprayed on the exposed paper reduces to a minimum the waste of this chemical. Such a device, which is nothing more than a galvanized-iron tray and drain pipe, can be made in the company shops at very small expense, and, considering the high price of potash at the present time, will pay.

Graphical Map Index

The installation of a graphical index for station maps, right-of-way maps and profiles has been the means of saving a great deal of time in our drafting room, by eliminating the necessity for referring to card or book indexes to find the required index number for these drawings, which are the most frequently used in the files. Briefly described, this system consists in filing such records by states, all the right-of-way maps for Illinois, for instance, being filed in one compartment, the door of which is labelled with large letters on the outside, "Right-of-Way Maps 61, Illinois" and a diagram map of the lines in Illinois showing the portion of line covered by each roll of map, with its index number, is placed on the inside of the door. Profiles are filed in the same way, while station plans have an alphabetical list on the inside of the door instead of the diagram map.

By this system of filing, all that is necessary to find a map or profile is to know the state it is in and then to go directly to the compartment labelled for that state and class of map in the filing case and obtain the index number from the diagram on the door of the compartment. This system can be applied as easily to a line with 10,000 miles as to one with but 100, and if desirable the subdivision can be made by operating divisions instead of by states. In the writer's opinion, however, the states plan is preferable, as state boundaries seldom change, while operating divisions are not so stable.

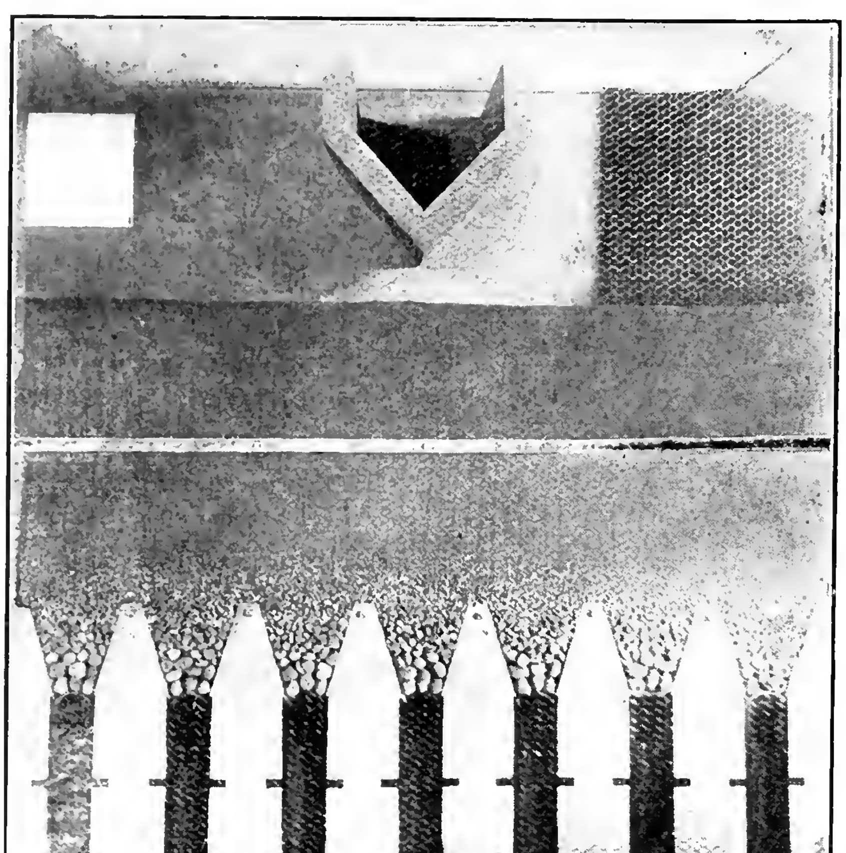
One of the most convenient appliances of which use can be made in the drafting room is a paper cutter such as is used in job-printing offices for cutting large numbers of sheets of paper at a time. We installed one of these cutters capable of cutting sheets 16 in. wide, about five years ago. It has proved a time-saving machine and is in constant use, not only by our own office but by nearly every other department in the general offices. Scrap paper from various sources suitable for scratch pads has been trimmed by this machine to pad size and made up into pads by the office boy, padding cement being used, in such quantities that we have not included a single scratch pad on our stationary requisitions in more than four years. Use can be made in this manner of obsolete report forms, circulars, specifications, etc., printed on one side only.

A drawing pencil just now is a fairly expensive article. The pencil holder is the best known medium for saving pencils and reducing pencil bills.

The last and possibly the most important item that the writer has in mind is *esprit de corps*, or what is more universally known as "team work." The force of men who are receiving the fair and square treatment which is due them and who are being accorded the small privileges it is always possible for their superior to extend them will develop the spirit of team work, and its effect will be to produce better and more work.

Model Explains Water Filter to Visitors

ONE of the difficult things to explain to laymen visiting water-works filter plants is the construction and operation of the underdrain system. At the Minneapolis filters a full-size model has been constructed with a wire-glass front to retain the 30 in. of sand and the six supporting gravel layers 14 in. deep. The model is 18 in. thick and shows seven troughs with the monel metal screens leading to 3½-in. cast-iron risers which were split with a power hack saw to show the section. Wood is used for the ridge blocks and wash-water



WIRE GLASS CONFINES SAND IN FILTER MODEL

trough, being painted the color of concrete. Two sheets of 44 x 88-in. wire-glass form the front, the joint being covered by a metal strip held by three ¼-in. rods. The glass is held also by No. 10 screws driven into the ridge blocks, holes being bored through the glass with file and turpentine. The model was built under the direction of W. N. Jones, engineer in charge of the filter plant and new construction.

History and Use of Easement Curves for Railroads

Review of Bibliography of Subject Indicates Great Variety of Curves Proposed—How Practice Developed

By Philip O. Macqueen
Baltimore, Md.

At the very beginning the writer wishes to state definitely that he has no intention of bringing forward any new theories or formulas for easement curves. The various methods now in practical use are explained clearly in a great many handbooks and other sources of reference, and it is the general opinion that a new method is entirely unnecessary. However, a short time ago the writer had occasion to make a brief study of the subject. In this connection he reviewed all of the bibliography to which he had access, and the following discussion may lead to a more uniform practice in the use of easement curves.

An idea of the extent of this lack of uniformity is gained by a summary of the names now in use, as follows:

The cubic spiral easement curve; the transition curve; the easement curve; the taper curve; the true transition curve; the elastic curve; the railroad spiral; the six-chord spiral; the ten-chord spiral; the railway transition spiral; the cubic spiral; the true spiral; the cubic parabola; the railroad taper, and the curve of adjustment.

In addition, the following complete curves have been suggested: The curve of sines; the parabola; Carnu's spiral, and the spiral of Archimedes. As is well known, however, all of these various curves, with the exception of the second class, can be divided into a very few groups in which the fundamental principles are the same, so that the actual confusion is much less than appearance would indicate.

Earliest Reference to Subject

The earliest important reference which the writer was able to find on the subject of easement curves is in Prof. W. J. M. Rankine's book, "A Manual of Civil Engineering," published in London, 1862. Professor Rankine gives a description of two curves, one proposed by Mr. Gravatt in 1828-1829 and one by Dr. William Froude about 1841. The first proposed the use of the curve of sines or harmonic curve. The second method deserves careful consideration, as this method is undoubtedly the foundation upon which the present accepted theories of easement curves are based.

Dr. William Froude, a well known English engineer and naval architect (1810-1879), during the period 1837-1844 was employed as construction engineer on the Bristol & Exeter Ry., England, when he proposed his "curve of adjustment."

Dr. Froude's rules, using his own words, are as follows: (1) Locate the center line of the railroad, using simple curves and tangents; (2) determine the length of the curve of adjustment by means of the formula $L = 300$ multiplied by greatest change of cant (in feet); (3) compute the shift as follows: Shift $= L^2/24 \times$ radius; (4) set out the curve by use of the formula $y = 4bx^3/a^3$, in which a = length of curve of adjustment; b = shift or gap; x and y = ordinates. The important similarity between Dr. Froude's curve and the curves now in use will be seen immediately. However, a period of nearly 40 years elapsed before the principles of this curve were put into into practical use. In fact, the use of easement curves began just a year after Dr. Froude's death.

During the period between 1830 and 1880 no practical use was made of easement curves on railroads, either in England or in the United States. In France, according to W. M. Gillespie, the parabolic curve was generally preferred. A simple method of locating the curve is given in his book, published 1849. It was recognized, however, almost in the beginning, that there was a decided element of danger in the use of simple curves—or, in fact, in the use of curves in general. It was also recognized that, in general, it was not the curvature but the change of curvature that presented the chief difficulty. Laws were made to fix the minimum radius for curves.

On the early English main lines no curves of less than 80 chains (about 1°) were allowed, but later this was reduced to 40 chains and then to 30 chains or about 3°. In the United States the minimum radius allowed on the Hudson River R.R. was 2062 ft. The superelevation of the outer rail was calculated by the same method as is now in general use and applied carefully. When consideration is taken of the easy curves and the comparatively low speed, 15 to 30 miles an hour, customary from 1820 to 1840, it will be seen that railroad travel was quite safe in this respect.

After 1840, however, a higher speed became customary, and practical methods were put into use to overcome the shock due to the almost instantaneous change of direction and sudden development of centrifugal force as the train passed from tangent to curve and curve to tangent. The first practice was to begin to elevate the outer rail on the tangent at a point from 100 to 200 ft. from the point of curve and point of tangent. The superelevation was changed gradually and reached its correct maximum at the point of curve or a short distance beyond the point of curve. This method, however, was only a partial solution of the problem, and the curious and interesting development of allowing the trackmen to "ease" off the curves soon became prevalent. As described by A. M. Wellington, this method is as follows: "The trackmen extend the curve back on the tangent usually 200 or 300 ft. by throwing the line inward at the tangent point, thus sharpening the curve beyond the tangent point, but easing the approach." This method is still in use by a few railroads both in this country and abroad.

Easing-Off Method Criticized

The result obtained by allowing the trackmen to "ease" the curves was a decided improvement over previous methods, but very naturally it caused considerable discussion among the more theoretically minded. William Airy in the *Engineer* of Nov. 27, 1868, deplores the custom and says that he saw two cases of derailment due entirely to the kinks in the curve caused by the easing-off process. In the discussion which followed this article one critic recommended that he "sack the platelayer." Nevertheless, the platelayers in gen-

eral were not sacked, and this method of curve easement was used with a fair degree of success for a period of almost 40 years, or from approximately 1840 to 1880. Dr. Froude's curve of adjustment, the cubic parabola, the elastic curve, and many others were advocated continuously, but the general opinion among construction engineers was that the adoption of these curves would simply be a case of too much refinement. In their turn, the locating engineers adhered strictly to the circular curve, on account of the simplicity with which it could be applied. Mr. Airy very amusingly notes that the "platelayers" considered it part of their duty to correct the mistakes made by the engineers.

That there existed a great necessity for correctly established easement curves was strikingly shown by C. D. Jameson in a series of three articles on the cubic parabola in the *Railroad and Engineering Journal* of May, 1889. Mr. Jameson says: "The author made a survey of 271 miles of railroad, which had been in operation for about 25 years. The survey was made with the idea of getting the alignment of the railroad exactly as it was at the time. All of the curves showed clearly upon being plotted that their ends had been eased off and a sharp point created a certain distance beyond the curve point. This was so in all cases and was due to the impact of the train and also to the work of the section men. The movement had been from 3 to 4 ft. from its original position, thus necessitating a continual widening of the roadbed upon the outside of the curves near their ends. This excessive width of roadbed was the first thing which called the author's attention to the condition."

First Practical Use

The first practical use of easement curves is accredited to E. Holbrook, in 1880. The curve is known as the "Holbrook spiral" and was used originally on the Pan Handle R.R. This curve gained recognition immediately, and is now in use on many railroads. The first engineer other than Mr. Holbrook to use the formulas extensively was G. W. Kittridge, who put spirals on many of the curves on the Pan Handle R.R., both east and west of Steubenville, Ohio. The general formula for the Holbrook spiral is given in the *Railroad Gazette* of December, 1880, and *Engineering News* of June 13, 1901, p. 429, and is $RL = A$; in which R = radius of curvature of spiral at any point; L = length of spiral measured from its origin; A = constant which determines the rate of transition.

The success attending the use of the Holbrook spiral created a renewed interest in the subject, and many new methods and formulas were soon brought forward, both in books and periodicals. An important article by A. M. Wellington was published March 11, 1881, in the *Railroad Gazette*. The "railroad spiral" by William H. Searles was published in book form in 1882, and it is one of the best known of all of the easement curves. In many cases, however, the railroads themselves used easement curves which were developed in their own offices and which were given only to employees in the form of blueprints. With the exception of the Searles spiral most of the new methods and tables were published during the period from 1890 to 1900. It is important, however, to note at this point that, although a renewed interest in easement curves was taken after 1880, nevertheless the railroads were slow to adopt them, and it was not until after 1900 that their use became general.

In 1911 a subcommittee of the American Railway Engineering Association made an examination of all of the different forms of easement curves in use. Their final report, which is published in the "Manual," 1915, contains the following: "Any form of easment curve is satisfactory: (1) In which the rate of increase in degree of curve can readily be changed to suit particular cases so that the length of easement curve shall be the same as the distance in which the outer rail is raised from nothing to full elevation; (2) which can be run in by deflection or by offsets with chords of any desired length; (3) which is of the general type of either the Searles spiral, the cubic parabola, or the Holbrook, Crandal, Talbot, and ten-chord spiral." The ten-chord spiral was recommended by the committee.

At the present time no railroad of any size is located or built without proper allowance being made for curve easement. The larger problem, however, is to "ease" the curves of roads in operation. In the *Railway Age Gazette* of June 17, 1910, the editor discusses at length the answers to a series of questions sent to 56 of the large railroads of the United States. On 20 railroads easement curves had been put in on all main lines and some branches, on nine railroads 75% of this work had been done, on 22 railroads more or less work had been done, and on five railroads no work had been done. The methods used varied considerably, but nearly all of them were based on the Searles spiral, the Holbrook spiral, the Talbot, Hood, and Stevens six-chord spiral, and easement was applied to all curves requiring an elevation of 2 in. or more for the highest possible speed. The consensus of opinion of the railroads in question was that the easing of curves resulted in, first, increase in comfort in riding and avoidance of swerving and unpleasant shocks to passengers; second, economy in track maintenance and reduced flange wear, and, third, reduced drawbar pull.

Strength of Waterproof Glues Wet and Dry

IN A recently issued sheet of "Technical Notes," the Forest Products Laboratory, Madison, Wis., gives information on the resistance of waterproof glues to water. Two types of such glues are in the market, those made from blood albumen and those made from casein.

The former must be used in a hot press, while joints made with casein glue are clamped together cold, for which reason the former are generally used only for thin material, such as veneer. Both kinds of glue are materially weaker wet than dry. Tests of casein-glued joints of wood showed generally only 20 to 40% of dry shearing strength. Similar tests of joints made up with blood glue showed strengths of 50 to 75% of the dry strength. However, when plywood made up with these glues is redried after being soaked, the original strength of the glue is very largely recovered.

The water-resistant qualities of both kinds of glue are so high that the acceptance test for plywood made up

with these materials requires no separation of the plies to be shown after either boiling in water for eight hours or soaking in cold water for 10 days. Airplane manufacture has called for the development of the highest attainable requirements by glues for making built-up structural members out of layers of thin stock. Under present commercial conditions, casein glues, when used to join maple test pieces, show shearing strength of 2000 to 2500 lb. per square inch. Blood glues show higher average strengths (no figures are given), but the laboratory expresses the belief that casein glues will in time be developed to the point of equalling them.

A Universal Weir Chart

By E. Earl Glass
Monrovia, California

IRRIGATION engineers and others using weirs for measuring comparatively small streams may find the accompanying chart valuable for ready determination of the discharges. The formulas are those evolved in the recent experiments conducted at Fort Collins, Colo., described by Victor Cone in Farmers' Bulletin 813 (United States Department of Agriculture, Washington.

The usual precautions must be observed in setting the weir and making measurements. A sufficient pondage should be provided to check the velocity of approach and the head, *H*, must be reared above the sharp-edged crest to the surface of still water. There should be sufficient fall below the weir to prevent any influence of backwater, and free circulation of air below the crest must be provided.

Curve No. 1 gives the discharge of a 90° triangular notch weir for heads to 18 in. The discharges of rectangular weirs for the same range of *H* are indicated by Curve No. 2, and the same for trapezoidal or Cipolletti weirs with length of crest, *L*, equal to 1, 1½, 2, 3 and 4 ft. are shown by the four curves marked No. 3. The discharges read from this diagram in cubic feet per second or in miner's inches agree with the tables in the publication mentioned above.

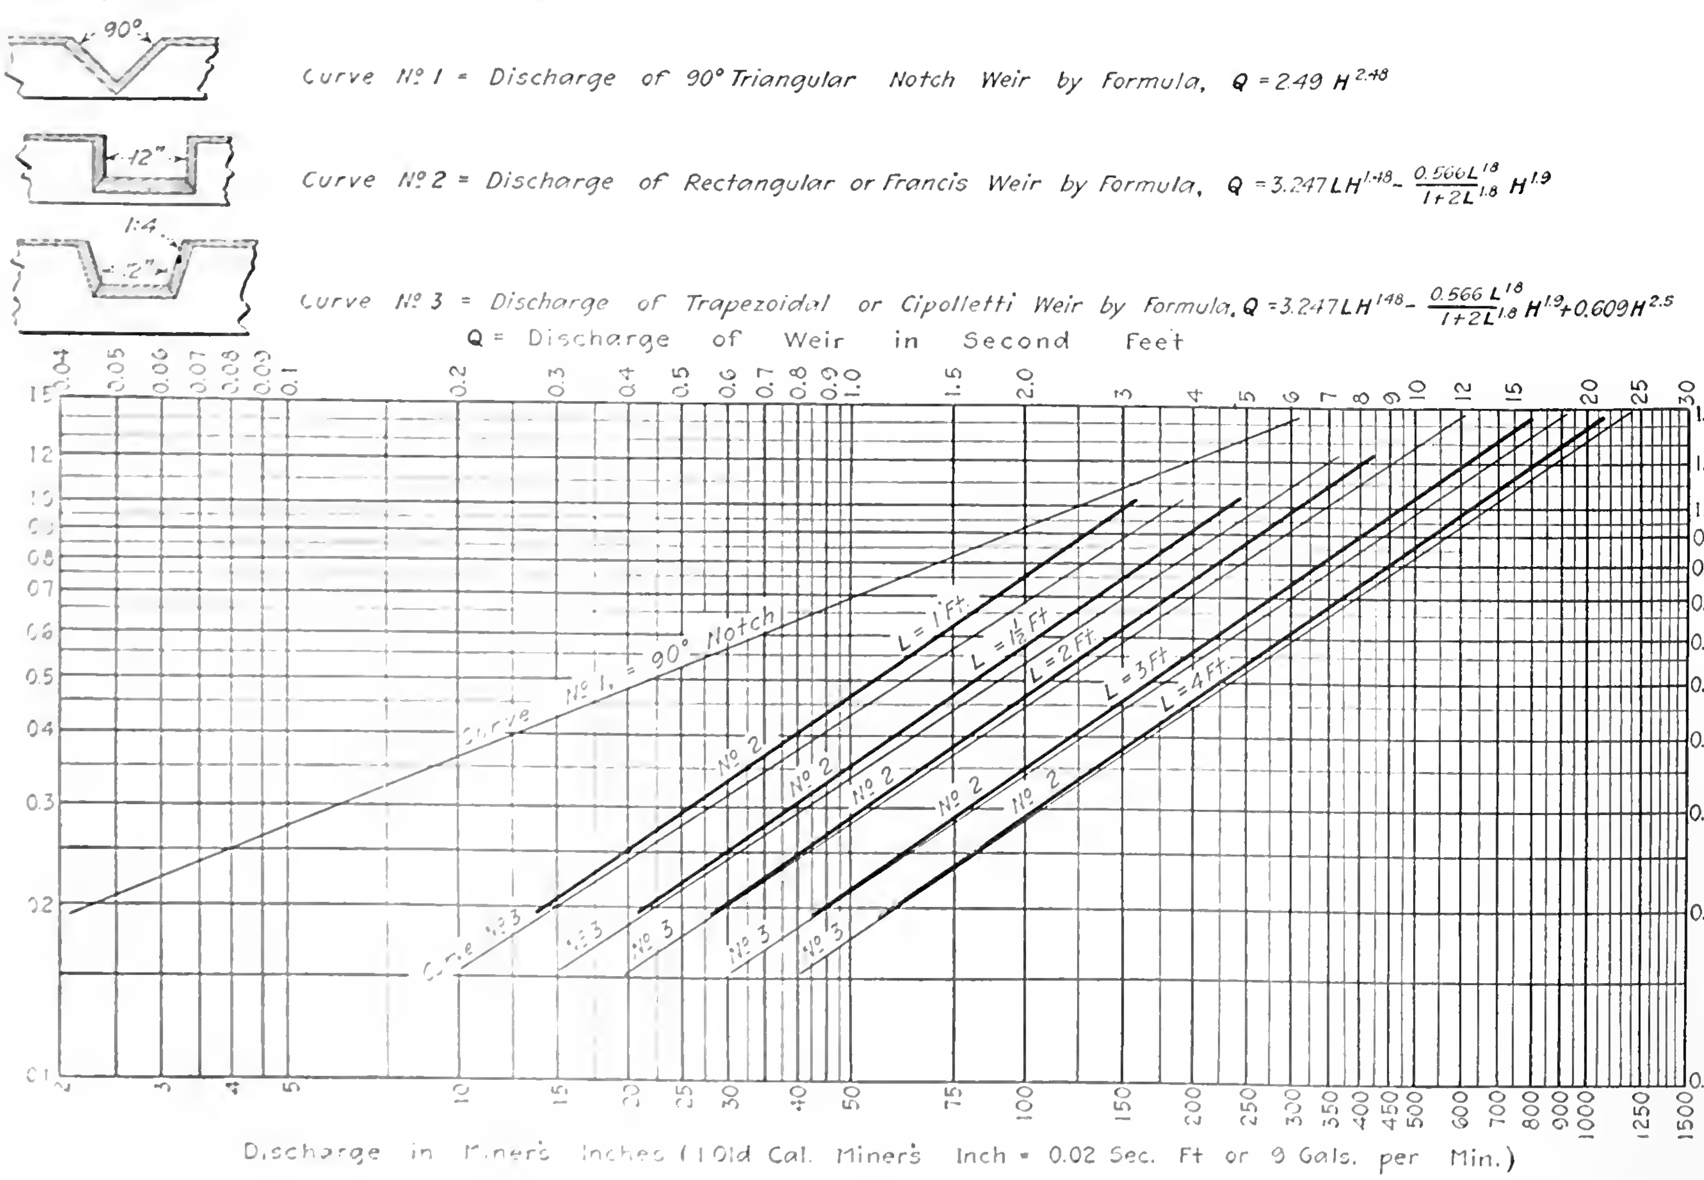
Concrete-Frame Factory Building Has Wooden Roof

Cost One-Half of Steel-Frame Design — Roof Sheathing Made Protection Easy During Severe Winter Weather

By W. E. Turner
Civil Engineer With Villadsen Brothers, Inc., Salt Lake City, Utah

CONCRETE-FRAME construction for factory buildings has so many advantages over steel in permanence, fire-resisting qualities, freedom from vibration, low maintenance, speed of construction and appearance —and, above all, in low first cost compared with steel at present prices—that it is surprising how seldom it was adopted even before the cost ratio became so marked. The main building of the Galigher Machinery Co., Salt Lake City, Utah, was first designed with a steel frame. The bids were so high that an alternative design for a concrete frame with a wooden roof was made, and the new bids developed the remarkable facts that the concrete frame cost one-half as much as the steel frame, and that the chances of delivery favored the concrete materials by 10 to 1.

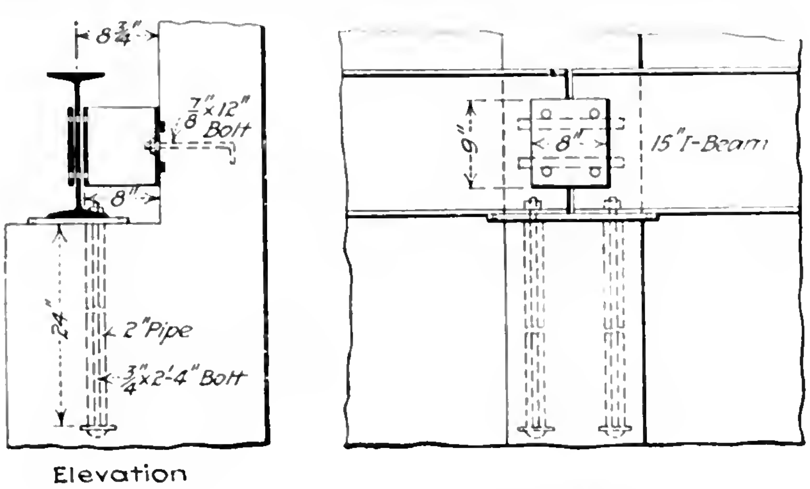
The Galigher Machinery Co. has a general machine shop business and also deals in various iron and steel products, with a steady output of filter presses. The flood of orders, overtaxing the company's old plant,

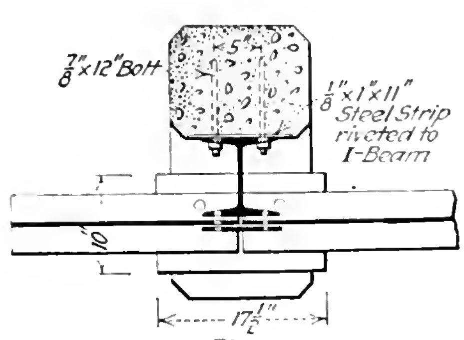


made it imperative to rush new buildings to completion during the severe winter of 1916-1917. The extremely favorable showing for the concrete frame was obtained simply by replacing the original open framework of steel beams and columns by one of concrete beams and columns, the roof and walls being filled in with other materials chosen with reference to their cost and appearance.

It was decided to build a wood roof on the concrete frame, utilizing for economy the large amount of form lumber which would have had to be sold at great sacrifice. A built-up sanded roofing with an asphalt base was used on the main building, but the rapid fluctuation in the prices of materials had altered the conditions before the warehouse was completed, and a tar-and-gravel roof was therefore adopted for that building.

One of the principal factors in keeping the cost on the concrete frame so much below that of steel was the uniformity of the design. Each bent is a duplicate of the preceding bent, and each beam has a corresponding beam in the next bay. The uniformity of the design reduced the cost of form detailing, and permitted the division of the building into three sections. The forms for Sec. 1 were re-used with practically no alteration on Sec. 2, and after that again on Sec. 3. The whole arrangements was so standardized that it was possible to carry the work out more or less like a manufacturing process.

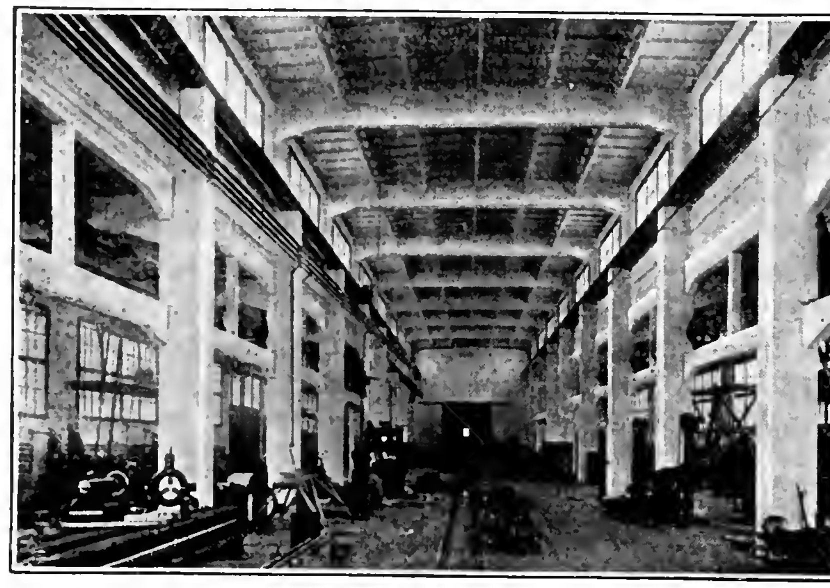




TYPICAL CONNECTION, STEEL CRANE BEAMS TO CONCRETE COLUMNS

A steam-driven stiffleg derrick with a 50-ft. boom, set on a truck, was placed to operate in the clear space down the center of the floor.

The forms came to the erecting floor from the saw mill in finished beam-and-column units, and were piled at the sides of the derrick under the boom, each piece placed according to a carefully prepared piling diagram. All reinforcing steel was fastened in place in the forms before erection. The derrick picked up the forms for the concrete framework and swung them into place. All that the carpenters on erection had to do was to drive the nails. As soon as a bent was set the derrick would swing the wooden purlins, rafters and sheathing into place, pick up the two steel crane beams, and then proceed to the next bent.



INTERIOR OF SHOP BUILDING

Lower beams and intermediate columns are for support of shafting and machinery

Every unit of form was detailed in the drafting room. Provision was made, as seen in the drawing reproduced, for setting little brackets for the support of wood purlins and throats were cut in the top of the form, to set the purlins in place during the form erection. The beam sides when stripped came off very easily, and left the purlins and all the roof in place. The sheathing and rafters were laid during form construction, so that they provided a good working platform for the pouring of the concrete, and covered in the roof area as part of the frost protection while the concrete was setting. Provision was made in designing the forms so that all beam bottoms would be left supported after the rest of the forms had been stripped and remodeled.

The frame beams were mixed 1:4, or approximately 1:1.4:2.6, and the columns 1:6. The grading of the aggregates was carried out as far as practicable by frequent visits to the pit, and by screening samples of sand from every load. As the cold weather had set in before the framework was poured, it was necessary to heat the mixing water and the aggregates. The hot water was obtained from the Utah Portland Cement Co. across the street, taking advantage of heat that was going to waste at the plant. The sand and gravel were heated by means of 2-in. perforated steam pipes laid on the ground under the sand and gravel piles. There was approximately 1 sq.ft. of heating surface in the pipes for each 6 sq.ft. of ground covered by the piles. That was sufficient to keep the materials hot through the coldest weather. The steam was supplied, at a pressure just barely above the atmosphere, by the boiler on the steam derrick, which was in no case engaged in erecting forms at the same time as when the concrete was being poured.

The temperature of the fresh concrete was probably about 120 deg. To protect the concrete still further against the cold, each section of the building was closed in with 8-oz. duck sheets, and salamanders were burned day and night. It was found that the concrete, even when not inclosed, would remain warm to the touch for about 24 hours after pouring. The heating of the concrete was governed by the idea that no dependence can be placed on any setting at a temperature lower than

40 deg. The heat was kept well above this minimum until the cement was well set. As a check on the proper setting of the concrete, test blocks were made in the form of 6-in cubes, and three or four of them were poured with every day's run and placed beside the most exposed beams to set under the same conditions as the framework. They were tested by crushing by Professor Beckstrand of the University of Utah, and his report was always consulted before the supports were removed.

The table herewith gives the results of tests on four of the cubes for the framework of the first section in a

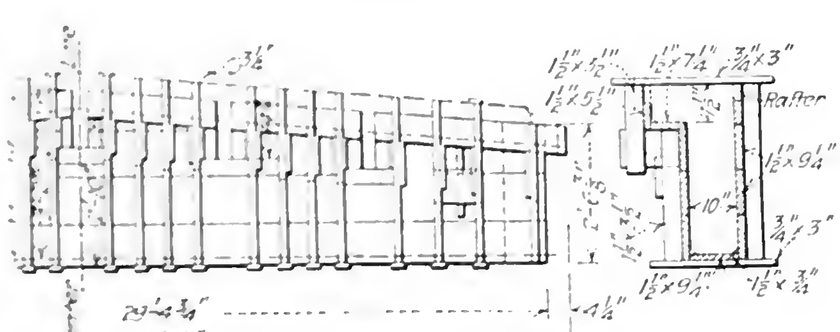
ULTIMATE STRENGTH OF CONCRETE SET AT LOW TEMPERATURE

Mixture	Ultimate Strength 6 × 6-In. Cube	Ultimate Strength lb. per Square Inch
1:4	93,050	2580
1:4	102,400	2870
1:6	52,300	1475
1:6	57,100	1600

portion which was not inclosed, where the concrete was poured at a temperature of 120 deg. and allowed to set for 41 days exposed to a temperature of 10 deg. above zero.

The whole interior of the building was whitewashed with hydrated lime, carrying a small proportion of salt, glucose and other ingredients. The woodwork, brickwork and plaster walls were all sprayed, but the concrete was for the most part brushed, in order to fill any little surface voids more thoroughly. The insurance rate on the buildings was quite noticeably reduced by the whitewashing, the saving being as great as 15% in the case of the warehouse. It is claimed that the presence of salt in the whitewash is an important factor in its fire-resisting properties.

Building work was carried on according to a very complete time schedule which showed the number of carpenters, laborers, and other workmen required at



DETAILS OF 30-FOOT BEAM FORMS FOR MONITOR

certain dates, the time of starting and finishing all subcontracts, and the time limit allowed for the delivery of all material. The time schedule was found of peculiar value in ordering brick, which had to come by the carload, and which could not be stored in very large quantities near the track. The plans for the main building were started in October, 1916, and it was completed ready for use on Jan. 31, 1917.

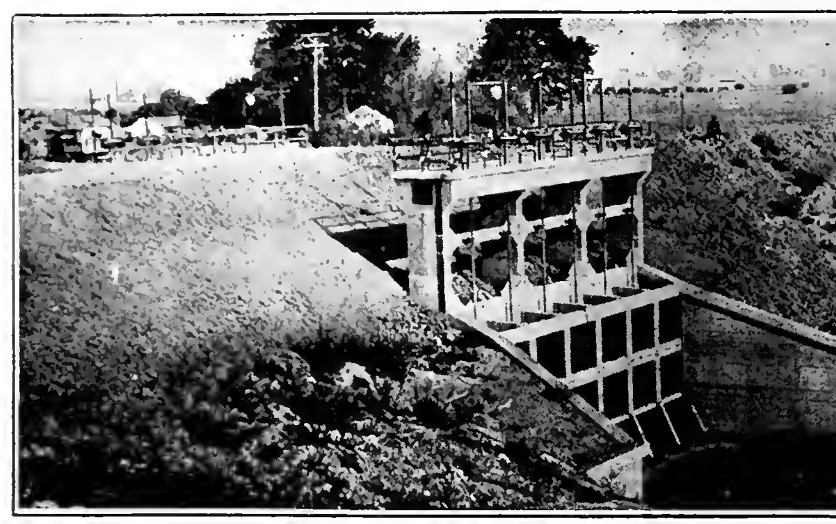
All work on the Galigher buildings was done under the supervision of Villadsen Brothers, Inc., engineers and contractors, Salt Lake City, and Leonard Cahoon, general superintendent of the Galigher Machinery Co.'s shops, all reporting to J. E. Galigher, vice president and manager of the Galigher Machinery Company.

Canal System Used Alternately To Irrigate and Drain

Low-Lift Pumps Required for Part of Area, But Much of It Is Served by Gravity Auxiliary Canals

A COMBINED reclamation and irrigation system, using the same canals for irrigating crops in the dry season and for draining off surplus waters in the flood season, has been developed in California. It is known as "District 108," and includes about 60,000 acres in the lower Colusa basin along the west side of the Sacramento River.

The canal system was first laid out on the reclamation district plan for draining the lands and keeping the water table down to a level safe for crop production. Then, in 1917, the state legislature revised the reclamation act to include provision for irrigation. After careful studies of the area affected, it was found that with the low gradients on which the canals were laid out some comparatively inexpensive changes in the canal system and the addition of headworks would make it possible to fill the canals by admitting water from the river. This necessitated, in some sections, pumping to get the water from the canals on to the land. The lift required was nowhere high, however, and by using a system of auxiliary canals a large portion of the area was served by gravity. The completed canal system will be such that no farming land will be more than two miles from a branch of the main canal system.



WILKINS SLOUGH INTAKE IS PROVIDED WITH TRASH ROCKS, FISH SCREENS AND REGULATING GATES

The general slope of the area is westerly, away from the river, falling 10 to 12 ft. in the first mile and 4 to 5 ft. in the second, after which it is quite level. The normal low water level in the river is about El. 28, practically the same as the ground level upon which 19 miles of the back levee is constructed. The lowest land in the district is about El. 22 and about 28,000 acres lie below El. 28. Thus almost half the total area could be, theoretically, supplied by gravity. The cost of checking is very low because of the regular, level surface.

It is proposed, should there be any temporary shortage of irrigation water, to siphon water in through the pumping plant, at the lower end of the district, installed for pumping out drainage. Another feature of the drainage system that is included in the irrigation plant is the culverts in the Howell Point cross levee near the center of the district. These culverts, provided

with gates at either end, are to be used when desired to maintain a higher water level in the upper half of the district than in the lower half.

The Wilkins Slough intake will control the entry of water from the Sacramento River into the canal system. It consists of six reinforced-concrete culverts 5 ft. square inside and set with the floor level at El. 20. Thus the tops of these culverts are 1 or 2 ft. below the lowest low water. The barrels are about 141 ft. long and terminate in retaining walls.

The intake structure is set back in Wilkins Slough about 150 ft. from the river bank, to avoid injury from river traffic or caving banks, and also because this afforded an easy way to maintain the levee during construction. When the intake was completed the channel to the intake was opened up by a large clamshell dredge during the high-water stage of the river, the levee over the intake culverts being reconstructed by the dredge at the same operation, using material dredged from the inlet channel.

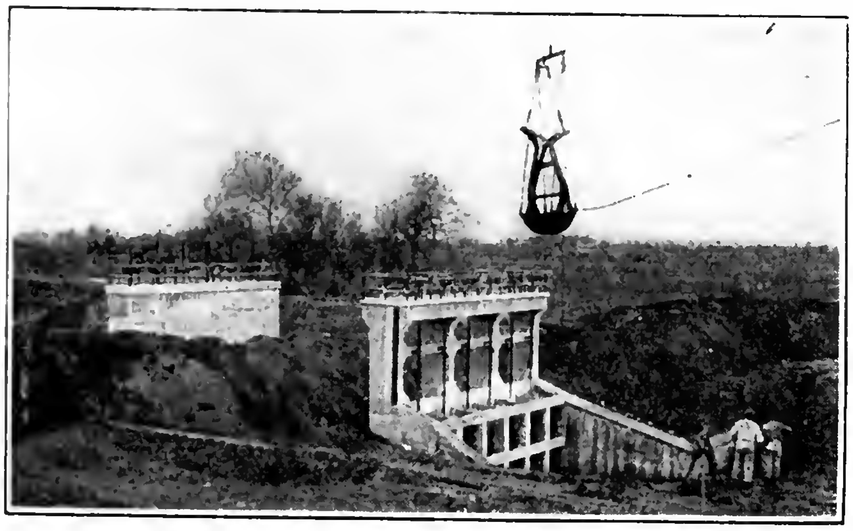
The headwalls on the riverward side support the operating mechanism for heavy, steel regulating gates. In front of these gates, sloping buttresses from the retaining wall also support steel trash racks and fish screens. Grooves were constructed in the concrete walls to permit of an emergency closure by stop logs in case the gates jam. As an additional precaution, reinforced-concrete wells were constructed near the center of the culverts, extending upward to the top of the levee at the landward edge of the crown. A second set of timber regulating gates was provided in these walls, permitting an entirely independent closure of the culverts. Three separate sets of reinforced-concrete collars or cutoff walls are provided. One of these, under each set of gates, incloses a heavy timber sheet pile cut-off wall driven 20 ft. farther into the substrata.

Test borings indicated clay, with a shallow stratum of hardpan to a depth of 10 ft. below the foundations of the structure, and no foundation difficulties developed. The total cost of the completed structure, including overhead charges for engineering, administration, etc., was approximately $100,000.

The intake is connected with the drainage canals by a system of main irrigation canals extending across the head of the district. The system classified as irrigation canals, and used chiefly for irrigation purposes, comprises four main canal divisions with a total length of approximately 11 miles, and a total volume to be excavated of about 751,000 cu.yd. The cost of the canal excavation, as estimated when the work was about 50% complete, was $195,000, or an average of about 26c. per cubic yard.

The canals between the intake and the upper end of the main drainage lateral of the eastern portion of the district were designed with a bottom width of 40 ft., side slopes of 1 on 1½, and a nominal capacity of 500 sec.-ft. The maximum depth of material to be excavated was not over 15 ft. The heaviest cutting was done with a dragline excavator mounted on two lines of car trucks and carrying a 4½-cu.yd. bucket on a 110-ft. boom. Other portions of the canal were dug with a smaller dragline, and with a dipper dredge mounted on car wheels and spanning the ditch.

The larger portion of the work, however, will be completed with floating clamshell dredges with 1¾-cu.yd. buckets, 75-ft. booms, and 28 x 80-ft. hulls. These machines can float in about 4 ft. of water, and can readily lift material to a height of 15 ft. or more above the water surface. Controlling works will be installed at the head of the main drainage laterals just below the junction with the main drainage canal, in order that



LEVEE OVER INTAKE CULVERTS WAS REBUILT WITH MATERIAL DREDGED FROM INTAKE CHANNEL

water may be held up across the district in the irrigation canals, or can be diverted down the drainage canals, as required.

The irrigation and drainage system and the intake were designed by Fred H. Tibbetts, civil engineer, San Francisco, engineer for Reclamation District No. 108. Fred C. Herrmann, consulting engineer, reviewed the plans for the intake. The Ajax Dredging Co., F. F. Cooper, president, of San Francisco, was the general contractor for the entire work.

Cantonment Fire Due to Faulty Masonry in Fireplace

Chimney Built of Scrap Material and Added After Frame Building Was Completed Found Full of Holes After Building Was Destroyed

FIRE in one of the officers' quarters at the United States Army General Hospital No. 3, at Colonia, N. J., last October entirely destroyed the building and caused the deaths of two of the medical officers sleeping in the building at the time, and the injury of several others who were trying to escape. Investigations of the fire were made by various officers immediately after the fire.

As a result of the investigations, it is apparently the opinion of the experts that the fire was caused through the faulty construction of a fireplace which was put into the building after it had been completed and while it was occupied.

The building was one of the typical cantonment-type timber-frame structures, one-story high and E-shaped in plan, having a headhouse and three pavilions extending therefrom. The center pavilion contained a lounge or rest room for the officers, and the remainder of the building was used for sleeping quarters. About six weeks before the fire some of the officers took it upon themselves to have built in one side of the lounge a large fireplace. For the construction of this fireplace

and chimney one of the soldiers in camp who said he was an expert bricklayer was called in.

Engineer officers examining the ruins of the building, which incidentally consisted only of a few charred timbers and the remains of the fireplace, state that the fireplace itself was of very poor construction. It seemed to have been built of scrap material, one officer stating that he had noticed five distinct classes of material and three grades of cement. These materials were 12 x 12 x 8-in. hollow-tile blocks, face brick, common brick, firebrick and concrete. The mortar used was evidently portland cement for the main body of the work with possibly lime added, fireclay for part of the fire lining, and plaster of paris for the last few layers of firebrick lining. Evidently, the mechanic had ransacked the camp for scrap material which he had put together as best he could. Officers examining the chimney after the fire found that it was full of openings which distinctly showed light through and which would readily have communicated fire to the surrounding timber.

A board of examiners, consisting of medical officers, did not seem to think that the fire could have originated in the chimney, but assumed that the start was probably due to either defective wiring or incendiary origin. While the engineer officers' report does not definitely so state, it is very evident that it is their opinion that the chimney was the source of the fire, and there seems to be also an unvoiced criticism of the medical officers for taking upon themselves the construction of a chimney and fireplace without proper engineering advice.

Latin and Greek as Preparation for Engineering

Dr. Mortimer E. Cooley, President of American Society of Mechanical Engineers, Advocates Teaching of Dead Languages

IN AN article published in *The Evening Sun*, New York City, Dr. Mortimer E. Cooley, dean of the colleges of engineering and architecture, University of Michigan, and president of the American Society of Mechanical Engineers, deplores the fact that in the future education of our youth Latin and Greek and other so-called dead languages are to play so small a part. He advocates the teaching of these languages as a means for training engineers for responsible citizenship. Extracts from his arguments favoring this educational procedure follow:

Even as a preparation for engineering I have for years considered that there was no better training than Latin and Greek. Most of the big engineers of today went to college when Latin and Greek were prime in the curricula. They were classical students—many of them. There was comparatively little of engineering science in those days and therefore plenty of time for something else than mere technical training.

Why, then, give our youth a smattering of this and that so-called practical thing as a preparation for college? How much better it is to give them something not only preparing them for college but starting them off in life so as to be of maximum use to themselves and their fellow men. Most young men have only four years in college; they have forty years afterward in which to learn and practice the bread-and-butter part of their life. The one great need today from our educational institutions is training for responsible citizenship.

Starting back in the grade schools, I would eliminate all fads and stress those things which make for an understanding and appreciation of natural things surrounding us.

Toward the end of the grades and before the high-school period I would start in with Latin, giving to it the importance that it formerly had, but teach it not as a dead but a live language; and along with it take up history and the natural sciences, all in preparation for later study of these subjects.

In the high school I would still keep away from fads and hammer away on the fundamentals, stressing all those things which fit one to live one's life better and getting out of it enjoyment for oneself and those with whom one has to live.

The college should follow along the same lines, stressing in the early years the things which make for general training, leaving the special things for a later period. Comparatively little specialization should, however, be done in the college. The work leading to the bachelor's degree should in the main be for general education. Following the college should come specialization in the field of one's lifework.

Advice to Young Engineers

This plan would add a year, perhaps two, but the delay would not really be any handicap. It certainly would not be so in engineering. One large employer of engineers complained that college engineers nowadays were unsatisfactory; that while they knew special engineering things extremely well, they did not know anything else; that what employers needed were young men of parts, those who could take part in activities not of a strictly technical character; that more than all else the world today needed engineers of imagination and vision to see beyond the walls built up around them in college.

For the young American going into engineering I would advise a thorough preparation in fundamentals, eschewing all fads, even manual training and the practical things thought so essential to his success, and including: Not less than two years of Latin, preferably three or four years; considerable history; some political economy; a good knowledge of English and of literature; a speaking knowledge of at least one foreign language, and if only one it should be Spanish; some philosophy and as much as possible of art, music and other things apparently having nothing to do with engineering.

This would bring to the world a type of engineer now rarely met—one, who besides being able to do the things required of him as an engineer, would be able to do other things vastly more important, it may be, and which only one with an engineering training could do. In a word, it would give to the world generals of engineering—masters of organized effort.

Studies of Compound Water Meters

Observations on compound water meters, with a view to their possible adoption by New York City as an aid in lessening under-registration, were made recently by the Department of Water Supply. Some notes on the subject were presented at the February meeting of the New York Section of the American Water-Works Association, by Fred B. Nelson, an engineer in the department. The tests indicated considerable saving. Particular attention was given to the regulating valve control between the small and the large meter. It was suggested that on 4-in. meters, for example, the bypass meter be increased in size so as to operate up to about 5 cu.ft. per minute, when the large meter should come into use and the bypass meter either be cut out, or, at least, the pressure difference on it be so cut down as to divert more abruptly to the large meter a flow sufficient for more accurate registration.

Letters to the Editor

Comment on Matters of Interest to Engineers and Contractors Will Be Welcome

A Definite Comparison—Engineer's Salary Versus Laborer's Wage

Sir—I have followed with keen interest the discussion in your journal with reference to the compensation received by engineers, as I will graduate from high school this June and contemplate taking up the study of engineering.

Last summer I visited my brother in Dayton, who is a graduate of one of the foremost engineering colleges in America and at the time was employed by the Bureau of Aircraft as a structural designer and was receiving a salary of $150 per month. He suggested that I get a job at McCook Field for the summer, as the Government was badly in need of men. This I did, and as I am unskilled I was hired as a laborer. On Aug. 1, my brother received his usual half-monthly pay, $75, while I received for the same period $80.40. Of course, I had put in considerable overtime, but so had he—including Saturday afternoons, Sundays and three evenings a week till 9.30, the only difference being that it showed up in my pay and not his.

As the result of this and similar conditions described by your readers, I am rather dubious about investing four years and $6,000 in a profession while such a premium exists on ignorance, for I feel as if it will be at least three years after I graduate before I will earn $160 per month, the equivalent of my earning capacity as a 17-year-old laborer.

New York City. LUCIEN ALTER.

More on Shear in Concrete

Sir—Not with the idea of continuing the discussion, but as a suggestion on some matters that the profession would do well to ponder, especially if revision in standards is contemplated, the writer would like to comment once more on the article and letters on the strength of concrete in shear which appeared in *Engineering News-Record*, of Feb. 27, 1919, p. 430, and Apr. 17, 1919, p. 783.

If the maintenance-of-way department of a railroad knew that a certain rail had an incipient transverse fissure, it would remove that rail from the track. There can be no doubt that these fissures and the rail failures that they cause are progressive. Other failures also are progressive. I have seen in broken axles undoubted proof that the failure was progressive. This is shown in the rusted portion of the fresh break, demonstrating that failure had begun some time before. This start of the axle failure is really the ultimate point of its usefulness. Repetition of the same load, or maybe less, is what breaks the axle. In a static test the axle that has started to fail may stand several times the load that it is commonly carrying.

This is a thing of which investigators and writers often lose sight. A concrete column that has begun to crack under a certain load may crack somewhere else under the same load repeated. A beam that has cracked, due to excessive shear of diagonal tension under a certain load, may crack somewhere else the next time the same load is applied, and keep on cracking until failure results. This is, then, the real, ultimate strength or ultimate point of usefulness of that beam in shear so far as the concrete is concerned, and not some higher load the beam may stand under very careful application of a static test.

I confess that I did not observe that test 4-AD-1 had flanges and stirrups but no concrete web, as Mr. Slater points out in his letter in the issue of Apr. 17. Why is not this test 4-AD-1 pertinent in determining how much of the shear passes through the web? It shows that even at a great disadvantage these two separated flanges enable the beam to carry half as much shear as one with a web to join them and make them act together. This test proves my contention exactly. Here is a beam without a concrete web which stood a shear about half as great as one with a web measuring nearly 90 sq.in. in area. It is my contention that in a reinforced-concrete beam with a web where the full shearing value is attributed to the concrete web, the unit shear in that web can be made to appear any desired intensity up to infinity by merely reducing the thickness of the web.

Pittsburgh, Penn. EDWARD GODFREY.

Private Employment Agencies Upheld

Sir—In your issue of Feb. 13, 1919, p. 328, C. E. Drayer, secretary of the American Association of Engineers, discussed the establishment of centralized employment offices by the engineering societies, as a means of eliminating the "leeching private agencies . . . sucking from the unfortunate engineer who is out of employment from 50 to 60% of his first month's salary." The following facts are submitted for consideration in this connection:

Under the fourteenth amendment of the constitution of the United States individuals have the right to engage in useful business. The United States Supreme Court in 1917 decided that a private employment agency was a useful business. This decision contained the following phrases: "Not inherently immoral, or dangerous to public welfare"; "such service is useful, commendable and in great demand"; "business is as legitimate as that of a banker, broker, or merchant, and may be said to be a necessary adjunct to modern business"; "business is not only innocent and innocuous but highly beneficial," and that "such agencies have been established for so long a time that they are now one of the necessary means whereby persons seeking employment are able to secure the same."

Private agencies have existed in competition with many forms of free service for many years. Men have not been compelled to patronize these offices, and are not now. The free methods of employment outnumber the paid agencies one hundred to one. The leading engineering societies have operated free employment departments for many years, presumably for the purpose of rendering service to their members as a whole and not as self-constituted redeemers of less than one per cent. of their members, who through choice patronize paid employment agents, against whom the worst that can be said is that they charge commis-

sions, though these commissions are covered in a signed contract in advance, and are contingent entirely upon the acceptance by the applicant of a satisfactory position.

What is to be shall be. If some new scheme of free employment service is to prove all-satisfying, then paid agencies will be no more. Until then, why not presume that the Supreme Court's appraisal of private agencies is correct and cease to insult the intelligence of those who prefer this method of finding employment?

A. G. FROST,

President, National Association of Technical, Educational and Commercial Employment Agencies.

Chicago, Ill.

Distributed Passenger Terminals

Sir—A rather erroneous idea of the terminal and traffic of the Aurora, Elgin & Chicago Ry. is given in the editorial on "Distributed Versus Centralized Passenger Terminals," in *Engineering News-Record* of Apr. 17, 1919, page 752. The trains of this electric railway connect with the Garfield Park branch of the Metropolitan Elevated Ry. at Laramie Ave. and run over this line for 6½ miles to a downtown terminal on Wells St., the west boundary of the loop district. Some of the elevated trains also use this terminal, but most of them go around the elevated loop. The Aurora, Elgin & Chicago Ry. trains do not handle local traffic on the elevated line and do not stop at the stations on this line, with the one exception of Marshfield Ave., a junction point, where inbound passengers can get off and outbound passengers may board the trains. The Aurora, Elgin & Chicago Ry. has its own ticket office and entrance at the Wells St. terminal, separate from the facilities of the elevated railway. Baggage is not handled on the regular trains.

The Chicago, Lake Shore & South Bend Electric Ry. runs certain of its trains over the terminal lines of the Illinois Central R.R. to the downtown terminal at Randolph St. These trains are handled by steam locomotives between Randolph St. and Kensington, 15 miles. Plans have been proposed at various times for bringing other south-shore electric lines into the La Salle terminal station by means of an elevated structure over the right-of-way of the steam lines. It has been proposed also to bring trains of the Chicago, North Shore & Milwaukee Electric Ry. into the city over the Northwestern Elevated Ry. As this electric line has its terminal at Evanston, 12 miles from Chicago, it is felt that it is handicapped by so long a transfer on the elevated trains, as passengers to Milwaukee and intermediate points find it more convenient to take trains of the steam railways at their city terminals.

Chicago, Ill. RAILWAY.

Utilitarian or Scenic Highway Locations

Sir—The writer was very much pleased to see your editorials in *Engineering News-Record* of Apr. 10, 1919, p. 698, in regard to the desirability of making our improved roads scenic rather than straight-line highways. Not only is it usually the case that the contour road involves very much less cost per mile, but, except in very irregular country, it will usually be found that the cost between terminals is also much less, although the distance will be somewhat greater.

The driver of a heavy truck, and for that matter the speed maniac, is chiefly concerned with getting between points in the shortest possible time. But growing sanity in regard to the use of motor trucks, and a better realization of the fact that the use of the 10 or 12 motor trucks required to handle the contents of an ordinary freight car results in a net cost to the community (where the haul is of any length) much greater than the cost of the same transportation on the railroad, whether steam or electric, is rapidly restricting the motor truck to its proper field of short hauls in the city, while the furious speeders are after all a small proportion of the users of the highway.

The average man is concerned to no small extent with the beauties of the country, and that road which winds somewhat so that the points of interest develop one by one as the ride proceeds, particularly appeals to him. This fact, in connection with the lower cost, would seem sufficient argument against the straight-line trunk.

Incidentally, there is another point of considerable importance against the latter road, when, as is so often the case, it involves considerable cutting. In a country where there is snow, these cuts serve as accumulators of snow, and, to a very considerable extent blocking of traffic through the winter weather results. This tendency to leave through cuts is often followed, even in cases where one side is little more than a shell. Such a proceeding leads to drift troubles in winter and often serves to spoil what might otherwise be a beautiful view.

The writer has particularly in mind a fine highway from Avon, Conn., to Hartford, over Talcott Mountain, where what should be a marvelous view of the beautiful Farmington River valley is blocked off by such cuts to a very considerable extent. In this case, the addition of a small yardage to make a side-hill excavation would have cleared most of these obstacles away. Unfortunately, this road is anything but an exception. Moreover, I am confident, although in this case I do not know from personal observation, that these cuts are sources of serious trouble in every snowstorm of any moment.

New Haven, Conn.

Thoughts From a Reader and Contributor to Technical Journals

Sir—We sometimes ask ourselves, What is the value of technical articles? The average engineer subscribes to technical journals in the hope that he will receive from them educational benefits in his line. Contractors and machinery makers take them to keep posted on business activities.

Lately the professional journals are taking an active part in trying to better the working conditions of the profession. It is a great and laudable work that strives to obtain for civil engineers the same wages as the aristocratic bricklayers and plasterers have earned for years. Looks as if we had hitched our wagon to the star.

We were too proud to fight, but we finally got busy and did a good job of scrapping in the Argonne. Marquis of Queensberry rules were laid aside. We have been too proud to unionize, but we are hitting

in that direction. "Civil Engineers' Local No. 23 Meets First Wednesday in the Month."

But to get away from sordid money thoughts back to the rarefied atmosphere of technical authorship. Technical journals would do well to solicit longer articles, those in which the author builds up his thought, and thus allows his readers to absorb a little real knowledge. "Be brief" is a good motto for a telegram, but articles which are merely a synopsis impress very few. All articles are not of universal interest. There may possibly be a few persons who read a technical journal from cover to cover, but the majority pick out one or two articles that come within their purview and interest. Consequently, articles that are worth reading should not leave out half the information—an author saturated in his subject expects us to do liaison work between disjointed paragraphs. Instead of being brief, be complete.

Renton, Wash. FRANK W. HARRIS.

Engineering and the Popular Magazines

Sir—I have just returned from the service and have examined with considerable interest the numbers of *Engineering News-Record* issued during my absence, particularly those articles pertaining to education, reimbursement, and the status of the profession. Perhaps a word from a young member of the profession would not be amiss.

It is true, perhaps, that the engineering profession has been underpaid, and correspondents have called attention to the fact that routine work may be performed by men not having the broader training of the engineer. Yet today we are constantly reminded that men of technical training capable of performing administrative work are in demand. Montesquieu, the French essayist, divided mankind into three classes—briefly, the captains, the lieutenants and the privates. An engineer is a member either of the first or second class. That being the case, shall we not avail ourselves of this opportunity for which a technical training is so valuable? In this connection we may note that a principal failing of engineers is general lack of knowledge of business methods and conditions. Why not estimate our abilities, and if found deficient, promptly remedy the evil?

Respecting the status of the profession and engineering education: The April number of *Harper's Magazine* contains an article entitled "The Chemists of the Future," similar to one I have long hoped some able engineer would write for publication in a popular magazine. If the status of the profession is to be raised, why discuss it only in engineering periodicals? Ellwood Hendrick, author of this article, says: "There is, nevertheless, a journeyman side to chemistry, and I think we should prepare for it. . . . Such a career provides a fair living, and it is not more monotonous than keeping accounts. . . . If we have been trained as laboratory helpers, without the theory and vision of chemists, then that is what we shall remain. . . . Of course, men will call themselves what they please, we cannot legislate titles. But it seems to me of vital importance that only those students of today should become chemists who are properly equipped to meet the g eat responsibilities which are there to encounter. It is the coming profession."

The general public has as little exact knowledge of the chemist's scope as it has of the engineer's. Assuming this, Mr. Hendrick writes lucidly, tactfully, so that the layman readily grasps the point when he speaks of catalysis, colloids, osmosis, etc. Here is a nine-page article in a publication suitable for telling the intelligent public the generalities of the profession's work. Cannot a competent engineer follow this worthy example? Cannot the purpose of raising the status of the engineer be gained more efficiently and to a wider extent by articles in the current magazines rather than in engineering periodicals? It should be remembered that as a class those who employ engineers do not read our literature. One very ready method would be a series of articles in our local newspapers describing the work of the various departments of the city engineering department and the necessary qualifications of the employees.

One other point of note in the above-mentioned article is related to engineering: "Municipal wastes must be conserved. . . . There are places along the East River where the water is not changed by the tide, and its condition is already septic. . . . Conditions must be changed and it is the chemist alone who can change them."

Shall the chemist outrun the engineer?

Washington, D. C. CHARLES W. BARBER.

Should Spend $1,000,000 on Topographic Maps

An annual expenditure of $1,000,000 for the topographic mapping of the United States is justified, in the opinion of Franklin K. Lane, secretary of the interior, in a letter to M. O. Leighton, chairman of the National Service Committee of the Engineering Council. Mr. Leighton had written to the secretary calling attention to the essential relation of the topographic mapping of the country to good engineering and the economic development of our resources. In replying, Secretary Lane said that the Geological Survey now has available a trained personnel sufficient to permit a large expansion of the Government's activities in topographic surveys; a summer school was established by the Department of the Interior for training young engineers in military mapping and to furnish the Engineer Corps with officers for this specialized service. Most of the men so trained are now available to supplement the regular topographic force of the Geological Survey. Mr. Lane's letter continues as follows: "For this reason, an annual expenditure of $1,000,000 on the topographic map of the United States is now justified both by the public needs and the ability of this department to perform this work economically and effectively. In such a program it is hoped that the states might increase their coöperative contributions to $500,000, especially as the coöperation for the two years past was necessarily interrupted by the military mapping being largely confined to a few border states. I am told that in several states the officials are now urging the completion of the coöperative mapping of their states within the next few years. . . . My present purpose is te submit a supplemental estimate to the 66th Congress, as you suggest, increasing the appropriation for topographic work to $500,000. The support of this larger program by the Engineering Council, representing as it does the great national societies, will be appreciated."

HINTS FOR THE CONTRACTOR

DETAILS WHICH SAVE TIME AND LABOR ON CONSTRUCTION WORK

Telescopic Pipe Carries Steam Supply to Traveling Derrick

TO AVOID the difficulties attendant upon the use of steam hose for a track derrick whose travel was several hundred feet, the "shotgun feed" was applied by E. B. Van de Greyn, chief engineer of the Beaumont Shipbuilding and Dry Dock Co. The device consists of three long pieces of pipe of three different sizes. The smallest one was connected to the traveler. The next one received the smaller one and had a stuffing-box on the end. In the same way this medium-size pipe passed through a stuffing-box on the end of a larger pipe and telescoped into it. The largest pipe was stationary, being attached to the steam main from the power house. This arrangement was found entirely satisfactory, very little steam was lost, and, while the pipe was lined up carefully at first, it was found later that such care was not necessary. At the bottom of the derrick or tower a water trap was provided to dry the steam before it reached the engines. This would, of course, have been necessary with any such long line, without regard to the telescopic feature. J. W. Link is president and general manager of the Beaumont Shipbuilding and Dry Dock Company.

Other Articles in This Issue of Interest to Contractors:

Compressed-Air Shortage Relieved by Waste-Prevention Campaign

SHORTAGE of compressed air became critical at the Fore River yard of the Bethlehem Shipbuilding Corporation, Ltd., a year and a half ago, just after production was sharply speeded up by the war demands. The period started with 150 to 160 riveting gangs, and in a few months this force had increased to 300 gangs. Even with the smaller number, however, the air was short, and often at 10 a.m. the pressure was down to 50 lb. A remarkably successful waste-prevention campaign was then inaugurated, and it solved the difficulty. The air consumption per gang was cut down to less than half, and the pressure was kept up to normal throughout the day.

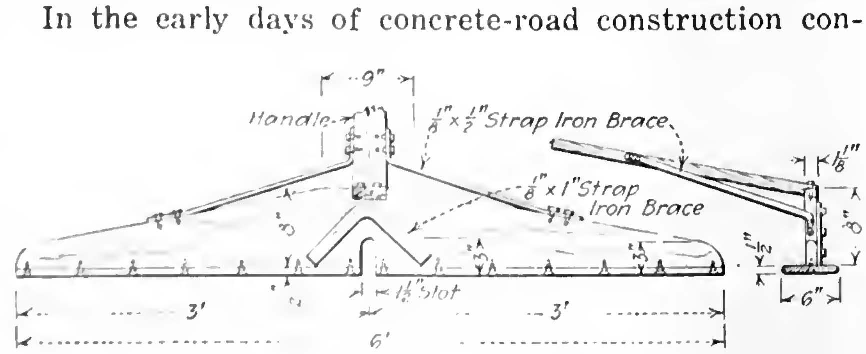
As soon as the shortage became critical, an investigation started by direction of the general manager, S. W. Wakeman, showed widespread evidences of leakage and waste. A 12-man patrol was sent out to stop leaks wherever found in the yard, and the shops were policed. The men of the patrols had orders to cut all leaky hose. Blowing snow off material by compressed air was also stopped. This positive work was aided by educational work through posters. In a short time the air consumption, which had run up to 60 cu.ft. per minute per riveting gang, was brought down to nearly 30, and then down to 25 or lower. On the biggest operating day, Aug. 1, 1918, there were 315 riveting gangs at work in the yard, which means several times that number of air tools in operation; yet the pressure was held up to 90 pounds. Addition of two 5000-cu.ft. electric compressors later increased the previous capacity of 12,600 cu.ft. per minute by displacement to a total of 23,600 cu.ft. Before the new machines were in, a 1000-ft. compressor was rented, and later two 1700-cu.ft. machines were borrowed from the equipment built for the new Squantum plant. Except for these two temporary additions, however, the old installation had to carry the load. A year ago the air consumption ran up to 11,000,000 cu.ft. in 24 hours, by piston displacement; the present consumption ranges from 8,000,000 to 9,000,000 cu.ft., in spite of a 50% increase in the number of gangs working. The following figures for three consecutive days, from a recent record sheet, are representative:

246 gangs, 26.61 cu.ft. per minute per gang, 9,000,000 cu.ft. displacement per 24 hours.
247 gangs, 24.23 cu.ft. per minute per gang
253 gangs, 22.32 cu.ft. per minute per gang
273 gangs, 23.70 cu.ft. per minute per gang

Split Float for Finishing Concrete at Expansion Joints

FINISHING the surface of concrete pavement at transverse expansion joints (where the expansion material projects above the surface), in order to give a uniform elevation on each side of the joint is accomplished by means of the split float illustrated. While the use of split templets on concrete-road work is not new, the float shown has some features which are of value.

In the early days of concrete-road construction con-



SPLIT FLOAT OF SIMPLE CONSTRUCTION EFFECTIVE AT TRANSVERSE JOINTS

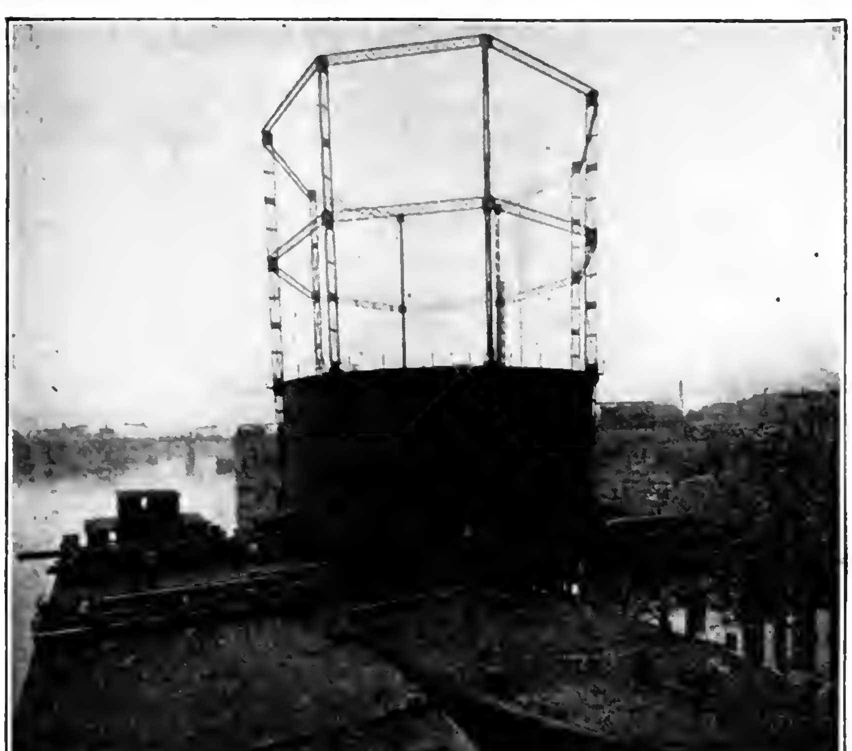
siderable trouble was experienced in making the adjoining slabs at the same elevation. The unevenness due to difference in elevation was disagreeable to traffic and caused excessive wear, often resulting in the destruction of the pavement. To overcome this, various methods, using split templets, etc., were devised; all of them required the finishing of the surface on the two sides of the joint independently. The device here described is so constructed that both surfaces may be floated at the same time, assuring uniformity.

The dimensions and construction of the float are clearly indicated by the illustration. In operation it is easy to tell at once where concrete should be removed or filled in adjacent to the joint, by the way the float rests on the surface. The slot is made to fit over the expansion joint as with the ordinary split straightedge, while the flat 6-in. board on the bottom floats the concrete to a perfect surface which is in the same plane on both sides of the joint.

This device, which was described in the *Concrete Highway Magazine*, was successfully used by the Connelly Construction Co. on the Bartlesville-Dewey road at Bartlesville, Okla.

Gas Container 70 Feet in Diameter Moved on Two Barges

THE gas container pictured herewith we recently moved a distance of 3 miles in Portland, Ore. It is 70 ft. in diameter and 75 ft. high, and weighs 300 tons. It was raised a distance of 15 ft. and loaded on rollers at Front and Everett Sts., then moved two blocks north



300-TON GAS CONTAINER BEING ROLLED ONTO BARGES FOR THREE-MILE VOYAGE

and two east, being lowered from the street to dock level, a distance of 28 ft. It was then rolled onto two barges lashed together, using hardwood rollers with block and tackle and a large gasoline engine. The barges were then towed three miles to the Northwest Steel Shipbuilding plant, where the tank was unloaded and raised 26 ft., moved across newly filled ground a distance of 2000 ft. (crossing a railroad track) and placed on its new foundation. The entire work required 71 days.

The tank was moved by Clay S. Morse, Inc., under the supervision of C. J. Disler, engineer of Le Doux & Le Doux, general contractors.

Pipe Line Lowered by Side Cuts Allowing Core to Squeeze Out

SINKING a 48-in. reinforced-concrete pipe line to grade by excavating along either side and allowing the triangular ridge or core to crush down under the weight of the pipe, was the method employed in lowering a part of the Signal Hill storm drain at Long Beach, Calif. About 300 ft. of pipe had floated above grade line in the 10-ft. trench, and backfilling was deposited before this condition was discovered, the maximum rise being about 14 inches.

In reopening the trench, excavation was carried down to 12 in. above the bottom of the pipe, and seepage water was then allowed to collect, the balance of the excavation being done under water. For this work the material was taken out only at the sides, the weight of the pipe, 900 lb. per linear foot, crushing down the ridge of soft, wet earth beneath it. The excavation was carried on in this way until the pipe had regained its original position. The advantage of this procedure was that the pipe was supported continuously and was lowered as a monolithic structure. Only one joint was damaged during the operation, but five had been cracked when the pipe rose.

Plans for the drain were prepared by R. V. Pearsall, of Long Beach, Calif., and James Kennedy, of Los Angeles, Calif., was the contractor.

Thaw Ice Cakes to Clear Foundation

ICE formation nearly 4 ft. thick piled up along the Mohawk River at the time when the General Electric Co. pumping station at Schenectady was built during the severe winter of 1917-18. The accompanying view shows how the contractor, Keith O. Guthrie, of Schenectady, got the impeding ice out of the way. The ice was first cut with steam jets, and pieces weighing several tons each were picked up with the nearby derrick and hoisted out of the way onto the adjoining bank.

NEWS OF THE WEEK

New York, May 8, 1919

New York Public Service Commission Abolished

New State Law Establishes Two Independent Commissioners—Nixon Appointed, but Parsons Declines

With the signing of the Foley bill by Governor Smith of New York State May 3 the Public Service Commission (of the First District), which has been carrying on both regulation of utilities and construction of rapid-transit lines in New York City for 10 years, was abolished, and a single utility-regulation commission was established to take up its regulative work. Under another legislative bill, not yet signed, construction of rapid-transit lines is to be handled by a separate organization under a rapid-transit construction commissioner.

Immediately following his signing of the new public-service law, Governor Smith appointed Lewis Nixon, state superintendent of public works, as regulation commissioner for the city. Mr. Nixon, graduated from Annapolis in 1882, was a naval constructor for many years, and then established a shipyard at Elizabethport, N. J. Later he was chairman of the new East River Bridge Commission which built the Williamsburg bridge, and subsequently became Commissioner of Public Works and acting borough president of Richmond (Staten Island), New York City. He was appointed Superintendent of Public Works for the State of New York in January. His deputy, Edward F. Walsh, succeeds to this position.

Col. William Barclay Parsons, 11th Engineers, to whom Governor Smith some weeks ago offered the position of rapid-transit construction commissioner, to complete the proposed reorganization of the Public Service Commission, has declined to accept. Until a construction commissioner is named, Mr. Nixon will perform the duties of this office. Three members of the Public Service Commission of five were in service at the time when the commission's existence ended: Travis H. Whitney, acting chairman and formerly secretary of the commission; F. J. H. Kracke and Charles S. Hervey.

Extensive Changes of Personnel in Fleet Corporation

Important changes in the Emergency Fleet Corporation took effect May 1. Chief among them was the retirement of Charles Piez as director general and Howard Coonley, as vice-president in charge of administration. At the same time Admiral H. H. Rousseau, head of the shipyard plants division, Daniel H. Cox, head of the steel ship division, and four other division heads retired. Steel-ship construction will hereafter be in charge of Pierce J. McAuliffe, hitherto first assistant. Capt. R. N. Bakenhus becomes head of the shipyard plants division.

Employment Bureaus

Engineering Societies' Employment Bureau, 29 W. 39th St., New York City.

American Association of Engineers, 29 S. La Salle St., Chicago. Service to members only, but Army or Navy Engineers in uniform who are eligible to certified membership may join without payment of entrance fees or dues while in uniform and for six months after discharge.

Engineers' Service Bureau, 57 Post St., San Francisco. Only applications by mail or wire will be considered.

Professional and Special Section, United States Employment Service, 469 Fifth Ave., New York City.

Reëmployment Committee of New York City for Soldiers, Sailors and Marines, 233 Broadway, New York City.

Pay and Classification of Engineering Positions

Engineering Council has appointed a committee to investigate the compensation of engineers and to formulate a standard classification of engineering positions, with corresponding rates of compensation. The general committee is organized in sections, each of which has charge of a particular field of engineering work. The chairman of the general committee is Arthur F. Tuttle, deputy chief engineer of the Board of Estimate and Apportionment of New York City. Mr. Tuttle is also chairman of the municipal engineers' section. The chairman of the section which is to deal with engineers in the Federal Government service is John C. Hoyt, of Washington, D. C., hydraulic engineer of the United States Geological Survey. The chairman of the railway engineers' section is Francis Lee Stuart, consulting engineer, New York City, late advisory engineer to the Federal Railroad Administration. Each of these sectional committees is proceeding with investigations and obtaining from as wide a field as possible records of such classifications of engineering positions as are now in force, with the rates of compensation.

Chamber of Commerce For Federal Highways

Annual Meeting at St. Louis Also Passes Resolutions for Water-power Development

The Chamber of Commerce of the United States, at the annual meeting held in St. Louis Apr. 30, passed resolutions urging the creation of a Federal Highway Commission, and Federal appropriations for highways; development of waterways and water-power, and a resolution against Government operation and ownership of businesses which can be successfully undertaken and conducted by private enterprise.

The resolution regarding a national highway system states:

"That highways are an integral part of our nation's system of transportation has been emphasized by the war, and an enormous development is at hand, so important as to require a comprehensive national policy, under which Federal appropriations for highways will be applied to national needs for interstate commerce, agriculture, postal delivery, common defense and general welfare.

"Congress should create a Federal highway commission, independent of present departments of the Government, composed of members from the different geographical sections of the country, to perform all executive functions of the Federal Government pertaining to highways, including those relating to existing appropriations in aid of state construction. Such a commission should act in coördination with any Federal agency that may have functions of articulating rail, trolley, water and highway transportation.

"Congress should make substantial appropriations for the construction and maintenance of a national highway system to serve the need for the maintenance of interstate travel and traffic.

"The commission should report to Congress a plan for continued aid for state construction of highways in the period beyond 1921, to which time the provisions of existing Federal-aid laws extend.

"Expenditures of funds should be permitted only for highways which are of a permanent type, having thorough drainage, substantial foundations, sufficient width and a capacity for traffic which will be reasonably adequate for future needs."

Another resolution favored the speedy completion of river improvements and water-way projects already authorized by Federal laws, and another the "true conservation of the water-power resources of the United States."

The resolution regarding Government

operation and ownership is as follows:

"The very essence of civilization is that there be placed upon the individual only that degree of restraint which shall prevent his encroachment upon the rights of others, thus realizing to the utmost individual initiative in every proper direction. Our form of government most effectively expresses and maintains this principle. Within our basic law exists ample provision for such changes as may, from time to time, be necessary to safeguard our people.

"It is therefore essential that our Government should scrupulously refrain from entering any of the fields of transportation, communication, industry, and commerce, or any phase of business when it can be successfully undertaken and conducted by private enterprise. Any tendency of Government to enter such fields should be carefully weighed in the light of its possible effect upon the genius of our Constitution."

Extensive Ship Cancellations to Readjust Program

In addition to 2,000,000 tons of steel ships the contracts for which have been cancelled since last November by the Shipping Board, 2,000,000 tons more are now being cancelled, according to a statement by Edward N. Hurley, chairman of the board. No details are given as to the sizes of ships and the yards affected. The statement refers to the necessity of balancing the fleet and also to the war prices of the contracts. Chairman Hurley says, "We feel that we should now be building only at peace prices," and states that the cancellation of all existing contracts is under contemplation, where keels have not actually been laid. This statement, issued from the Shipping Board office Apr. 25, is amplified and somewhat changed by a statement issued May 5. According to the latter, the type of vessel that will be most largely needed for post-war ocean carriage is a combined freight and passenger vessel of at least 12,000 to 15,000 tons dead weight carrying capacity, and the cancellations are to be made with a view to preparing for placing orders for this type of ship.

Plant-Disposal Section Created To Sell Shipyards

Preparing to put on the market the Emergency Fleet Corporation's interests in shipyards and ship-fabricating plants, the Director General has established a plant disposal section of the corporation, in charge of B. E. Grant, hitherto engineer of the shipyard plants division. Property totaling several hundred million dollars in value is involved, and it is desired to put these great interests into private hands as going concerns. It is stated that the corporation already has an offer from one of the Southern concrete yards to take over the yard, with a view to building a concrete dry dock.

11th Engineers Parade in New York

Unit That Held Germans Before Amiens Marches Down Fifth Avenue Soon After Arrival

The 11th Engineers of the United States Army, the unit that held the Germans before Amiens a year ago last March, paraded down Fifth Avenue, New York City, Apr. 30, led by its commander, Col. William Barclay Parsons, a few days after the regiment's arrival at the port of debarkation at Hoboken, N. J. Thirteen hundred of these men, who had served overseas for 22 months, marched between cheering crowds along Fifth Avenue from 96th St. to 34th Street.

Col. William Barclay Parsons marched with his staff at the head of his command. He was accompanied by Lieut. Col. William T. Chevalier. Maj. Charles D. Drew led the first battalion and Maj. B. A. Value the second. In the official reviewing stand, opposite 82nd St., were Governor Smith, Mayor Hylan, Deputy Police Commissioner Rodman Wanamaker, Brig. Gen. F. V. Abbott, and Maj. Gen. D. C. Shanks, in charge of the port of debarkation at Hoboken.

At 34th St. the regiment swung off the avenue and proceeded to the Pennsylvania Hotel, where a dinner tendered by the Military Engineering Society was served. J. Waldo Smith, chief engineer of the Board of Water Supply, City of New York, and chairman of the Committee of Welcome of the Military Engineering Society, introduced Colonel Parsons, who spoke of the pride of the engineering profession in the deeds of his men. Colonel Parsons declared that two things in the regiment's war career had almost escaped the notice of the public.

"A year ago last March," he said, "when the Germans began their great offensive, flinging masses of men between the British and French line, which bent and fell back, but—thank God!—never broke, and when General Pershing was told that two regiments of engineers were needed at the very front, there was never any question about the first regiment chosen—it was the 11th. They thought for some time before selecting the second regiment.

"The other thing is the rise of the enlisted men. Sixty-eight became commissioned officers during the war."

Free Service Bureau of Contractors' Association

In the interest of obtaining competent general contractors' employees, the Associated General Contractors of America have established a free service clearing house for members. G. W. Buchholz, acting secretary, 111 W. Washington St., Chicago, has issued a call as follows:

"Whenever you are obliged to dispense with the services of a general foreman, superintendent, engineer, estimator, bookkeeper, or any other employee whom you consider worthy, send his name and address to this office, with a short description of his abilities and past record, salary that you have been paying him, whether he is married or not, and if he is willing to go to any part of the country. If you contemplate increasing your force in any way, notify this office, stating the type of employee you desire, approximately what his duties will be, and the amount of salary you expect to pay."

National Conference on Training for Commercial Engineering

A national conference on "Business Training for Engineers and Engineering Training for Business Men" will be held in Washington, D. C., June 23-24. This conference is called by Commissioner of Education Claxton on behalf of a conference committee on commercial engineering recently created by the Department of Education. Representatives of all general interests, all educational institutions, commercial organizations, and engineering societies will be invited to participate.

Active Discussion Expected at A. S. T. M. Meeting

Unusually active discussion of test methods and results will mark the 1919 meeting of the American Society for Testing Materials, according to present indications. While committee reports will be less extensive than in normal years, and it is likely that only one or two new specifications will be presented, the program of papers will be of exceptional character. A topical discussion of "Magnetic Analysis of Steel" is to be made a prominent feature. The meeting will be held at the Hotel Traymore, Atlantic City, N. J., June 24-27.

In the field of iron and steel, a subject of special importance at present will be covered by a paper on "Deep Etching of Rails and Forgings," by K. E. Hofammann and F. M. Waring. Other important papers are: "Modern High-Speed Steel," by J. A. Mathews; "Some Fatigue Tests of Nickel Steel and Chrome-Nickel Steel," by H. F. Moore and A. G. Gehrig, and "The Influence of Very Low Percentages of Copper in Retarding the Corrosion of Steel," by D. M. Buck. The discussion of magnetic analysis will be opened by five papers, including among other things the application of the method to ball-bearing races, rifle-barrel steel and railroad rails. In nonferrous metals, season-cracking of wrought manganese bronze will be further discussed by P. D. Merica and R. W. Woodward.

Half a dozen papers on cement and concrete of an unusual degree of interest are to be presented. They include "Theoretical Studies of the Surface-Area Method of Proportioning as Applied to Concrete," by R. B. Young; "Proportioning of Pit-Run Gravel for Concrete," by R. W. Crum; "Modulus of Elasticity of Concrete," by Stanton Walker; "Effect of Fine-

ness of Cement," by D. A. Abrams, and "Cements Producing Quick-Hardening Concrete," by P. H. Bates. Instruments will be dealt with in papers on "The Strainagraph and Its Application to Concrete Ships," by F. R. McMillan; "A Fatigue-Testing Machine," by F. N. Farmer, and "A Machine for Measuring Hardness of Thin Metal Sheets," by S. L. Goodale. In the field of preservative coatings a new view of the subject will be presented under the title of "Paint a Plastic Material and Not a Viscous Liquid; The Measurement of Its Mobility and Yield Value," by E. C. Bingham and Henry Green. A number of more specialized papers are on the program.

The evening session of June 24 will be a memorial session for Dr. Edgar Marburg, late secretary of the society. President G. H. Clamer, Provost Edgar F. Smith, John M. Goodell, Robert W. Leslie, Arthur N. Talbot and Robert W. Hunt will speak of Dr. Marburg's activities and his work for the society.

To Retire as Secretary of Municipal League

Clinton Rogers Woodruff, for the past 25 years secretary of the National Municipal League, has announced in a letter to Lawson Purdy, president of the league, that he will not be a candidate for reëlection. Mr. Woodruff expects to devote his entire time to the practice of law. In part, Mr. Woodruff's letter to Mr. Purdy follows:

"On May 28 next I shall have completed 25 years of service as secretary of the National Municipal League. Elected at the first meeting held in New York City, I have served continuously ever since. During this period the movement for higher municipal standards and democratic city government has developed to a point where a larger share of my time and attention is required than my other interests will permit me to give. I am therefore reluctantly forced to the conclusion that I must retire, so I hereby give notice that I shall not be a candidate for reëlection to my present position."

Kansas City Viaduct Contract Let to Low Bidder

Settlement of the controversy over the contract for building the Twenty-third St. Trafficway, Kansas City, has been reached by letting the contract to the low bidder, the A. S. Hecker Co., of Cleveland, after the latter agreed to guarantee that the cost should not exceed its estimate. As noted in these columns four weeks ago (p. 743), the city council refused to award the contract to the Hecker company, and asserted that the cost-plus form of contract did not protect the city. In its final form the contract provides a fixed maximum price of $716,000 for the work; the city shares equally with the contractor in any reduction of cost below its estimate of $666,000.

Program of National Traffic Association Meeting

The annual meeting of the National Highway Traffic Association will be held at the Automobile Club of America, 247 W. 54th St., New York City, May 14. Among the speakers and their subjects are the following:

Afternoon session, 2:30 p.m., "Development of Rural Motor Express Throughout the United States," by F. W. Fenn, secretary of the motor truck committee, National Automobile Chamber of Commerce; "Transportation Surveys for Rural Motor Express Routes," by J. H. Collins, member of the highway transport committee, Council of National Defense; "Wanted, Rural Motor Express in the State of New York," by James E. Boyle, extension professor of rural economy, Cornell University; "Signposting for Through Routes in Municipalities, and Detours During Highway Construction," by Elmer Thompson, secretary of the Automobile Club of America.

Evening session, 8 p.m., presidential address, "Highway Transport Engineering" (illustrated), by Arthur H. Blanchard; "The Townsend Highway Bill and the Work of the Federal Highway Council," by H. G. Shirley, secretary of the Federal Highway Council; "Highway Requirements for Twentieth-Century Transportation," by W. G. Thompson, state highway engineer of New Jersey; "The Control of Traffic on Feeder Highways," by Edward J. Mehren, editor of *Engineering News-Record*, George H. Pride, president of the Heavy Haulage Co., and George M. Graham, manager, Pierce-Arrow Motor Car Co. The first motion picture created to show the high cost of bad roads and the advantage of motor transport, entitled "The Open Road to a Greater America," will be shown by the educational department of the Universal Film Mfg. Company.

Motor Truck Impact Tests Made By Bureau of Public Roads

Tests of importance to road builders, automobile builders, state authorities in control of speed laws, etc., were made May 5 by engineers connected with the Bureau of Public Roads of the Department of Agriculture on roads just outside of Washington, D. C. For the first time, a direct measurement of the impact of trucks on roads was made. The engineers mentioned have invented a system to measure this impact by the compression of a copper cylinder set in a chamber in the road, which is similar to the system used to measure the explosion in a rifled gun.

The device, which is the invention of Prevost Hubbard and A. T. Goldbeck, was tested on the roads of the agricultural experimental farm on the Potomac River in Virginia, in the presence of the designers, and of T. H. MacDonald, the new engineer in charge of Federal-aid roads, as well as John M. Goodell, F. H. Jackson and A. T. Smith, all connected with the Bureau of Public Roads, and the Washington representative of *Engineering News-Record.*

Details of the results have not yet been tabulated. The engineers expect to be able to announce results which will be of importance to road builders, automobile tire builders, and others.

Some Highway Engineers Coming Home

The War Department announces, in accordance with a cablegram received from General Pershing, that a few units of the 23rd Engineers have been assigned to early convoy for return to the United States from France. The units so far scheduled to come home are the fourth battalion, the wagon-train headquarters and wagon companies Nos. 1, 2, 3, 4 and 5. No information is obtainable, according to the Washington correspondent of *Engineering News-Record*, as to when the remainder of the 23rd Engineers is to return, but it is believed in Washington that the conferences which Secretary Baker had with General Pershing while in France have influenced the decision to return some of the highway engineers at this time, and it is hoped that the remainder of the regiment will be back before the road-building season is over. It is stated in Washington that other engineering units are now being scheduled for early return. Announcements as to the return of other engineering units may be expected in cablegrams from General Pershing from day to day from now on.

Proposed Legislation in Illinois to Develop 40,000 Kilowatts

The water-way scheme which has passed the senate of Illinois and which will provide a transportation waterway from Chicago to down-state and Mississippi River points, contemplates the removal of a dam in the Desplaines River at Joliet, and the construction of a modern 40,000-kw. power plant four miles farther south at a site known as Brandon's Road. At the same time, there is in the legislature a bill which will enable the Sanitary District of Chicago to bid on the power from this site, either developed or undeveloped. Should the bill pass in its present form it would enable the Sanitary District to bid not only on the new power at Brandon's Road, but also on the power from the old site, which has been the cause of so much court action in which the Economy Light & Power Co. was an interested party.

Civil Service Examinations

New York.—Junior assistant engineer, State Engineer and Highway Department, $1200-$1440 per year, May 24. Apply to State Civil Service Commission, Albany, N. Y. File applications before May 24.

New York.—Bridge designer, Public Service Commission, First District, $1501 to $2100 per year. Apply to

State Civil Service Commission, Albany, N. Y. File applications before May 24.

For United States civil service examinations listed below, apply to United States Civil Service Commission, Washington, D. C., or to any local office of the commission, for form 1312.

Highway bridge engineer, $1800 to $2100 per year, junior highway bridge engineer, $1200 to $1600 per year, Bureau of Public Roads and Rural Engineering, May 21. File applications in time to arrange for examination at place selected by applicant.

Engineer in forest products, $1860-$3000 per year; assistant engineer in forest products, $1200-$1800 per year, Forest Products Laboratory, Madison, Wis., May 27. File applications before May 27.

Chief of road survey party, $1800 to $2100 per year, transitman for road surveys, $1200 to $1800 per year, highway draftsman, $1200 to $1800 per year, Bureau of Public Roads and Rural Engineering, May 29. File applications before May 29.

Senior engineer and senior architect, Interstate Commerce Commission, $1800-$2700 per year, June 10. File application before June 10.

Assistant material engineer, Bureau of Construction and Repair, from $4.48 to $6.40 and upwards per diem. No date specified. Applications should be filed without delay.

Valuation engineer, $3600-$4800 per year, and assistant valuation engineer, $2500-$3600 per year, technical staff, income-tax unit, Bureau of Internal Revenue, Treasury Department. No date specified.

Calendar

Annual Meetings

AMERICAN ASSOCIATION OF ENGINEERS, 29 S. LaSalle St., Chicago; May 12-13, Chicago.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS, 29 W. 39th St., New York; May 16, New York.

NATIONAL CONFERENCE ON CITY PLANNING; 19 Congress St., Boston; May 26-28, Niagara Falls and Buffalo.

AMERICAN WATER-WORKS ASSOCIATION; 47 State St., Troy, N. Y.; June 9-13, Buffalo, N. Y.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS, 29 W. 39th St., New York; June 16-19, Detroit.

AMERICAN SOCIETY OF CIVIL ENGINEERS; 29 W. 39th St., New York; June 17-20, St. Paul-Minneapolis.

AMERICAN SOCIETY FOR TESTING MATERIALS; University of Pennsylvania, Philadelphia; June 24-27, Atlantic City, N. J.

AMERICAN CONCRETE INSTITUTE; 6 Beacon St., Boston; June 27-28, Atlantic City, N. J.

Engineering Societies

The Southwest Water-Works Association will hold its annual convention in Kansas City, Mo., June 23-26. A feature of the convention will be "round table talks," at which water-works engineers and superintendents will be given an opportunity to speak briefly on various problems with which they have recently been confronted.

The American Association of Engineers will discuss the following subjects at the annual meeting May 12-13 in Chicago: "Relation of Other Societies to the A. A. E., Local, State and National Societies, Engineering Council, Engineering Institute of Canada"; "Relation of Engineers to Each Other in Employment"; "Relation of Engineering Organizations to Engineering Education"; "Recognition of Engineers through Proper Compensation and Through Self-Improvement and Service"; "How Far Will A. A. E. Go Into Politics?" To "Employment Department, New Fields and Opportunities" will be devoted a whole session. Col. Walter Dill Scott will speak on "Fitting the Engineer to His Job."

The Tidewater Virginia Technical Engineers is the name adopted for the new society organized at Norfolk, Apr. 23, at a meeting of local engineers. The following officers were elected: President, Capt. Whit. P. Tunstall; vice-presidents, W. B. Bates and John F. Benson; secretary, R. W. Bonney; assistant secretary, R. Johnson Neely, and treasurer, G. Hubbard Massey. The new organization has about 100 members. The intention is announced of becoming a chapter of the American Association of Engineers.

The Canadian Military and Civil Engineers' Association has been formed by officers of engineering units of the Canadian Expeditionary Forces, according to a statement made by Maj. F. J. O'Leary, late brigade major, First Canadian Divisional Engineers, who recently arrived from France. The object of the association is announced to be to protect the interests of its members regarding pensions, war-service gratuities and civil reëstablishment, as well as rendering financial assistance where required. The officers, elected in France, include the following: Gen. Sir A. C. MacDonnell, Col. A. McPhail, Lieut. Col. J. M. Rolston, and Lieut. Col. E. Peppler.

The Detroit Engineering Society held a joint meeting May 1 with the Detroit-Ann Arbor Section of the American Institute of Electrical Engineers, at which A. A. Oswald, research engineer, Western Electric Co., New York, spoke on "Wireless Telephony and Telegraphy in War." A regular meeting of the society was held May 2, which was addressed by John L. Harper, chief engineer, Niagara Falls Power Co., who spoke on "The Past and Prospective Power Development at Niagara Falls and Hydraulic Problems Connected Therewith."

The Utah Society of Engineers held a meeting Apr. 23 devoted to a discussion of the engineering phases of the production of sugar. The following papers were presented: "Mechanical Operation of Factory," by W. Y. Cannon, assistant consulting engineer, Utah-Idaho Sugar Co.; "Process and Chemical Control," by B. R. Smoot, assistant general superintendent, Utah-Idaho Sugar Co.; "Design of Factory" by A. P. Cooper, consulting engineer; "Byproducts" by Mark Austin, general agriculturist, Utah-Idaho Sugar Co.

The Engineers' Club, of Columbus, Ohio, will open its new club rooms May 15. A reception will be held to mark the event. The new officers to be installed May 15 are: President, **J. J. Morgan**; vice-presidents, J. E. Payne and J. R. Withrow; secretary, **Arthur** Richards, and treasurer, T. H. Brannan. The retiring president and secretary are, respectively, E. G. **Brad**bury and Clyde T. Morris.

The Omaha Chapter of the American Association of Engineers recently elected the following officers: President, W. R. McKeen, president of the McKeen Motor Car Co.; vice-presidents, J R. Houghton and J. A. Bruce; secretary, E. Trimble, construction equipment contract department, Union Pacific Co.; and treasurer, W. J. F. Sackriede.

The Municipal Section of the St. Loius Chapter of the American Association of Engineers has been organized with the following officers: E. Paffrath, chairman, and George Grimm, Jr., secretary. One vice-chairman will be elected from each of the five city departments.

The Engineers' Club of Philadelphia held a joint meeting May 6 with the Philadelphia Association of Members of the American Society of Civil Engineers, at which George W. Fuller, consulting engineer, New York City, spoke on the "Coming Duties and Opportunities of Engineers." The annual meeting of the club will be held May 20. The subject of the annual presidential address, by the retiring president, J. Franklin Stevens, will be "The Engineers' Club; Retrospect and Prospect." Following the presidential address Jamison Handy, vice-president of the Bray Studios, Inc., will deliver a paper, illustrated with motion pictures, on "The Motion Picture's Un-

known Part in Winning the War," treating of the secret use of motion pictures during the war for instruction and other uses. The weekly luncheon of the club, May 6, was addressed by Capt. C. J. Clarke, U. S. A., who spoke on "The Relationship of the Wounded Soldier to Business," and the meeting on May 13 will be addressed by Maj. J. A. Vogleson, U. S. A., who will speak on "Camp Sanitation."

The Dayton, Ohio, Chapter of the American Association of Engineers recently elected the following officers: President, E. J. Correll; vice-president, G Calvert; secretary, H. Gellin; financial secretary, L. Born, and treasurer, L. E. Ettinger.

The Twin City Chapter of the American Association of Engineers elected the following officers at the recent annual meeting: President, Frederick K. Bennett; vice-presidents, W. B. Irwin and A. V. Duncanson; secretary, R. C. Smith; treasurer, E. M. Bolmgren.

The Rochester, N. Y., Engineering Society held a meeting May 7 which was addressed by Maj. John F. Coneybear, Ordnance Department, U. S. A., who spoke on "Machine Guns." A meeting will be held May 9 at which Charles C. Zoller will be the speaker.

Personal Notes

WALTER A. FISCHER, formerly designing and constructing engineer on water-works and hydro-electric plants in California and New Mexico, and more recently hydraulic engineer, Construction Division, U. S. A., has been appointed advisory engineer for water upply, Construction Division of the Army, succeeding Lieut. Col. Dabney H. Maury.

CAPT. LOUIS D. KOOP, 211th Engineers, U. S. A., who recently received his discharge from the service, has been appointed chief engineer, Mark C. Tredennick Co., builders, New York City. Captain Koop also served with the 102d Engineers and was constructing quartermaster at Camp Wadsworth, South Carolina.

HENRY C. MEYER, JR., WILLIAM E. S. STRONG, and BASSETT JONES have become associated under the firm name of MEYER, STRONG & JONES, INC., consulting engineers, with offices at 101 Park Ave., New York City, and will specialize in power plants, and mechanical and electrical equipment of buildings and industrial establishments.

RODMAN M. BROWN, chief engineer, city building department of Omaha, has resigned to become general manager, Stiles Construction Co., now engaged in the erection of the Western Motor Car Co.'s new building. It is announced that the Stiles company will open a permanent office in Omaha.

W. R. ARMSTRONG, engineer maintenance of way, Union Pacific System and St. Joseph & Grand Island Ry., has been appointed assistant chief engineer, with jurisdiction as well in the Oregon Short Line, Los Angeles & Salt Lake R.R. His headquarters are in Salt Lake City. Mr. Armstrong was born in 1869 and was graduated from Kansas State University in 1890. His first railroad experience was with the Kansas City, Pittsburgh & Gulf R.R. (now the Kansas City Southern Ry.) in location work, and he afterward became division engineer. After nearly 14 years' experience in engineering and operating departments on various railroads, Mr. Armstrong went to the Oregon Short Line in 1905. He was employed on special engineering work during his first year with that company, and later had charge of construction of the Yellowstone Park branch and of the line from Huntington to Homestead, Ore. He later became superintendent of the mountain division and was appointed chief engineer and general manager in 1913. In 1916 he was appointed engineer maintenance of way, Union Pacific System.

KARL R. KENNISON has been transferred from the middle Atlantic district, United States Shipping Board, Emergency Fleet Corporation, at Baltimore, to the Southern district, where he has been appointed assistant district plant engineer, with headquarters in New Orleans.

MAJ. H. J. BURT, Construction Division, U. S. A., who for the past 18 months has been expediting officer, engineering branch of the Construction Division, has received his discharge from the service and has resumed his association with HOLABIRD & ROCHE, Chicago, as manager.

MAJ. ALLAN M. JACKSON, Canadian Engineers, who has just returned from two years' service overseas, has been appointed chief engineer and superintendent of construction for the Brant County, Ontario, highway system.

FRED R. WHITE, head of the road department, Iowa State Highway Commission, since 1915, has been appointed chief engineer of the State Highway Commission, succeeding T. H. MacDonald, whose appointment as engineer of the Federal-aid road act was noted in *Engineering News-Record* of Apr. 3, 1919, p. 689. He was born in 1884 and was graduated from Iowa State College in the civil-engineering course in 1907. His first engineering work was with the Florida East Coast R.R., on the construction of the Long Key viaduct. He entered the service of the Iowa State Highway Commission in 1908, two years later becoming associated with the Morgan Engineering Co. In 1911 he returned to Iowa and engaged in bridge-construction work for Cerro Gordo County, afterward entering the service of the State Highway Commission as field engineer.

CHARLES F. WILSON, for several years deputy city engineer, Yakima, Wash., has been appointed city engineer, succeeding N. A. Gilman, whose resignation was noted in *Engineering News-Record* of Apr. 10, 1919, p. 747. C. DE VERE FAIRCHILD has been appointed deputy city engineer.

WILLIAM H. ADAMS and ROBERT J. CUMMINS have dissolved the partnership of ADAMS & CUMMINS, consulting engineers, Detroit and Houston, Tex. The Northern business of the firm, with headquarters in Detroit, will be continued by Mr. Adams, and the Southern business, with headquarters in Houston, by Mr. Cummins.

CLEMENT A. HARDY, who for some years has been in the sales department of the Whiting Foundry Equipment Co., Harvey, Ill., has engaged in private practice as a consulting engineer, specializing in industrial-plant layouts, with offices in Chicago.

R. B. ROBINSON, engineer maintenance of way, Oregon Short Line, with headquarters at Pocatello, Idaho, has been appointed engineer maintenance of way, Union Pacific System and the St. Joseph & Grand Island Ry., succeeding W. R. Armstrong, appointed assistant chief engineer, as noted elsewhere.

CAPT. HARRY P. LETTON, Engineers, U. S. A., who was recently discharged from the service after 14 months with the Expeditionary Forces, largely in the water-supply service, has become associated in partnership with GRANT & FULTON, engineers, Lincoln, Neb., under the firm name of GRANT, FULTON & LETTON.

E. V. WILLARD, acting state drainage engineer of Minnesota, has been appointed commissioner of drainage and waters under the new drainage laws abolishing the state drainage commission and creating the position of commissioner.

EDMUND P. BURKE, who during the war was cost engineer, Engineering Division, United States Housing Corporation, has opened offices in the Kresge Building, Detroit, to engage in general engineering practice.

WILLIAM J. NORTON, of NORTON, BIRD & WHITMAN, has completed his work as general superintendent of the Aberdeen Proving Grond contract of the Maryland Dredging & Contracting Co., and has opened offices in New York City, in addition to those in Chicago, Baltimore and Boston. He will resume his consulting work on utility rate regulation problems. In association with

the Withington-Roberts-Wrights Co., Cleveland, industrial architects and engineers, he will engage in general industrial engineering.

L. W. HELMREICH, assistant engineer, Missouri Public Utilities Commission, has been appointed engineer of the recently organized Arkansas Corporation Commission, which will have under its jurisdiction the general supervision of public utilities operating within the state.

SYDNEY W. TAYLOR, JR., civil engineer, San Francisco, who during the war served as secretary of the Capital Issues Committees for the 12th Federal District, has resumed his practice, having opened an office in San Francisco.

HARRY C. COONS, assistant engineer, Eastern Washtenaw Good Roads District, Michigan, has resigned to become district engineer, Michigan State Highway Department, with headquarters at Farmington.

LIEUT. COL. DEWITT P. OLSON, Engineers, U. S. A., who since his return from France has been engaged as military instructor, Iowa State Agricultural College, has been appointed state highway engineer of Idaho, succeeding H. C. Allen, resigned.

CAPT. C. T. BISSELL, Construction Division, U. S. A., has received his discharge from the service and has returned to his former position as engineer, National Board of Fire Underwriters, with office in New York City.

J. J. COAN and EDWARD M. FULLER have become associated under the firm name of COAN & FULLER, engineers and contractors, Salt Lake City, Utah. Mr. Fuller recently resigned as construction engineer of the Utah Fuel Company.

VICTOR MAYPER, who recently has been engaged in Government work in Cuba and Panama, has returned and has opened offices for the practice of engineering at 15 E. 40th St., New York City.

MAJ. MYRON S. FALK, formerly chief, Raw Materials Branch, Explosives, Chemicals and Loading Division, has been promoted to the grade of lieutenant colonel, assigned to the Nitrate Division, Ordnance Department.

H. A. SEWELL, HANS STRASLSUND and C. W. STRAIGHT have organized the Interstate Engineering & Construction Co. with headquarters at Newport, Wash., and will engage in engineering construction.

FRANCIS E. DANIELS, Sanitary Corps, U. S. A., who acted as camp sanitary engineer, Camp Lee, Virginia, has received his discharge from the service and returned to the engineering division of the Pennsylvania State Department of Health, with office at Harrisburg.

HARLAND BARTHOLOMEW, consulting engineer, St. Louis, has been formally retained as consulting engineer for the City Planning Commission of Omaha.

CAPT. MAURICE R. SCHARFF, Engineers, U. S. A., who recently received his discharge from the service, has returned to his former work as principal assistant engineer, Morris Knowles, Inc., engineers, Pittsburgh.

DAVID A. MCCLOSKEY, formerly assistant engineer to the State Engineer, District No. 6, Pennsylvania Department of Highways, has been appointed engineer of Blair County.

R. T. SMITH, formerly of Temple, Tex., has been appointed city engineer and superintendent of water-works at Waxahatchie, Tex.

J. LEE PLUMMER, JR., and LEWIS R. OWEN have become associated under the firm name of OWEN & PLUMMER, civil engineers, Johnstown, Penn.

D. L. MCLEAN, district engineer at Shoal Lake for the Greater Winnipeg Water District, has been appointed office engineer, Manitoba Drainage Commission.

C. B. MCCULLOUGH, professor of civil engineering, Oregon Agricultural College, Corvallis, has been appointed state highway bridge engineer.

E. G. ATKINSON has been appointed assistant city engineer of Schenectady, N. Y.

ARTHUR FRANK, previously connected with the engineering department of the Excelsior Machine Co., St. Louis, has joined the engineering staff of the P. E. Gray Construction Co., Tulsa, Okla.

R. H. PENNORTZ, assistant engineer, Kansas Highway Commission, has resigned to become Oklahoma representative for the Barrett Co., New York City.

VINCENT G. SHINKLE has become a member of the firm, F. W. FREEBORN ENGINEERING CO., Tulsa, Okla., specialists in valuation of oil and gas properties.

J. E. JELLICK, senior resident engineer, Los Angeles County, California, Road Department, has been appointed division engineer, Wyoming State Highway Commission.

R. W. SPOFFORD, who was placed on the retired list of the Navy after the armistice, has returned to the J. G. White Management Corporation, New York City, and has been appointed general manager of the Manila Electric Railway & Light Co., Manila, P. I., for which the White corporation acts as operating manager.

HENRY S. EVANS, formerly of the firm of Evans & Evans, engineers, Altoona, Penn., has been appointed general manager of the Engineering Service Co., Inc., Johnstown, Penn.

R. O. RENSHAW, Huntington, W. Va., has been appointed county engineer of Ritchie County.

JOHN C. BAGLEY, state fire prevention engineer of Indiana, has resigned to become sales manager of the Obenchain-Boyer Co., Logansport, Ind.

E. J. UMSTEAD, formerly chief draftsman, mechanical division, Bureau of Water Supply, Pittsburgh, has been promoted to division engineer.

E. DRINKWATER, consulting engineer, Montreal, Can., has removed his Montreal South office to Rooms 212-13, 180 St. James St., Montreal.

EDWARD J. SMITH, hydraulic engineer, New York City, has established offices in El Paso, Tex., located in Rooms 812-13, Mills Building.

OBITUARY

HERMANN SCHUSSLER, for nearly 50 years engineer for the Spring Valley Water Co., of San Francisco, died in that city Apr. 27, at the age of 76. He entered the company's service in 1866 and remained in its employ as chief engineer until 1909. During this period he designed and constructed the company's entire system, including a large, concrete, subterranean filter-gallery system in Alameda County, Crystal Springs, San Andreas and Pilarcitos dams (San Mateo County), the conduit system conveying the water to San Francisco, and the distributing system in San Francisco. In 1909 he resigned as chief engineer to devote more time to his private practice. In his private practice as civil and hydraulic engineer he was identified with a number of works in California, Oregon, Nevada and Hawaii, and in a consulting capacity made numerous investigations, report and plans on development work in California. Mr. Schussler was consulting engineer for the California-Oregon Power Co. at the time when the Copco dam was built.

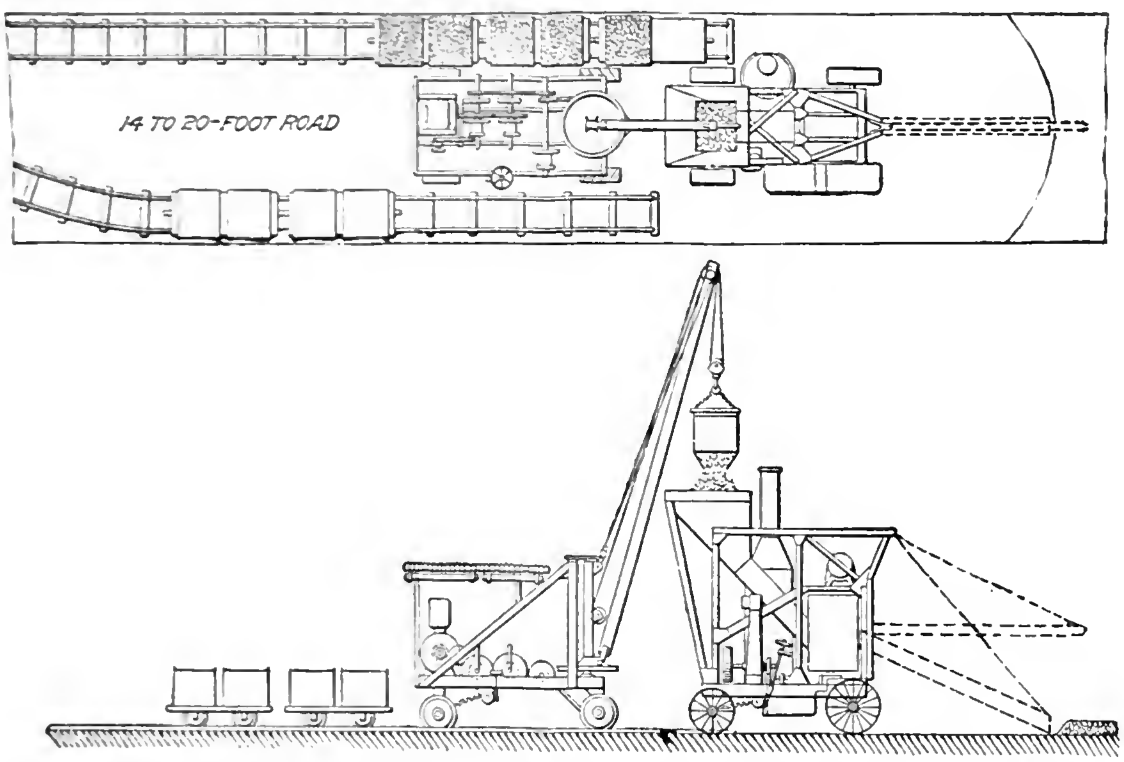
MAJ. JOHN WILLIAM MARK, 302nd Engineers, U. S. A., who since his return from France had been attached to the Engineer Officers' Training School at Camp A. A. Humphreys, Virginia, died in New York City May 2.

Self-Propelled Crane for Charging Concrete Mixer

A self-propelled crane for transferring "batch" hoppers from industrial railway cars to the charging hoppers of concrete mixers is being manufactured by the John F. Byers Machine Co., of Ravenna, Ohio. A similar device is used with steam power and a longer boom with clam attachment, for unloading and transferring aggregates from cars to the bins at the siding.

The layout for using the crane in connection with a concrete mixer is shown in the accompanying illustration. The crane carriage is of such width that it can operate upon a 14-ft. roadbed with a line of industrial track on each side. The crane is equipped with two friction drums, a forward and reverse propelling mechanism, a boom swinger and a bull wheel. The power is supplied by a 10-hp. gasoline engine. The capacity of the crane is two tons at a 10-ft. radius. While this machine may be used with the ordinary hoist-hopper mixer, the drawing shows a combination which, it is asserted, saves 25% on first cost of mixer and about 10 sec. on each batch, by dumping directly into the mixer drum.

Wide wheels are used so that the apparatus can move easily over the subgrade. It is said that this device will overcome many of the difficulties which have attended feeding concrete mixers from industrial railways by a derrick attached to the mixer.



PLANT LAYOUT USING SELF-PROPELLED CRANE FOR CHARGING MIXER

Purify Water in Large Swimming Pool by Ozonization

Purification of the water in what is said to be the largest swimming pool in the world, in New Krug Park, Omaha, Neb., will be accomplished by what is known as ozonization by the Ozone Co. of America, according to reports of the contract. The pool has a water surface area of more than an acre and holds 1,000,000 gallons of water.

Trade Organizations Begin Work on National Association Building

During the present week, work was started upon a building which it is planned to make the national home for all trade associations now located, or which will locate in the future, in New York City. Among the advantages which are expected from this plan are: Closer coöperation between allied industries; greater convenience for business men desiring to see several associations; special advantages for coöperative meeting rooms, and added prestige due to having a high-grade building devoted to the interests of business men, in the heart of the hotel, railroad and subway terminal districts of New York.

The building will be near the corner of Fifth Ave. and 43d St., extending through the block to 44th St. It will be 20 stories high, having about 275,000 sq.ft. of floor space, and will be terraced above the 12th floor to conform to the New York zoning law for conservation of light. An arcade with display rooms will extend through from 43d St. to 44th St. It is the first large business building enterprise started in New York since the armistice was signed. The contract was let to Fred T. Ley & Company.

The name of the structure will be the National Association Building. It will be ready for occupancy the latter part of next January. Further information may be obtained by addressing Willard C. Brinton, consulting engineer, 17 W. 44th St., New York City.

Railroad Administration Purchases 2,000,000 Ties

Through L. S. Carroll, chairman of the purchasing department of the United States Railroad Administration, the Pacific Coast fir lumbermen have received an order for 2,000,000 railroad ties, aggregating 75,000,000 ft. b.m. Of these 500,000 ft. will be ordered from the Oregon mills, while the remainder will be purchased in Washington. The ties will be No. 1 common lumber, running about 40 ft. to the tie. The purchase price was $20 to $21 per 1000 ft. b.m. The specifications require heartwood. The ties are to be used on the New York Central, the Baltimore & Ohio, the Pennsylvania and other Eastern railroads.

Business Notes

The Chicago Bridge and Iron Co., Chicago, Ill., has moved its general sales office from the Chicago works to the 15th floor of the Old Colony Bldg., which quarters it occupied before the war.

The Philadelphia Vitrified Brick Co., Philadelphia, Penn., has been licensed to manufacture wire-cut lug paving brick by the Dunn Wire-Cut Lug Brick Co. of Conneaut, O., becoming the 75th licensee of that company. The Eastern works of the company are at Saxton, Penn.

The Dean Bros. Steam Pump Works of Indianapolis, Ind., has opened a sales office at 141 Broadway, New York City. H. Meacham has been appointed district sales manager.

The Reichert Mfg. Co., of Milwaukee, Wis., has changed its corporate name to the Metal Forms Corporation. The product will be the same as that manufactured heretofore, the new trade name being "Metaforms."

The Nichols-Moore Co., with offices at 11705 Detroit Ave., Cleveland, Ohio, has been organized to carry on a general advertising business. The organizers are Druses H. Nichols, formerly managing director of the Allied Publicity Bureau, and John C. Moore, formerly assistant director of the same organization.

Trade Publications

The Republic Creosoting Co., of Indianapolis, Ind., has issued a new catalog which gives scientific and practical information pertaining to creosote wood-block flooring, and its advantages in shop practice.

"How Business With Foreign Countries Is Financed" is the title of a pamphlet issued by the Guaranty Trust Co. of New York. It is published for the benefit of exporters and importers and others having business or financial relations with foreign countries. It contains 28 reproductions of specimen forms of drafts,

letters of credit, bills of lading, invoices and other documents generally used in connection with the financing of exports and imports, together with explanatory notes. It will be sent on request.

"Coaling Ships Mechanically" is the title of a handsomely illustrated 8½ x 11-in. booklet just issued by the Michener Storage Co., 17 Battery Place, New York City. The illustrations depict inside and outside apparatus for coaling large ocean liners.

The Taylor Instrument Co. of Rochester, N. Y., has just issued a general industrial catalog of Tycos instruments, containing 422 pages. The catalog contains useful information in regard to temperature-indicating, recording and control apparatus.

The Portable Machinery Co., of Passaic, N. J., has issued a folder on the subject, "Over 1000 Scoop Conveyors." The folder is illustrated and describes the loaders.

The American Lava Company, of Chattanooga, Tenn., has issued a 16-page pamphlet on the subject, "Lava for Mechanical and Electrical Purposes." The booklet describes the composition of the company's product, which is machined from mineral steatite.

"Truscon Standard Buildings" is the title of a booklet issued by the Truscon Steel Co., Detroit, Mich. Descriptions and illustrations of the various sizes of standard buildings made by the company are given.

Common Labor Becoming Scarcer

Only Lively Construction Can Prevent Serious Shortage — Labor Just Sufficient for Moderate Amount of Work Now Under Way

By Alden W. Welch

Common labor is not plentiful. Nationally, the situation is that there is just about enough common labor to supply the present moderate demand. If construction were normal there would be a serious scarcity. To those who look beyond the moment, the situation is worthy of serious consideration.

There are many indications that construction work will soon get under way in an encouraging volume. Prices of materials are high, but bids on construction projects do not appear to be excessive. In numerous instances they are less than the engineer's estimate.

PRESENT COST OF COMMON LABOR

	Rate per Eight Hour Day	Class of Common Labor
Atlanta	$2.44	City pays
Atlanta	2.40-2.68	Contractors pay
Baltimore	3.20-3.60	All
Baltimore	3.68	Shipyard
Boston	3.60	Concrete
Boston	3.60-4.00	Common
Dallas	2.40	Building
Dallas	2.50-2.80	City pays
Denver	3.50	City pays
Detroit	4.00	All
Kansas City	4.60	Common
Los Angeles	3.50-4.00	Common
Los Angeles	3.50-4.50	Wheelbarrow
Los Angeles	3.50-4.00	Sewer
Los Angeles	4.50	Hod Carriers
Los Angeles	4.00	Paving
New Orleans	2.40	Common
New York	4.00	Concrete
Pittsburgh	3.60	Common
St. Louis	2.00-2.16	Concrete
St. Louis	2.16-2.40	Brick
St. Louis	2.80	Sewer
St. Paul	3.60	Common
San Francisco	3.50-4.00	Nonunion

On Apr. 30, proposals were received in Albany, N. Y., on 19 highway projects. In every instance there were bids under the estimate. In most cases, all the bids were lower than the estimate.

Conceive of prices of construction materials falling to a more attractive level. A boom would probably result. Much labor would be needed. A shortage of common labor would ensue, and wages would advance.

The price of common labor varies throughout the country—as shown by the tabulation—and, in view of the cost of living, is nowhere excessive. The labor problem is not one of cost but of availability. A trip to the Federal Custom House in New York will discover a long line of aliens procuring passports to return to their native lands. One financial paper estimates that soon a million will have left New York, bearing with them $1,000,000,000 in money plus $1,500,000,000 in annual productive effort.

This heavy exodus is not being compensated for by immigration, which is practically at a standstill. During the war there came to this country not more than 1,000,000 workers—only 25% of the normal influx. This shortage, added to the million now leaving, creates a total shortage of 4,000,000. The longer construction work is put off, the more serious will become the labor situation.

North to South to West

Boston faces the likelihood of a carpenters' strike this month, as the union agreement lapsed May 1, when the carpenters were to ask $8 for eight hours' work, against the present $6.40. Concrete workers receive 45c. per hour; concrete laborers, 45, 47 and 50c. Stonecutters and quarrymen are on strike.

T. M. Barr, Federal director for Maryland of the United States Employment Service, states that the common-labor market in Baltimore is satisfactory—a steady stream of applicants, with employment for all. Wages average 40 to 45c. per hour.

In Atlanta, Ga., labor is not overabundant, though sufficient for present needs. The city pays $2.75 for a nine-hour day; contractors, $3 to $3.35 for 10 hours.

Dallas, Tex., reports just enough labor to supply present demand. The general opinion is, in view of the $17,000,000 worth of road bonds voted in Texas, that when work gets under way common labor will be very scarce.

In the building trades in Kansas City, Mo., labor conditions are fairly normal. The War Labor Board has under consideration the demand of the structural iron workers. Plasterers and carriers are striking for 68¾c. per hour; but work is not delayed, because their places are being filled by building laborers at 57½c. Labor in paving work is plentiful, and this class of work is booming.

In Detroit, Mich., the supply of common labor just meets the demand. Contractors pay $5 for a 10-hour day.

Denver, Colo., reports excellent conditions in the labor market. There is a heavy demand for farm labor, not only in Colorado, but in Idaho and South Dakota as well, with offered wages of $50 to $60 a month, with board and lodging. Considerable building is under way in Denver, and in the building trades there is practically no idle labor. Bricklayers receive $7 for an eight-hour day, and expect to demand $8 this spring. Carpenters and painters are paid $6.40. Contractors complain of a shortage of common labor, especially for grading, teaming and mining. The city pays $3.50 for common labor. Telluride, near Denver, calls for 100 machine men, mine men and muckers. The railways are doing little new construction, but track men are in demand. Track work is usually lively at this season, owing to the winter damage in the mountain districts. The strike of the Leadville miners has been settled. The men resisted a decrease from $4.50 to $3.50, compromising on $4.

Since the adjustments reached by the employers and unions in San Francisco, Seattle and San Pedro, unemployment on the coast has greatly decreased. The total in California is 12,000 unemployed, of whom 7300 are laborers; in Washington, 7000; in Oregon, 4000. About half these men are unskilled laborers. Work in the country districts has improved; but the large corporations, including the public utilities, are undertaking no important projects.

In Los Angeles labor is usually plentiful, but not since the armistice has it been scarcer. The Employment Division of the United States Department of Labor reports a decrease in the number of unemployed since Mar. 15, when 9000 was the estimate. The absorption of the surplus of that class of labor used in construction, including building, has been especially rapid in the past few weeks. Agricultural activities have also claimed many men. There have been urgent calls, recently, for common labor on several highway contracts in southern California. Mexicans constitute about 15% of the supply. Before the war they received $1.25 to $2.50; the present rate is $3.50, and some are demanding $4, the prevailing rate for American labor. Plainly, the market is tightening.

Danger in Thawing Concrete

THAWING out a frozen surface of concrete with the warm concrete which is to form the next layer in the mass seems to have been practiced successfully in two recent dams, but the engineer's testimony on another page is noted there as a record, not as a recommendation for general practice. For a superficial, recent surface freezing such a scheme may work, but the probabilities of stratification due to delayed setting or reduced strength would point to the greatest care in using this method where weak horizontal planes might threaten future danger.

Hauls for Export Freight

PORTS are essentially national institutions. No matter how extensively they are financed by the city or state where they are located, or how largely they benefit that city or state, their fundamental purpose is to link up domestic and foreign trade centers. Too often this has been forgotten and the port has been developed as an isolated unit, in the hope that time would force both land and water trade routes to utilize its mechanical or possibly geographic advantages. A superior line of attack is that indicated in the analysis of the Mississippi Valley possibilities by J. R. Bibbins, on another page, where trade is studied as a unit from the American consumer to the foreign producer or vice versa, and the whole rate structure—on land and on sea—analyzed, not with a view of promoting any one port, but with the idea of so distributing the foreign trade movement as to produce the most economic through carriage of freight, regardless of local advantages. As was pointed out in these columns some months ago, this requires national thinking and doing in transportation matters, and surely the time came long ago when this was necessary. Persistence in the old policy has been wasteful.

Selling the Spruce Equipment

LIKE a tragedy of the great war, the sudden demise of spruce-production activities in the Northwest at first seems the untimely ending of a promising enterprise. In the Vancouver cut-up plant, so recently teeming with workers, there is now the dead silence of a great warehouse. The sharp contrast is to the engineer-visitor a persistent suggestion that something must have gone wrong. But this is only the illusion that may arise when military activity enters the field of engineering. An abandoned project from the engineering point of view does indeed suggest an untimely ending, but military endeavor runs in a different channel—one in which sudden interruption often indicates attainment of purpose. It was so with the Spruce Production Division. Its work was well planned and consummated with skill. Now that its military purpose has been served, a most commendable policy is directing the closing up of affairs in such way as to interfere as little as possible with trade conditions in the Northwest. To dump $10,000,000 worth of equipment and materials on the market at cut prices would have demoralized local conditions for years to come. Yet disappointed bidders turned upon the spruce corporation with bitter criticism when offers below market values were rejected. Rumor spread that at Vancouver Barracks there was a "junk pile" where brokers were profiteering at the purchaser's expense. Nothing could have been farther from the truth. The orderly array of equipment and the systematic records of the stock are truly surprising, when the difficulties under which it was handled are considered. The Secretary of War and the Chief of Staff on a recent inspection visit commented on the care that the equipment had received and the splendid condition in which they found it. First and last the soldierly precision that has characterized the spruce-production work warrants a "well done."

Responsibility for Tank Failure

NO NEW technical teachings are found in the circumstances of the Boston molasses-tank failure recorded in this issue. The case was simply one of a structure designed and built too weak for its service; it was not more than half as strong as it needed to be. Engineers know thoroughly well how to build tanks so that they will be safe, and they have nothing to learn, therefore, from the manner of failure of this scamped piece of construction. But they may well learn, or try to learn, in another respect. It is evident that they do not know how to make sure that their technical skill and knowledge will be applied to the use of the community. They have failed in not creating conditions such that only safe engineering structures can be built in Boston —or, for that matter, in any other city. The blame for this rests on the engineering profession, for in the long run the safety of structures that may endanger life and property is the concern of the engineering profession as a whole. Where does the responsibility lie and how is it to be made a means of protecting the public? Courts of law will be called upon to consider the case, and they will doubtless attend to the responsibility of the men who built the tank; of those who, while supposedly guarding public safety, allowed it to be built, and of those who put the tank to use and continued to use it in spite of the fact that they might and should have known its dangerous condition. But, beyond this, there is the further question of engineering responsibility. Was an engineer concerned in the construction of the tank? Did this engineer jeopardize the reputation of the pro-

fession by grossly faulty work, or perhaps by yielding technical authority to an incompetent superior? Or, did state and city permit a dangerous structure to be erected without the assurance that an engineer's skill and science had been applied to it? Finally, does the name engineer in Boston mean either competence or responsible authority? Questions such as these go to the very heart of some of the conditions now agitating the profession, and give substance to discussions of professional regulation, of the obligation of competence, and of the need for group action by engineers.

The Professional Conscience

SURELY the malpractice of whatever engineers were connected with the fatal molasses tank is a matter of personal concern to the technical community, just as definitely as a lawyer's malpractice is of concern to the legal community wherein he labors. There is such a thing as a professional conscience, and it is rooted in the simple but compelling truth that the reputation and the livelihood of every member of the profession depend on the good conduct of every other member. Lawyers have organized bar associations to be custodians of the legal conscience. But who is the custodian of the engineering conscience? When we study this question carefully, and find an answer, we shall have set a signpost that, in the confusion of movements for local, state, national and ultra-centralized organizations, points unmistakably to the ultimate unit of structure in the professional community—the local group.

Output Versus Wages as the Contractor's Problem

CONTRACTORS need to spend more time in developing output and less time in deploring high wages. When two or three are gathered together, the wage topic soon takes precedence. Wages are high and they will continue high. Output has not climbed with wages; it has slipped back. The problem is clear. What contractors have to do is not merely to *talk* about the worker's wage demands but to get busy increasing his output. The modern method of procedure is to enlist the worker's interest and coöperation—just what the big industrial organizations, like the White Company, the Standard Oil Company and others, are now trying to do. Action along constructive lines is to be expected of strong men; grumbling is not.

Methods of increasing output are available. One hesitates nowadays to mention scientific management; its fanatic disciples have made the name a jest among contractors. Nevertheless, the reasonable professors of this "science" have developed ways of increasing the output of workmen. Some of these ways are being employed partially. The workman has been the chief obstacle to their general adoption, for two principal reasons: The practices were imposed from above and aroused the workman's resentment against dictation, and the workman saw in these practices only an attempt to increase production without an adequate increase in remuneration. The workman's conclusion may not have been justified. The important fact is that such was his conclusion. Again, the task of the contractor is to meet the condition and not to deplore its existence.

The coöperation of labor in devising better methods has seldom been formally enlisted. Instead, the plan has been formulated by the employer and imposed by declaration, and labor was expected to espouse the reform with zeal. It did not. It will not do so, and it cannot be expected to de so without the conviction which the employer has of the need and the benefit of the plan and the further conviction that labor will become a direct beneficiary. Labor's attitude is largely justified. Without similar understanding and assurance the contractor would not accept a declaration by the owner of, say, a new method of estimating monthly payments.

Labor will help to increase production if it is made to understand the necessity and is assured a share in the gain. This is not the statement of a visionary; too many contractors are demonstrating its possibility for it to be successfully denied. As an example, the statement by J. B. Lippincott in *Engineering News-Record*, of Mar. 27, 1919, p. 605, may be noted. With the necessity for increasing output put squarely before the unions, Mr. Lippincott reports that they "took a keen interest in assisting in improving unit costs." Similar testimony is given by word of mouth from other construction managers. Contractors cannot logically complain of labor inefficiency until they have tested the worker's response to this sort of treatment. The spirit of coöperation will be found latent in a greater number of union labor leaders than contractors are accustomed to credit with fair thinking.

In any event, let us be done with mere wailing over high wages. He who is acting along lines that have brought success to others may have some right to complain—but we are inclined to think that he is not the man who is complaining.

Higher Standards For Road Construction Will Mean Higher Prices

CHANGES in concrete-road construction practice which will alter contracting methods in some important particulars are forecast by the action, noted on page 955, of the conference of highway engineers of the leading road-building states of the Mississippi Valley. The recommendations of this conference, while they do not commit anyone to definite action, are the mature conclusions of the highway officials who participated, and in general it may be expected that they will dictate practice in the present season's construction and to a greater extent in the construction of coming seasons. Evidence in support of this belief is found in the new specifications of the Division of Highways of Illinois, which were reviewed in *Engineering News-Record* of Apr. 10, 1919, p. 735. In some particulars the requirements of the Illinois specifications are even more exacting than those recommended by the conference.

As was stated editorially by *Engineering News-Record* of Mar. 27, 1919, p. 599, opinion is becoming settled that the wet mixtures which have been used are no longer permissible for road construction. Concrete mixed so dry that it must be compacted by tamping, and a rigid control of consistency by slump tests in the field, will in a year or two be common requirements in specifications for concrete roads. A general tightening up of the control of subgrade construction, cold-weather work, and finishing and curing, will accompany the demands for richer and stiffer concrete mixtures. As a whole, construction standards will be raised.

Revision of contracting methods must naturally follow these revisions in construction practice. In accomplishing this revision the public-roads officials has a part to play as well as has the contractor. No obstacle stands in the contractor's way to meeting the new requirements except agreement on prices. *Construction will cost more.* Not merely are materials and equipment more expensive and wages much higher, but richer mixtures of tamped concrete cost more to place and finish. Public-roads officials must revise their standards of prices as they have revised their standards of quality and perfection of workmanship.

Even then there remains this question: Are the roads built on the new standards worth the added price? The engineers responsible for the new standards will say, Yes. Some experienced contractors, men ranking as engineers, have said, No. In theory the engineers have the better of the argument and should be supported. For the final answer, however, do we not need to wait the test of service?

Scientific and Technical Employees of Government Form Union

THE scientific and technical employees of the Government departments and agencies in Washington have taken steps to form a branch of the Federal Employees' Union No. 2, which is a part of the American Federation of Labor. This union has now about 21,000 members, and has been very active in connection with Congressional bills affecting employment in Government service in the District of Columbia. The formal vote to join this union was taken at a meeting May 8, at which 185 scientists and engineers favored the plan and 132 favored a permanent organization without affiliation with the American Federation. The leading speaker for the union plan was Dr. Edward B. Rosa, chief physicist of the Bureau of Standards, and actively interested in the American engineering standards movement, as recorded in the two preceding issues of *Engineering News-Record.*

The news that some of the men long prominent in Government scientific and technical work have organized a labor union and have become associated with the American Federation of Labor will startle those who have not followed the recent developments in collective bargaining and do not appreciate the particularly hard lot of the Government specialist. He has been driven by the hopeless condition in which the high cost of living leaves him to take decisive measures to present his plea for fair treatment to Congress. A characteristic incident is the assumption by Thomas H. MacDonald of the duties of the nation's roadbuilder, salary $6000, and the practically simultaneous resignation of H. K. Bishop from the Bureau of Public Roads to become chief engineer of the Indiana Highway Department, salary $7000. Congress asks Mr. MacDonald to make a financial sacrifice in order to accept the most responsible highway post in the country; the experienced business men on the Indiana Highway Commission offer Mr. Bishop the proper compensation for the work. In that difference of viewpoint lies the fundamental explanation of the decay that is beginning to take place in Government scientific and technical work. It is a matter of personnel, of the impossibility of doing good work continuously without reasonable compensation. The unionizing of the Government scientist and engineer is proceeding rapidly only because these classes like the work, appreciate the honorable position of Government service, and wish to stay in it if there is any way to bring to the attention of Congress in a convincing way their present unfortunate condition. If Congress does not heed the warning, the Government departments will suffer seriously.

This decision to have a union of the scientific and technical staff in the District of Columbia has another disturbing aspect. Salaries are paid to these men under two plans. Congress sometimes allots a lump some for a group of investigations, and the bureau chief and his superior, the cabinet officer at the head of the department, then fix the number and salaries of the men engaged in this work. This allows considerable flexibility in arranging the work and selecting men for it, and is the system under which all the activities of the Bureau of Mines are conducted. The second system is the designation by Congress of the grades of men to be employed, the compensation in each grade, and the number of men in each; this is known as the statutory-salary system, and all the work of the Patent Office is conducted under it. In most bureaus there are both statutory and lump-fund salaries, and, so far as scientific and technical work is concerned, the lump-fund system is much better. Congress desires the statutory system, however, on the ground that it enables that body to control the activities of the bureaus more effectively than under the lump-fund system. The difficulties it presents to a bureau chief can be understood by picturing the predicament of a chief engineer of a railroad who was told at the beginning of each year just how many grades of assistants from office boys to chief assistants his staff should contain, how much each man was to be paid and how many men in each grade he could have.

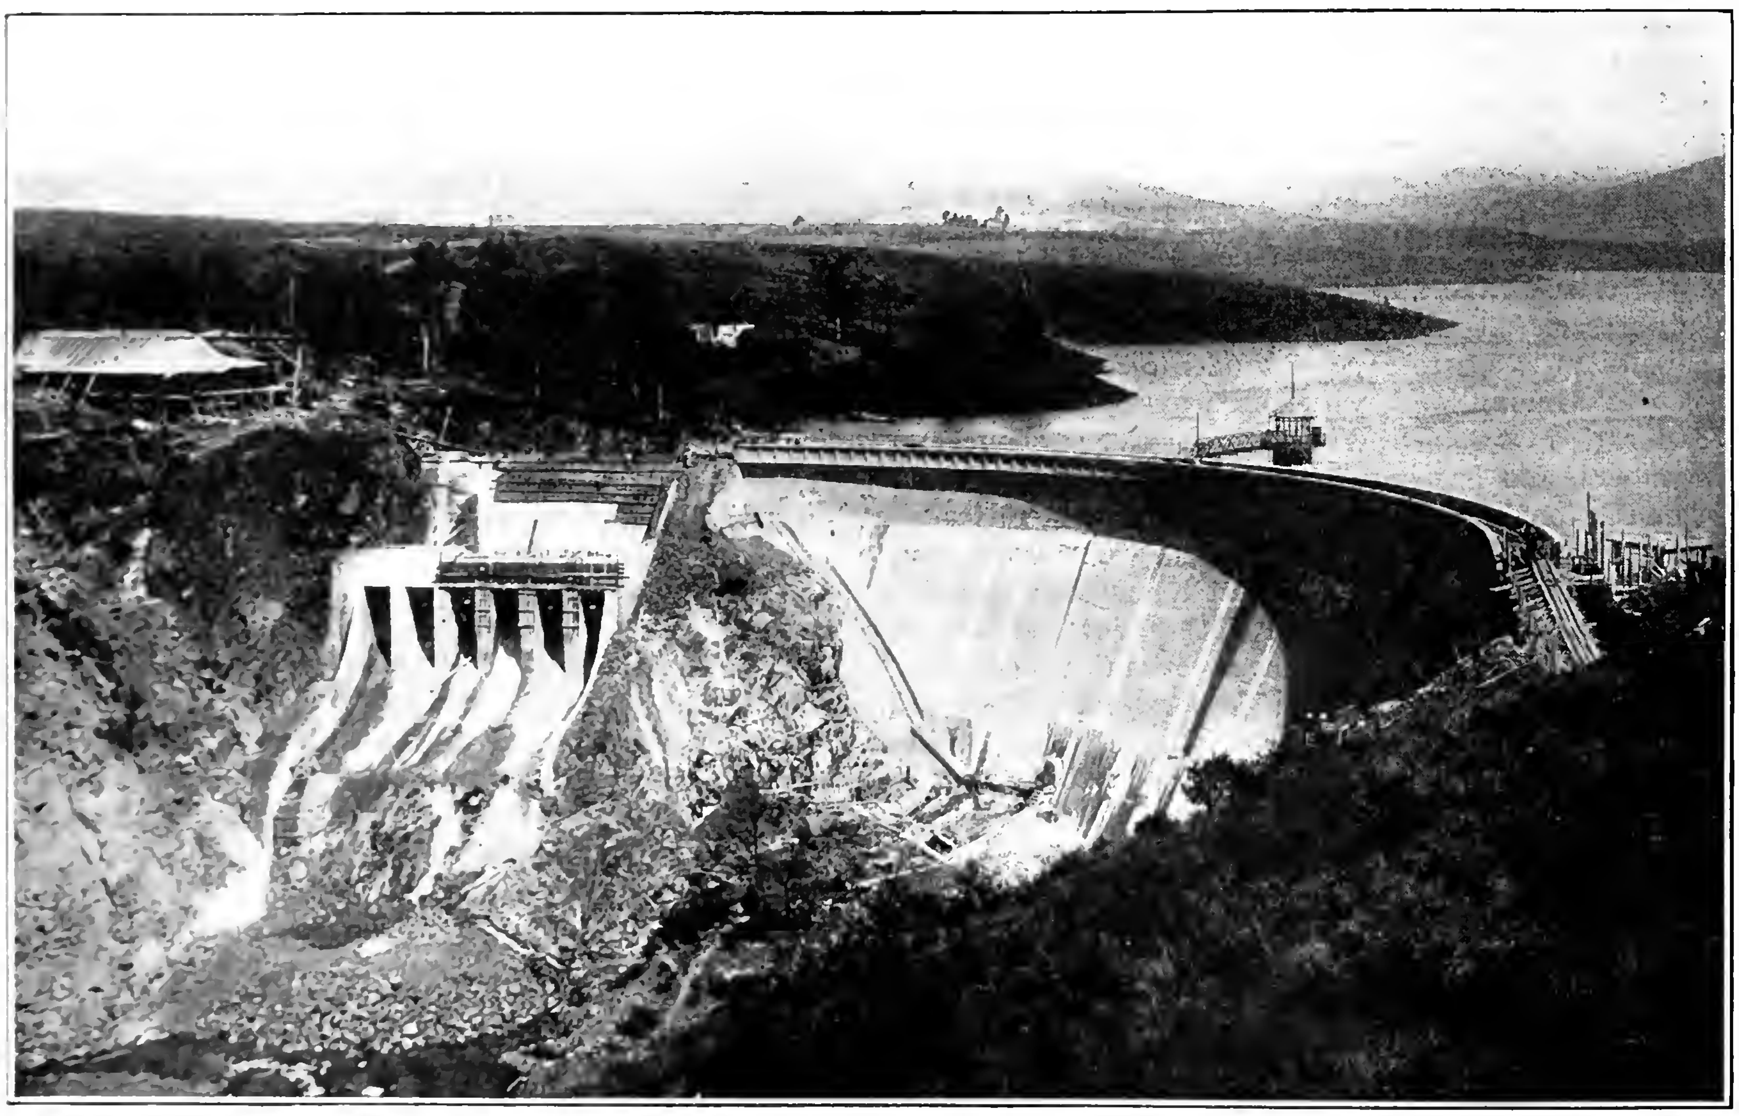
Through the efforts of the Federal Employees' Union No. 2, a joint Congressional committee has been appointed to study a readjustment of the salaries of practically all Government employees in the District of Columbia, in order that work requiring similar qualifications and involving like responsibilities may be uniformly compensated. The bureau chiefs responsible for carrying out the work efficiently and satisfactorily fear that the outcome will be the placing of all Government work on a statutory basis. If this is done, the difficulties of a bureau chief will be greatly multiplied, and the salaries of these chiefs should be substantially increased in most cases. It will then be practicable to increase the salaries of other bureau employees to the amounts that similar responsibilities command in private life. As a matter of fact, the most underpaid men in Government service are the bureau chiefs, and the next in the scale of inadequate compensation are the employees at the bottom of the scale of salaries. How some of the latter have managed to live during the war is a mystery to all but themselves. With them it was a question of mere existence, with bureau chiefs it was a question of duty to their families conflicting with duty to the country, and in the grades between the top and bottom the question was one in which both considerations entered in many cases. The public—at least the public which understands the conditions—will certainly sympathize with the attempt of the scientific and technical employees to secure adequate compensation, even though it may not hold that unionization is necessary to make Congress act justly.

Sweetwater Dam Enlarged for the Third Time

Latest Reconstruction Adds to Height, Provides Siphon Spillways and Enlarges Weir Spillways to Take Care of Maximum Flood—Second Time Dam Has Been Given More Spillway Capacity

By H. N. Savage
Consulting Engineer, Sweetwater Water Co., San Diego, Calif.

TWICE overtopped, each time with an unprecedented flood flow, and three times enlarged to provide either larger storage or larger spillway capacity, the Sweetwater dam, near San Diego, Calif., is a notable example of the revision of an engineering structure to meet new conditions not considered when it was built. The latest flood, in January, 1916, was about three times as great as any previously recorded, and required the reconstruction just being completed. While repairing the 1916 flood damage, there was a general remodeling of the structure which provides for passing a flow of 45,000 sec.ft. This included the construction of new siphon spillways and the enlargement of the previously built weir spillway.



DOWNSTREAM VIEW OF DAM WITH SIPHON SPILLWAY ON LEFT

The dam, seven miles from San Diego Bay and ten miles east of San Diego, Calif., was projected by the San Diego Land & Town Co. and put under construction in 1886. The purpose of the reservoir to be created was to impound the seasonal, and not infrequently torrential, run-off from the drainage basin of the Sweetwater River to insure an adequate and continuous supply of water for irrigation and domestic purposes for use in connection with a large area of land located adjacent to the bay and City of San Diego in the southeast, and which the company was developing for sale for suburban homes and for growing citrous fruits. Construction was commenced in accordance with designs developed by F. E. Brown, who had then only recently designed and constructed the famous Bear Valley dam.

The supervision of the engineering and construction work on the Sweetwater dam was subsequently, and before any material construction progress had been made, turned over to the late James D. Schuyler, who redesigned and supervised the construction of the dam, which was completed in 1888.

The structure, which was of uncoursed rubble masonry, was 90 ft. high above lowest foundation; 333 ft. long, exclusive of spillway bays; 46 ft. thick at base and 12 ft. thick at top; of the arch type, with a radius of 213.3 ft. It created a reservoir with a maximum storage depth of 70 ft., having a maximum length of about four miles and a width of one mile; impounding capacity, 6,000,000,000 gal. of water, equal to about 18,000 acre-feet.

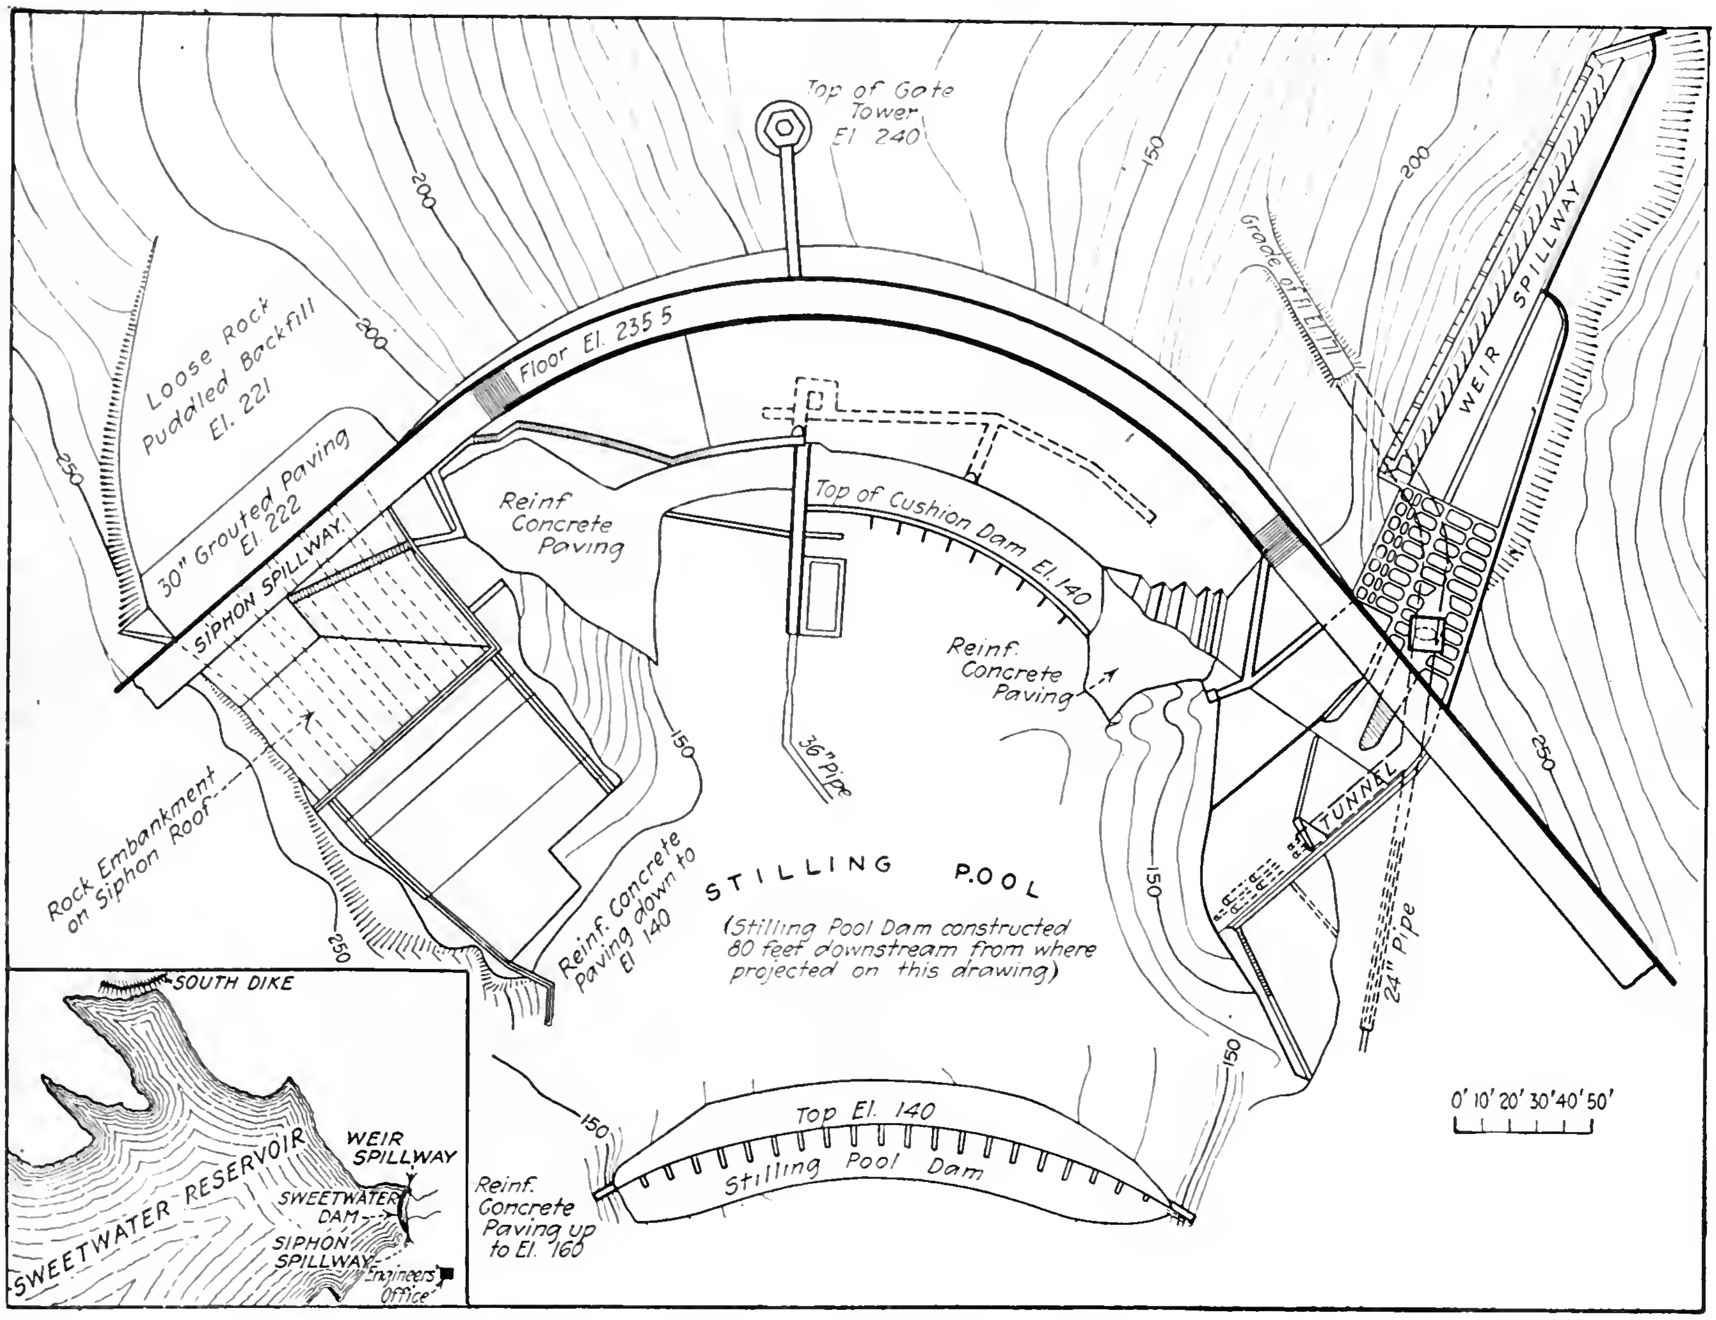
The Sweetwater River has its source in the Cuyamaca Mountains of the Coast Range. The maximum elevation drained is 6515 ft. The river flows southwesterly and discharges into San Diego Bay. The drainage basin has a length of 40 miles and an unusually uni-

form width averaging about 4½ miles. The total area of the basin above the dam is 186 square miles.

The mean annual rainfall at San Diego, as observed for the past 66 years, has been slightly less than 10 in., and has varied from a minimum of about 5 in. to a maximum of 16.03 in., except for the years 1883-84, when it was 27.59 in. The mean monthly rainfall for the 66-year period has been for July, 0.06; August, 0.10; September, 0.08; October, 0.36; November, 0.96; December, 1.79; January, 1.84; February, 1.98; March, 1.48; April, 0.62; May, 0.32; June, 0.06.

The months having greatest precipitation have been December, 1873, 5.46 in.; March, 1893, 5.50 in.; December, 1879, 6.30 in.; January, 1895, 7.33 in.; January, 1916, 7.56 in.; February, 1884, 9.05 in. Excessive rainfall (2.50 in. in 24 hours) has occurred but three times during the period. The rainfall for the 24 hours of Jan. 19, 1895, was 2.15 in., and for the 24 hours of Jan. 26-27, 1916, was 2.41 in. The rainfall on the Sweetwater drainage basin normally increases with the elevation, closely approximating 0.6 in. for each 100 ft. increase in elevation. Southwesterly winds approaching hurricane velocity usually accompany maximum rainstorms. Winds with maximum velocities have occurred as follows: March, 1912, 43 miles per hour; February, 1914, 45 miles per hour; January, 1916, 54 miles per hour.

Neither observations nor gagings had been recorded of the discharge of the Sweetwater River previous to 1886. When the dam was constructed in 1886-8 a discharge capacity of 1800 cu.ft. per sec. was given the spillways. Some additional capacity was provided by the blowoff pipes; this, together with the storage afforded by the reservoir, was then deemed by the engineer sufficient to handle any flood which might occur. In March, 1893, the rainfall was 5.50 in., and the flood into the reservoir reached the extreme volume of 5500 cu.ft. per second. The spillway capacity was thereupon substantially increased. In the month of January, 1895, the rainfall was 7.33 in., causing a flood which developed a peak discharge of 18,148 cu.ft. per second, which continued for over one hour. The Sweetwater dam was overtopped to a maximum depth of 22 in., notwithstanding all the spillways and blowoffs had been opened well in advance. The water poured over the top of the dam for 40 hours before the spillways and the blowoffs sufficiently reduced the volume to bring the storage down to the level of the parapet, the mean flow for the 24 hours, including the peak, having been 7200 cu.ft. per second.



PLAN AND LOCATION DIAGRAM OF SWEETWATER DAM NEAR SAN DIEGO, CALIF.

Upon the writer, then acting as chief engineer, devolved the responsibility of making the repairs which had been necessitated by the flood of 1895, and extensions to the Sweetwater reservoir structures to handle safely and pass a flood of equal volume or of somewhat greater volume, if one such should occur. The late James D. Schuyler, at the writer's request, collaborated in formulating the designs for the repair and extension

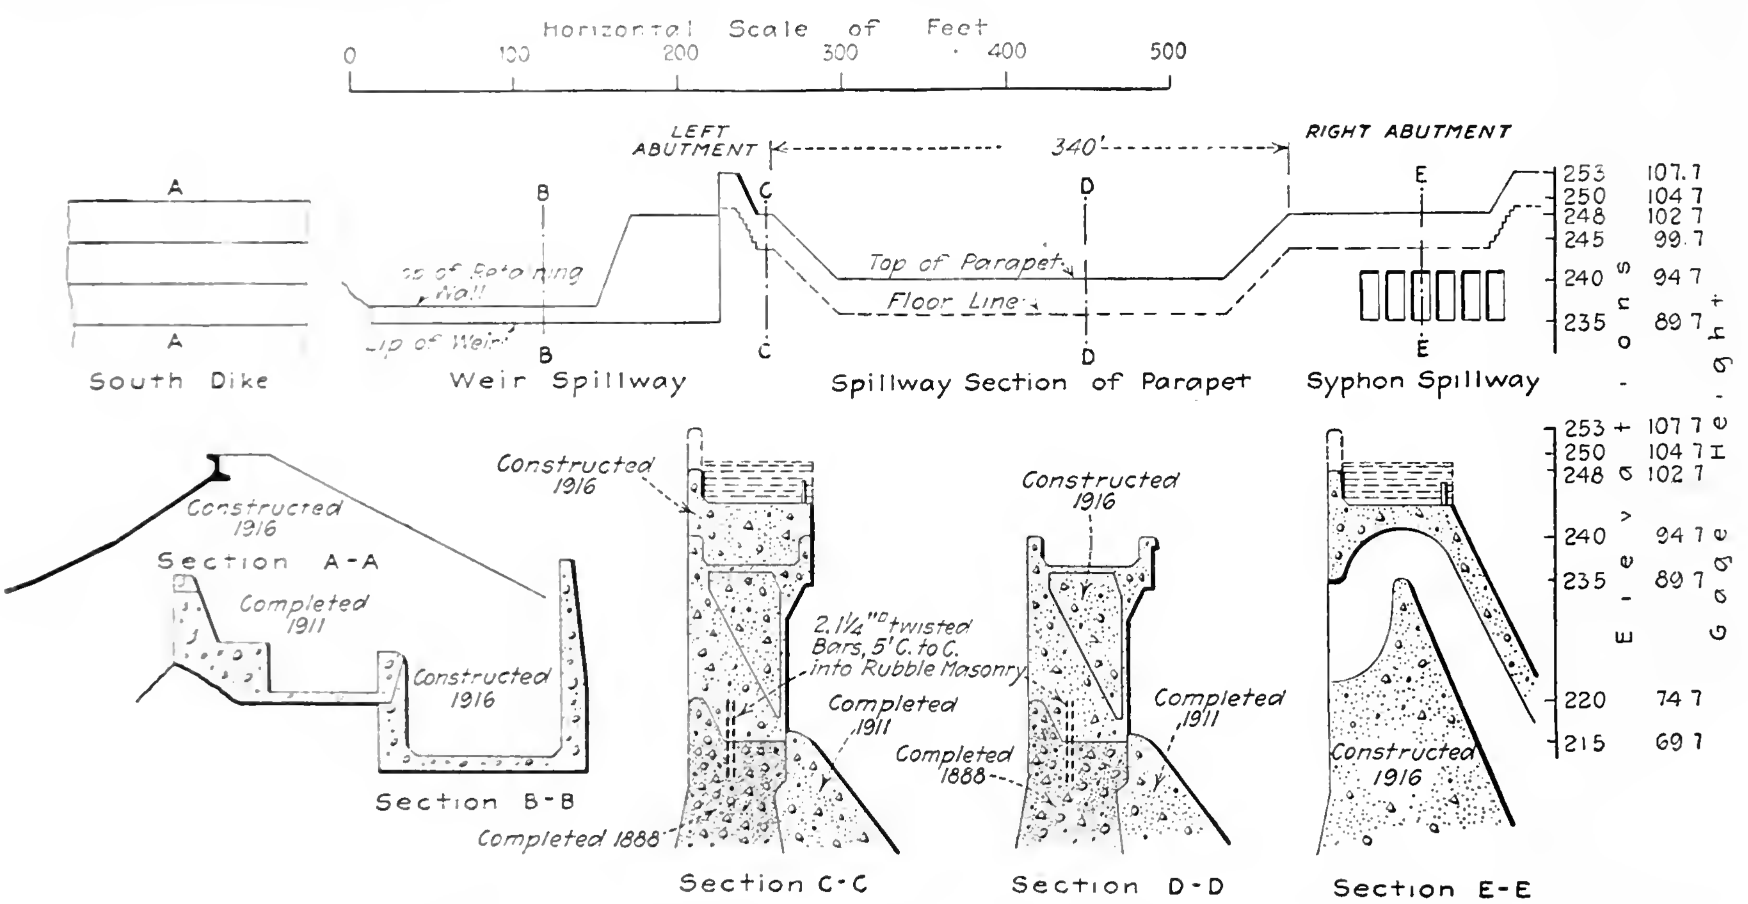
work. The discharge capacity of the spillways was materially increased by adding four bays to the original seven and by doubling the effective depth of all the bays. A flood-discharge tunnel, which had previously, in 1889, been driven from about the midway elevation of the reservoir around the left abutment of the dam, was put under control to discharge through four blowoff pipes—two 36 in. and two 30 in. in diameter—each fitted with tandem operating and emergency gates.

Provision was also made for the central 200 ft. of the dam to be safely overtopped in emergencies, by increasing the height of the parapet wall at either end of the dam to prevent its being flanked by passing floods, and by constructing a 15-ft.-high masonry structure across the cañon 50 ft. downstream to form a water-cushion basin to prevent the Sweetwater dam, if overtopped, from being undermined.

Opportunity was also accepted to increase the reservoir storage 25% by adding 5 ft. to the effective height of the dam, thereby bringing the normal reservoir height up to gage 75 ft., or El. 220 ft., based on sea level.

The Sweetwater Water Co. early in 1910 decided to increase further the storage capacity of the reservoir by 70%. The writer was prevented from responding to the water company's call by reason of other exacting duties, and the late James D. Schuyler was selected for the responsible task of preparing the plans for the extension. This work was described by Mr. Schuyler in *Engineering News* of Mar. 30, 1911, p. 369. He raised the effective height of the dam 15 ft., thus bringing the normal reservoir surface up to gage 90 ft., or El. 235 ft., based on sea level. Previous to the extension of the dam in 1910-11 the stability of the structure had been dependent on its arch plan. The resultant of pressures, with a reservoir full and the dam overtopped, fell well outside of the toe and some distance downstream therefrom. The dam, as extended, was thickened at the base by 30 ft. and transformed into one of the usual gravity type in that the resultant of pressures with a full reservoir fell inside the middle third. It had a factor of 2 against overturning. An additional factor of safety of very considerable but indeterminate amount was retained by the arch plan of the structure. As completed in 1911, the height of the dam above the lowest foundation was 108 ft. to the fixed lip of the spillway at El. 233 ft. above sea level. The spillway was provided with stop planks at El. 235 ft., corresponding to reservoir gage 90 ft., at which elevation the reservoir had a storage capacity of 35,051 acre-feet on an area of 1055 acres.

The spillway was located along the reservoir at the left end of the dam, with which it was monolithic, and consisted of a concrete-lined channel controlled by a weir lip 234 ft. long with its crest corresponding to reservoir gage 90 ft. One hundred and seventy-two feet of the crest was fitted with stop planks resting on cast-iron frames, and could be lowered to gage 88. Its rated capacity was 5500 cu.ft. per second.



PROFILE SHOWING DIFFERENT RECONSTRUCTIONS OF SWEETWATER DAM

The spillway, together with the blowoff pipes through the tunnel and the storage in the upper portion of the reservoir, was deemed by the engineer sufficient in capacity to control and pass a flood similar to that of 1895, which was the greatest previously recorded.

An earth embankment, known as the south dike, 650 ft. long, with its crest corresponding to reservoir gage 97.7, at El. 243, and having a height of 23 ft., had been constructed across a saddle in the rim of the reservoir basin one mile south of the dam.

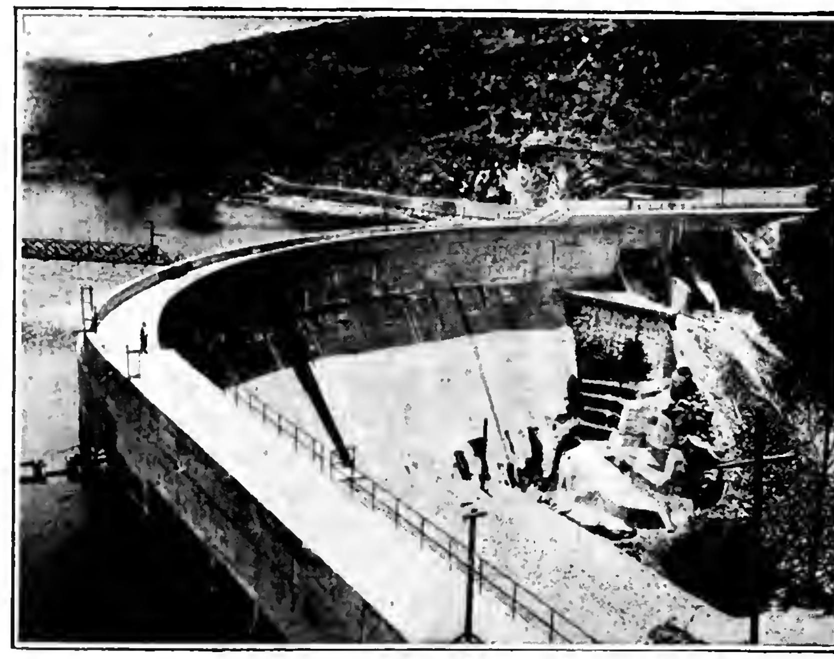
Beginning Jan. 14, 1916, there was an extraordinary storm period in the vicinity of the dam. The storm was in two sections, the first, occurring between Jan. 14 and Jan. 20, giving a precipitation of 5.11 in., and the second, between Jan. 25 and Jan. 28, giving a precipitation of 3.09 in. at the dam, with much greater precipitation on the higher slopes of the watershed to the east, which at a distance of only 10 miles back up into the drainage basin from the Sweetwater reservoir. The precipitation amounted to 10 in. in the 24 hours of Jan. 27, of which 7 in. fell in 14 consecutive hours, thus

largely accounting for the unprecedented flood discharge which followed.

The first section of the storm filled the reservoir to gage 92.9 ft. and to within 22 in. of the top of the parapet, and the second section came upon the top of the full reservoir. This storm raised the reservoir to gage 98.34 ft., corresponding to El. 243.64, overtopping the parapet of the dam 3.66 ft. and overtopping and destroying the south dike.

No apparent damage was done to the masonry section of the Sweetwater dam by the flow of 3.66 ft. in depth over its parapet. At the north end of the dam, as extended, there was a section 90 ft. long with a maximum height of 20 ft., composed of an earth-and-rock embankment with a concrete core wall and parapet. This embankment was washed out and a channel 90 ft. wide was eroded around the north end of the dam to a depth of about 45 ft. below the top of the parapet, or to El. 195. At the south end of the dam the rock against which the dam abutted was also cut away by the water to a width of 20 ft. and a depth of 40 ft. Views of the damage appeared in *Engineering Record* of Feb. 12, 1916, p. 225.

In both cases this erosion is explained by the nature of the rock upon which the dam is founded. This is a porphyritic rock intersected by innumerable cleavage planes by which the rock is divided into blocks held together by some cementing material easily softened by water and slowly disintegrated by air. The rock is a suitable and reliable material for foundations so long as it is protected from running water.



LOOKING ACROSS DAM TOWARD WEIR SPILLWAY

The flood of Jan. 27, 1916, produced an estimated maximum peak discharge of 45,500 cu.ft. per second for a period of over an hour, and an average discharge of over 20,000 cu.ft. per second for a 24-hour period including the peak. As a basis for developing plans for spillways it was deemed advisable to provide a total capacity sufficient to handle a discharge one and one-half times that produced by the flood of Jan. 27, 1916.

All computations to determine the spillway discharge required are based upon the reservoir being filled at the beginning of a flood to normal capacity, gage 90 ft., El. 235.

A flood of similar characteristics to that of Jan. 27, 1916, but having a peak discharge of 50,000 cu.ft. per second, as modified by the temporary impounding capacity on the normal reservoir above the crest of the weir spillway, at gage 90, El. 235, would be controlled and safely passed by the spillways as provided, and only require their operation up to a maximum discharge of 32,000 cu.ft. per second, and the maximum water in the reservoir would not exceed gage 98, El. 243.

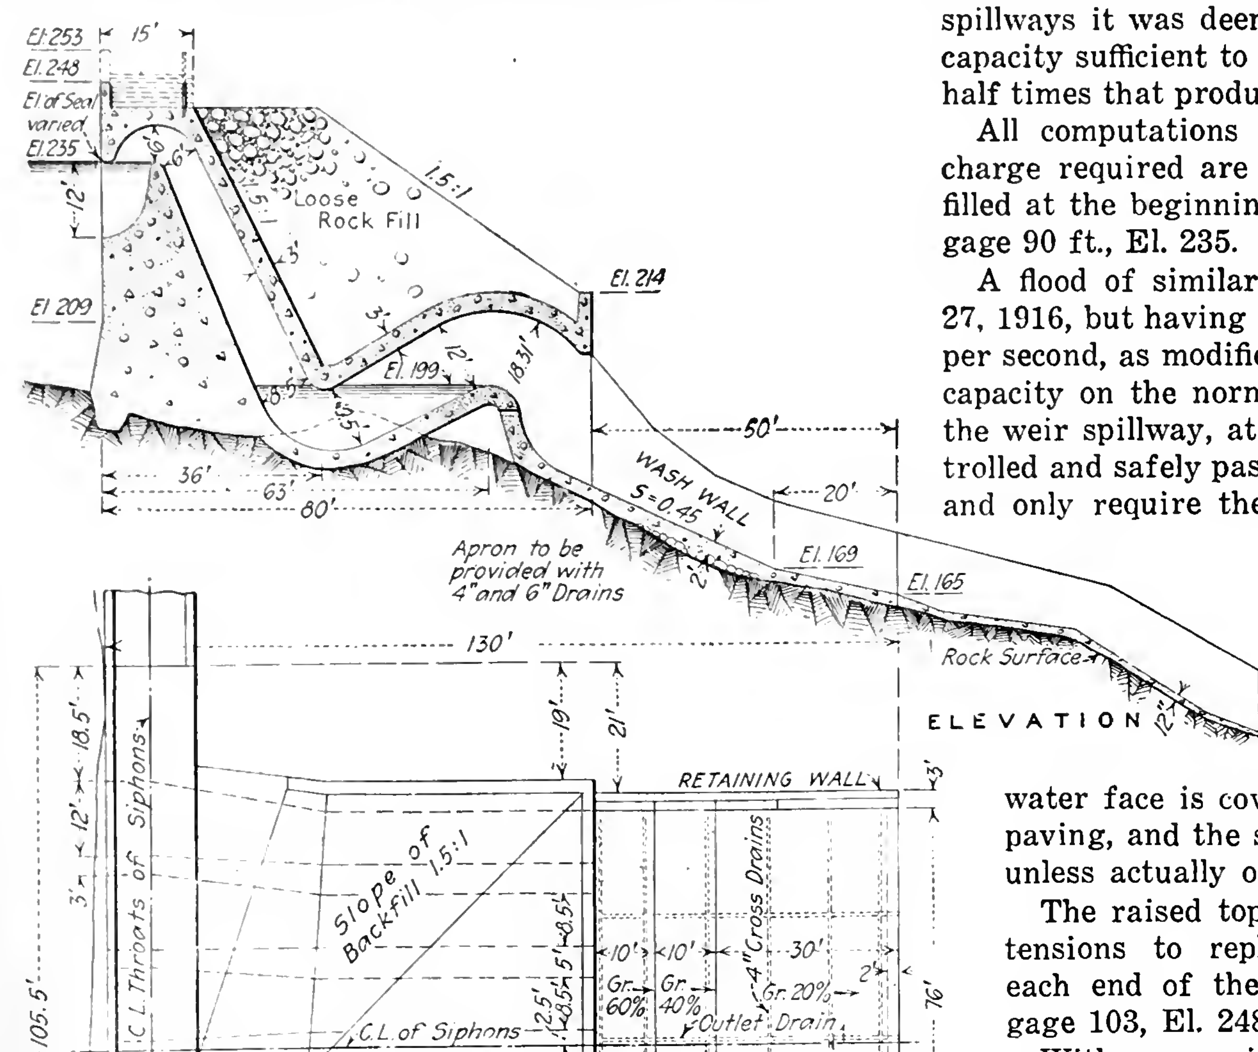
In the design for the south dike the top was fixed at gage 105, El. 250. The water face is covered with a reinforced-concrete paving, and the structure should not be damaged unless actually overtopped.

The raised top of the parapet wall of the extensions to replace the eroded abutments at each end of the Sweetwater dam was fixed at gage 103, El. 248.

With reservoir gage 103, the spillways will dischage 50,000 cu.ft. per second continuous flow, and before the south dike could be overtopped, gage 105, the spillways' discharge would increase by about 25 per cent.

The extreme ends of the parapet walls have also been raised to gage 108, El. 253, to prevent the Sweetwater dam from being flanked by any flood which can occur.

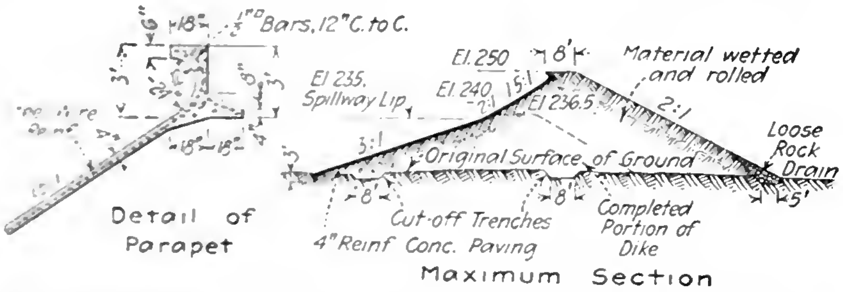
The new location of the south dike is somewhat within the reservoir basin from its former



DETAILS OF SIPHON SPILLWAY ON SWEETWATER DAM

location, due to the erosion by the escaping flood waters at the original site. The new alignment was dictated by the local topography. The south dike is 1260 ft. long and 37 ft. high from the bottom of the front-face concrete cutoff wall. The foundation and the materials available for construction both indicated that the structure should be an earth embankment. The material used was about half clayey adobe and half gravelly, ranging from fine to small boulders. The latter, when sized larger than 3 x 4 in. in the two largest dimensions, were rejected and placed on the lower portion of the downstream slope for drainage and paving. The embankment was placed in 6-in. layers, sprinkled with water and compacted to 4½-in. thickness by a 10-ton roller having corrugated faces on all of its wheels. The water face is sloped from the base up 3 horizontal to 1 vertical, changing successively to 2 : 1 and to 1½ : at the top portion.

The water face is protected from wave erosion by a concrete paving 4½ in. thick, reinforced with steel wire mesh No. 8 B.w.g., spaced 4 in. c. to. At the top the paving merges into a steel reinforced-concrete parapet curved to deflect waves back onto the surface of the reservoir and prevent them breaking over the top of the dike. A coat of crude oil containing 30% asphaltum was applied to the downstream slope and top



ENLARGEMENT OF SOUTH DIKE ON SWEETWATER DAM

of the dike, at the average rate of 5.6 gal. per square yard of surface, to prevent the growth of vegetation, the burrowing of animals, and erosion by rainstorms.

The topography and the geological formation of the reservoir basin restricted the location of all spillways to the immediate vicinity of the Sweetwater dam.

The necessity of replacing both abutments of the dam, which had been eroded away by the flood, made it advisable for economical reasons to combine the spillways with the gravity extension at either end of the dam. The topography of the gaps dictated materially the type of both end spillways.

In making studies and comparative estimates preliminary to deciding on the final designs, it was found advantageous to divide the total spillway capacity required about equally among the three structures which it was found most advantageous to provide and construct. The capacity of the original weir spillway at the left end of the dam was very materially increased by means of a connected channel, with a relatively wide and deep cross-section, located parallel with and back of the original channel. Three ports left in the gravity extension from the left end of the dam serve as dischargeways for the left spillway.

Provision for overtopping the central 236 ft. of the dam in emergencies was made by raising the top of the gravity extension at both ends of the dam by eight feet.

A siphon-type spillway, made up of six independent rectangular tubes each 12 x 6 ft. at the throat, was decided on for the right end of the dam. An efficiency factor of 70% was used in computing its discharge capacity. The type was selected for several reasons; prominent among them were the automatic action approaching maximum capacity whenever water rises above the normal flow line, such as a flood discharge into a reservoir already filled.

In this instance the siphon-type structure provided a necessary support for the perpendicular abutment rock below the dam, and on account of the height of the lip permitted the placing and maintenance of a rock embankment to protect the vertical face of the rock abutment above and adjacent to the end of the dam. The roof of the siphon-spillway feature also furnished a foundation for a rock embankment to protect the vertical face of the rock abutment below the dam to prevent its ravelling. The rock embankments at the north end of the dam were made of rock excavated from the additional left weir spillway channel, which was trammed across the top of the dam. The rock wasted on top of the siphon-spillway roof, weighing about 6000 tons, is also a very desirable additional factor in resisting the tendency of the water discharging through the siphon tubes to set up vibration in the structure.

During maximum flood discharge there will be a potential horsepower of about 175,000 in the water discharging through the siphon, of which about one-half may be destroyed in entering, passing through and discharging from the structure.

In order to protect the rock abutments and foundations in the vicinity of the base of the dam from further erosion, which might be disastrous, a stilling pool dam has been constructed across the cañon 300 ft. below the base of the Sweetwater dam. It is of the hollow buttressed type, 15 ft. high, 200 ft. long, with its upstream face sloping with an angle of 45° with the horizontal.

The relatively high-up abutment rock, down against which water from over the top emergency spillway will impinge, has been protected with concrete paving averaging 1 ft. thick, reinforced with wire mesh spaced 4 in. c. to c., hung on iron pins spaced about 5 ft. c. to c., holes for the pins having first been drilled into the face of the sloping rock cliffs.

The emergency repair work on both the Sweetwater dam and the south dike was rushed forward under Superintendent W. M. Gates, in charge of temporary construction, Don Moore in charge of team work. Repair of main pipe lines was carried on under miscellaneous foremen with forces obtained from the Western Pipe and Steel Co. R. H. Willcomb acted as resident engineer and made all the designs for the permanent work under the immediate and continuous supervision of the writer.

An emergency contract for the placing of 10,000 cu.yd. of earth material in the south dike was awarded to Henry G. Fenton, contractor, of San Diego, and an advertisement was gotten out and bids were received for building the three principal schedules of the repair and extension work on the Sweetwater dam, the stilling pool dam and the south dike. The contract for the south dike work was awarded to the C. L. Hyde Construction Co., and the contract for the other schedules was awarded to Henry G. Fenton, W. A. Stebbins and W. M. Gates.

C. F. Fulton, B. B. Boyd, E. I. Fisher and E. P. Watson, Jr., acted as instrumentmen and inspectors at different times on the work.

What the American Army Engineers Did in the War

The following tribute to the fighting and working engineers of the United States Army is a part of an official report on the war made by Benedict Crowell, assistant secretary of war and director of munitions. The entire report will tell in detail the extent of America's participation in the mechanics of the war. These extracts are printed here to give wider circulation to this official recognition of the American engineers' work in the 17 months of war.—EDITOR.

IN DESCRIBING the activities of the engineers, we are carried to the front itself, into the zone beaten by enemy fire, where machine-gun bullet, bursting shell, and deadly gases have brought sudden death and painful wounds to many members of the technical services. A large proportion of the engineers are combatant troops, constituting in the American Expeditionary Forces about 8% of the total combatant troops engaged. These troops, trained and equipped to march and fight as infantry, demonstrated their fighting qualities during the war on numerous occasions, both when used as infantry to increase the rifle strength of that arm and when fighting as engineers to obtain possession of terrain as a preliminary to the exercise of their technical art in its organization.

From the day the first sector was taken over by American troops in November, 1917, until the Meuse River was passed and the enemy, in flight, sought an armistice to save his armies from destruction, the combatant engineers—the "sappeurs" of French soldier lore and song—fought and bled in a manner never to be forgotten. Railroad engineers, nominally considered noncombatant, fought with a will at Cambrai, dropping their tools to take arms and fight stubbornly shoulder to shoulder with their British brothers with whom they were learning to work under the peculiar conditions of the front. From Cantigny to Chateau Thierry, engineer troops fought as well as worked, and often not only advanced with the infantry under or through the barrage but actually led the first wave, to demolish or remove the obstacles placed in its path. Through the days, when from March 21, 1918, until July 18, 1918, the German army made its rapid plunges toward Paris until checked and thrown back at the Marne near Chateau Thierry, the sapper troops fought and worked with the infantry of their divisions, enduring the same dangers, privations and hardships, and winning equal honors and commendation.

They Fought as Well as Worked

In the drive at St. Mihiel and through the Argonne, the combatant engineers played a conspicuous part. Advancing with the tanks, they made possible the passage of many difficult points for these lumbering monsters, against which was directed a particularly destructive fire. Using elongated torpedoes of high explosive, they prepared passages for the infantry through the broad, barbed-wire entanglements, echeloned in depth by numerous separate lines, each to be breached and passed before the objective could be gained. In this work the engineers fought as well as worked, reducing the machine-gun nests that hindered their operation, cleaning up the strong points that delayed the advance of the tanks they were assisting, and throwing extemporized foot-bridges across the streams which barred the further advance of the infantry.

Actually fighting, taking prisoners, reducing machine-gun positions and combat groups, the combatant engineers did their part in the winning of the reconquered ground, as well as the lion's share of its organization for the defense and the maintenance of the communications behind it. In this last respect alone, the engineers, as combatant troops, opened across No Man's land the first communications practicable for the light artillery, which pressed forward immediately behind the infantry troops to their support and protection.

Filling in trenches, removing wire entanglements, building trestles across wide mine craters, searching for and rendering inoperative treacherous mines and traps of extreme ingenuity and destructiveness, the sapper found a wide field of operations for the exercise of his functions.

Shattered and obliterated by four years of shelling and mining, trenching, and countermining, the "roads" across No Man's Land existed only on the map, and as they retreated the Germans demolished and obstructed the highways behind the old front from which they had been driven, with the thoroughness and attention to detail for which they are noted.

Road Building Under Enemy Fire

As our infantry advanced, upon their heels, literally speaking, came our engineers, to attack the problem of providing for the artillery and the supply trains a means of following. From the standpoint of the road builder in civil life, their methods were crude in the extreme, but for the military purpose and the pressing immediate needs, their road-building achievement was adequate. The engineers sometimes reopened abandoned quarries, and sometimes started them where none had existed before, to obtain a supply of road material, which was supplemented and in some cases replaced by the use of débris from ruined villages and shattered farmhouses. From demolished structures many useful materials were extracted and adapted to the military purpose by the engineers. Where bridge and trestle timbers were lacking, deserted buildings—in one case the tower of a ruined church— filled the need. Where shell hole or crater yawned a remnant of a stable wall might be pulled down by ropes and man-power, and broken up to fill the void.

Through the dense woods, the soft forest floor offered no support even to the light artillery, and miles of corduroy and brush path were built to permit the guns to advance to the reinforcement of the attack. In many places the tactical situation admitted of insufficient time to build even the crudest paths, and then the engineers fell to and assisted the artillery and the supply wagons to get through and over the bad spots, replacing guns on the road where they had run into the ditch, righting and reloading combat wagons when they had turned over in shell holes or deep ruts.

While thus engaged the sapper troops were subjected to the fire of the enemy artillery seeking to prevent the advance of the supporting guns, and, further, they were working within the zone of combat enemy aviators, the rattle of whose deadly machine guns, as they plunged at low altitude toward a busy working party, was as much to be dreaded as the high-explosive bombs which they dropped.

Behind the combatant engineer troops, extending through the service of supply to the base ports and across the ocean to the United States, was an organization of technical noncombatant supply and administration. The work of these production, construction, and supply departments in France was organized under the administration of three divisions of the office of the Chief Engineer. These were the division of military engineering and engineering supplies, the division of construction and forestry, and the division of light railways and roads.

The division of military engineering and engineering supplies was charged with the procurement, standardization, and distribution of all classes of supplies used by engineer troops and with the current investigations into new developments of the art of military engineering. The division of construction and forestry was charged with all construction work in the service of supply, and also with the procuring of forest products for the American Expeditionary Forces. At the signing of the armistice its organization totaled 150,823 men, of whom about 127,000 were constantly engaged in production work. The light-railway and road regiments of engineers attached to the armies at the front, while their duties did not carry them so far or so much into the zone of enemy fire, may be considered as combatant units, since they operated with and in support of combatant troops in the field. To the light-railway regiments were assigned the construction, operation, and maintenance of the light railroads of 60-cm. gage, a great quantity of which was used during the war.

Engineering Profession Responded Nobly

To furnish the necessary organization of technical troops and specialists the original engineer arm of the United States Army was increased to 131.5 times its pre-war strength, and the proportion of engineer troops relative to the total forces was increased from 1.6% to 10.8%. To accomplish this, a heavy demand was made upon the technical professions and upon the industries of this country. In filling this demand most necessary assistance was given by the engineer societies and the engineering journals, whose patriotic work demands the highest praise.

In situations requiring special knowledge, almost always there could be found some specialist capable of adapting himself and his work to the military needs. Engineer officers for the combatant regiments were younger members of the technical professions, who were sent to the training camps provided for the purpose and there given the essentials of strictly military knowledge. This training was later supplemented by courses in engineer and line schools located in France. The training officers of the regiments were supplied from the Corps of Engineers, these men having both the military and technical knowledge fitting them for the command. The diversity of education and experience necessary in all branches of the engineer service may be understood by a consideration of the duties of the different units sent to France during the war—specialist units, in addition to the strictly combatant divisional regiments, who also numbered among their commissioned and enlisted personnel many technical specialists, men of high attainment.

We had, for instance, seven railway-construction regiments, two railway-construction battalions, one regiment and five battalions for railway maintenance-of-way, two battalions for maintenance of railway equipment, four regiments and one battalion to operate our main military railways in France, three regiments to operate the light railways in France and their repair shops, two regiments for operating the regular railway shops, two regiments and six battalions for constructing buildings and other general construction work, two regiments for storing and transporting engineer supplies, a forestry regiment, a light-railway construction regiment, a regiment for building roads, a water-supply regiment, a mining regiment, a quarrying regiment, a technical regiment for handling surveying, sound ranging, and location of enemy positions by means of special apparatus, three survey and printing battalions, two railway-transportation battalions, an electrical and mechanical regiment, several companies to operate cranes, a camouflage service, five inland-waterway companies, five ponton trains, a ponton park, a railway-transportation and stores battalion, and also a searchlight regiment.

Upward Pressure Test Pipes Constructed in Concrete Dam

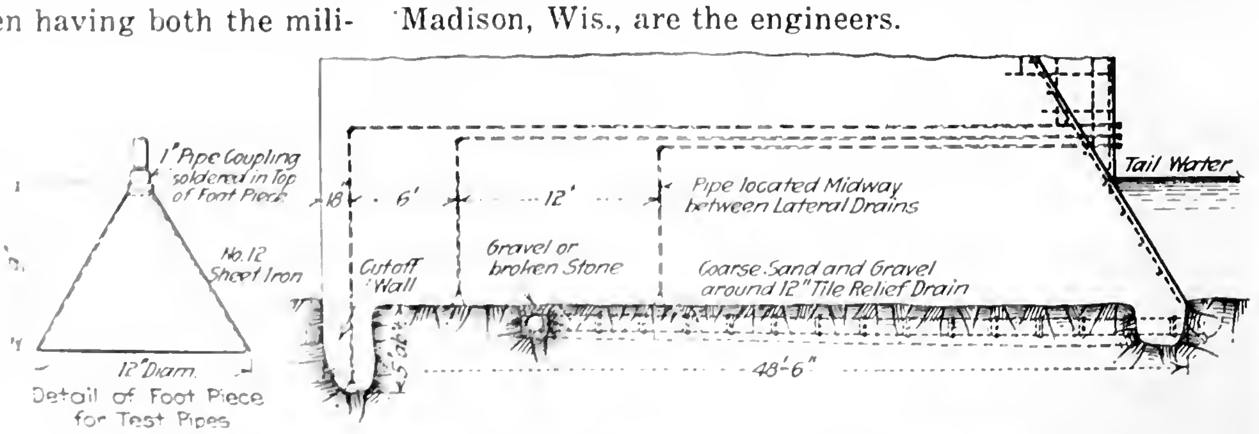
UPWARD-pressure test pipes were constructed in the base of the new Brule River dam in Wisconsin. This dam is constructed of concrete, and is about 70 ft. high, 6 ft. wide on top, and 48½ ft. wide at the base, and will sustain an average working head of 60 ft.

Provision is made for underdrainage by the use of a 12-in. vitrified tile drain, placed longitudinally with the dam, as indicated by the drawing and connecting with 12-in. lateral drains at right angles spaced every 20 inches.

To determine the effect of upward pressure, if any exists under the dam, 1-in. iron pipes were placed as shown on the drawing. Construction was simple, the only special detail being the inverted cone collector resting on the rock bed. Great care was taken to see that no concrete got under the cone.

It is believed that after construction is completed and the water is raised to full head these pipes will afford observations on upward pressure which may be of value.

The dam was built for the Peninsular Power Co., of Wisconsin. Daniel W. Mead and Charles V. Seastone, Madison, Wis., are the engineers.



PIPES CONSTRUCTED IN DAM TO TEST UPWARD PRESSURE

Concrete Highway Construction Standards Raised

Mississippi Valley State Road Officials Recommend Tamped Concrete and Heavier Sections—Action Affects Wide Territory

BETTER built subgrade, heavier slab sections, graded aggregates, slump consistency tests, tamped concrete, and more intensive finishing are recommended for concrete roads by the Mississippi Valley Association of State Highway Departments. The exponents of this advanced doctrine are, moreover, putting its precepts into practice. A notable example is the Division of Highways of Illinois, whose new specifications were reviewed in *Engineering News-Record* of Apr. 10, 1919, p. 735, and May 8, 1919, p. 905. Other state highway officials announce that their practice will be similarly modified as conditions make action practicable.

The decision to revise standards of construction was reached at a two days' conference of the association members held in Chicago in February. With the highway departments of eight states represented, the standards of practice of the American Concrete Institute (See "Proceedings," Vol. XIV, p. 517) were considered, section by section, changed and extended as the delegates decided, and the original document as altered was adopted as recommended practice. The changes extended to minor details, but only those of broad significance to the contractor call for particular mention. They include pavement design, but relate for the most part to materials and methods of construction. Quoted matter contained in this article shows the alterations as adopted.

Heavier Slabs and Better Concrete

Concrete roads less than 18 ft. wide are inadvisable, but if single-track roads must be built a width of 9 ft. is recommended and no road widths between 10 ft. and 16 ft. are approved. The width of traveled grade is set at 24 ft. for all roads, and 8-ft. shoulders are advised for all widths of slab. A slab uniformly not less than 7 in. thick is specified for single-track roads, and for two-track roads up to 20 ft. wide the minimum thickness is 7 in. at the edges and 8 in. at the center. These thicknesses are roughly 1 in. greater than those set by the standards of the American Concrete Institute.

A 1 : 2 : 4 concrete is suitable when the slab is finished by machine; for hand-finishing the proportions are 1 : 2 : 3½. Consistency is to be governed by slump tests. "For this test 6 x 12-in. cylinders should be tamped full of the concrete as mixed and the cylinder immediately removed. For work that is to be finished by hand, the slump of the concrete upon removal of the cylinder should not exceed 6 in., and for work that is to be machine-finished, the slump should not exceed two inches."

Emphasis is put on the field testing of aggregates. Sieve grading, using Nos. 100, 48, 28, 14 and 4 screens, is specified. Volumetric tests for silt are approved for field determination, but unless this test shows less than 7% of silt materials are not to be accepted for construction until the quantity of silt is determined by the weight method. Fine aggregate must all pass a No. 4 screen, but natural sand or any mixture up to equal parts of sand and screenings is acceptable, provided the screenings are from durable stone and are without dust. For coarse aggregate, besides pebbles and broken stone, "slag of suitable quality and uniformity" is acceptable.

Stress is laid on subgrade construction. It is recommended that the subgrade be not trenched out, and that it be kept higher than the natural berms, so as to provide drainage directly to the side ditches. A 10-ton macadam-type roller is recommended, and very careful rolling is urged. "If the rolling at any time causes the subgrade to become wavy, the rolling should be stopped immediately over the wavy parts, and the soft material investigated. In clays, this is almost always due to moisture and, unless it is possible for it to dry out by the sun and wind without delaying the work, it should be removed and replaced with dry clay or other suitable material that can be rolled in a satisfactory manner. If any depressions develop they should be filled with acceptable material as the rolling progresses."

It is recommended that the rough grading be completed very close to the intended cross-section of the subgrade and to the full width of the shoulders. The finished subgrade immediately ahead of the concrete should be corrected to proper cross-section, using a templet.

Where the aggregates are stored on the subgrade the latter should be completed fully in sections not exceeding 600 ft. in length, immediately before the aggregates are deposited. The surface should be brought to true cross-section, using a templet or other acceptable method, and the roller should be kept in constant operation while the aggregate is being delivered. Wherever possible, hauling over the finished subgrade with teams or motor trucks should be avoided.

Concreting Practice Made More Definite

Two-bag batch mixers are recommended for concrete-road work. The mixer should be equipped with "a boom and bucket or some other mechanical device that will deliver concrete of a proper consistency; also with an automatic timing device and a device that will accurately measure the water for each batch." The attention of mixer manufacturers "is directed to the advantages of perfecting a mixer that will shorten the time necessary for proper mixing and permit the inspection of the batch before delivery."

Duplicate pumping machinery should be provided, with booster pumps on long pipe lines. Steel side forms should be used.

The concrete may be transported from the mixer to place on the subgrade in any manner which avoids the segregation of materials. Every effort should be made to arrange for closing concrete-road work in the autumn on or about such date "as the Weather Bureau reports for the locality for the past 10 years indicate the probability of temperatures materially below the freezing point." If circumstances necessitate continuing work for a short period after freezing weather is likely to occur, precautions should be observed which will insure positively that the concrete may not become frozen under the most extreme conditions of temperature for the period, "as indicated by weather reports for the past 10 years." Concrete should be absolutely protected from freezing by suitable means for at least seven days after placing.

When mixtures of relatively dry consistency are used, "mechanical strikers and tampers should be used." Machines should be so constructed and operated that they strike off and thoroughly tamp the concrete, and that they "may be readily operated over the same area repeatedly." If a mechanical finisher is not used after

the spreading, the concrete should be thoroughly hand-tamped by means of a tamper "of the nature of a strike-board operated by one or two men stationed at each end of the tamper on opposite sides of the roadway." Hand-tamping should be vigorous and sufficient to consolidate the concrete in such a manner as to leave the surface behind the final strikeboard "true to grade, crown and surface, and absolutely free from porous places."

Trained Inspectors Essential

Inspectors should be selected with great care. The remuneration of an inspector should be sufficient to secure a man of the following qualifications: "Practical experience, knowledge of specifications and construction, absolute integrity, quick decision, sound judgment, forceful personality, common sense and the ability to command the respect of the contractor." The inspector should have broad perspective and should be able to distinguish between essentials and nonessentials. It is recommended that inspectors of concrete construction receive a preliminary course of training in their duties, including a study of materials and the interpretation and significance of laboratory and field tests.

Put New Chords on Drawbridge Carrying Traffic

Engineer Plans Work to Avoid Closing of Busy Street — Bridge Swings Free of End Supports While Riveting Is Done

The reinforcement of an old swing bridge without the use of falsework and without putting the bridge out of service was a difficult piece of work accomplished successfully at Chicago. The particular methods employed were adopted in order to avoid serious interruption to travel on a heavy-traffic street.

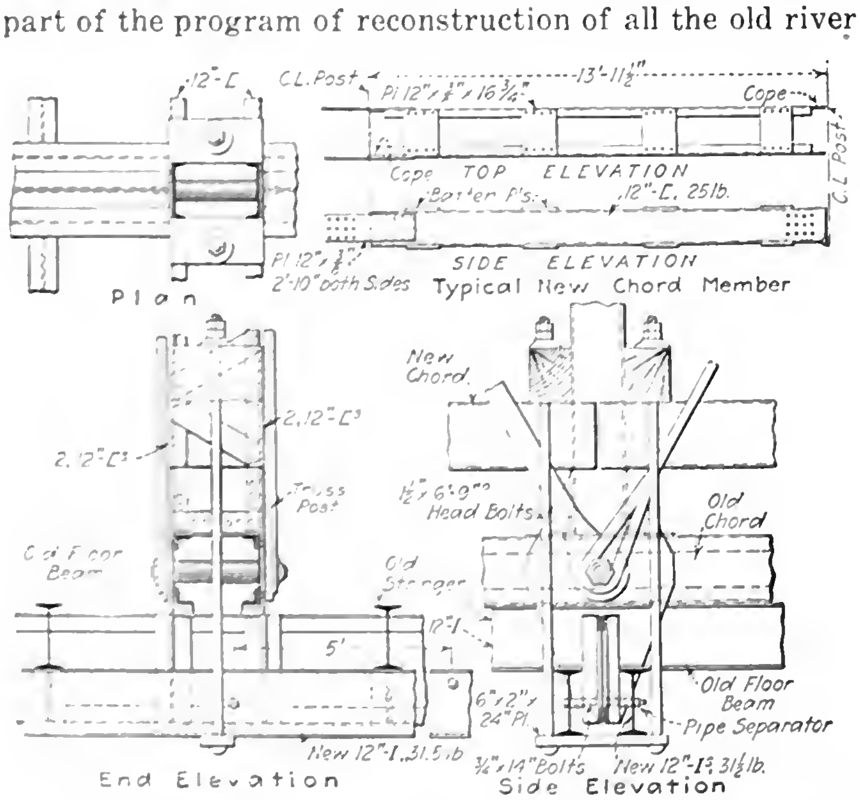
The repair work was of an unusual character, consisting in the application of new bottom chords and floor-beams to the Clark St. bridge over the Chicago River. The work was imperative on account of corrosion and general deterioration, coupled with the necessity of retaining the old structure until funds are available for its renewal. Its replacement will be part of the program of reconstruction of all the old river bridges at Chicago. The swing span, built in 1889, is 208½ ft. long, with three through trusses spaced 21 ft. on centers.

New bottom chords for the reinforcement of the trusses were located above the floor, for convenience of erection. They were composed of pairs of 12-in. channels placed with the flanges inward and connected by batten plates at top and bottom, the flanges being cut away at the ends to allow the webs to be riveted against the truss posts. Splice plates were placed outside of the chord joints on these posts.

While the riveting was being done the bridge swung free, being supported entirely at the center and being clear of end supports. Thus there was no upward reaction in the trusses, and although the bridge tipped as cars ran on and off there was no difficulty in fitting the new chord members.

Deterioration of the floor-beams and their connections made it necessary to provide additional supports for the stringers, which were in good condition. At each panel point two wood blocks were placed across the new chord and against the post, forming supports for the threaded ends of two hanger rods whose upset heads carried a bearing plate. Upon each pair of plates were placed the ends of two 12-in. I-beams, one on each side of the old plate-girder floor-beam, and these were drawn up against the stringers by means of nuts on the hangers. The I-beams were secured in place by through bolts spaced about 5 ft. apart and located alternately at the center line and top of the webs. These bolts passed through pipe separators fitted between the webs of the I-beams and old girders.

This method of reinforcement was planned by F. H. Avery, engineer of bridge construction and repairs, Department of Public Works, under the direction of John Ericson, city engineer, and Thomas G. Pihlfeldt, engineer of bridges. The work was done by city forces under Mr. Avery's supervision.



TYPICAL NEW CHORD MEMBER AND ARRANGEMENT OF NEW I-BEAMS SUPPORTING STRINGERS

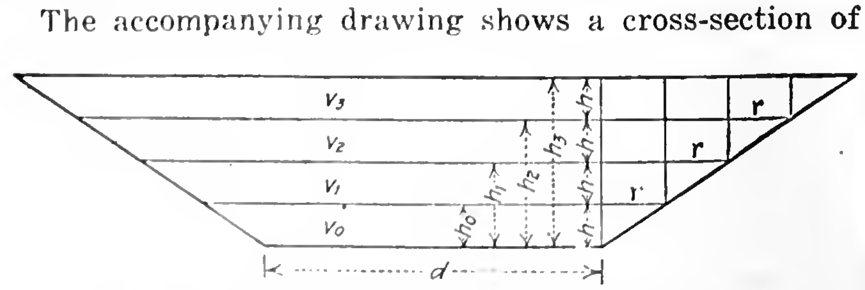
Laying Out a Reservoir Gage Table

By E. D. Cole
Chief Engineer, Empire Gas & Fuel Company, Bartlesville, Okla.

In computing a gage table for a circular reservoir with sloping side walls, it is customary to figure the volumes for each inch of height, measured from the gage plate on the bottom. The necessary computations in this case are somewhat long and tedious, owing to the reservoir being considered as the frustum of a cone with volumes increasing with the height above the gage plate by a constantly increasing increment.

The writer recently had occasion to figure such a gage table for a 350,000-bbl. oil-storage reservoir of this type, and devised the following formulas, showing the relation between succeeding volumes corresponding to equal values of height. By this method succeeding volumes are easily and quickly figured for as many values of h (height) as desired.

The accompanying drawing shows a cross-section of



SECTION THROUGH CIRCULAR RESERVOIR

an inverted frustum of a cone, corresponding to a cross-section of the reservoir, divided into horizontal sections, whose volumes are represented by:

V_0, V_1, V_2, V_3, corresponding to equal values of h, as h_0, h_1, h_4.

The volume of V_0 is obtained by computing the center section of height h_0 and diameter d and adding to it the volume represented by the area of the triangle $a\ c\ e$ of height h_0 and width r times the circumference at the center of gravity of the triangle. This volume is given by the formula:

$$V_0 = \tfrac{1}{4}\pi (d)^2 h + \pi (d + 2/3\, r)\left(\frac{r\,h}{2}\right) \qquad (1)$$

Volumes V_1, V_2 and V_3 are given by the formulas:

$$V_1 = \tfrac{1}{4}\pi (d + 2r)^2 h + \pi (d + 2r + 2/3\, r)\left(\frac{r\,h}{2}\right)$$

$$V_2 = \tfrac{1}{4}\pi (d + 4r)^2 h + \pi (d + 4r + 2/3\, r)\left(\frac{r\,h}{2}\right)$$

$$V_3 = \tfrac{1}{4}\pi (d + 6r)^2 h + \pi (d + 6r + 2/3\, r)\left(\frac{r\,h}{2}\right)$$

The relation between succeeding volumes is obtained by subtracting V_2 from V_3, V_1 from V_2 and V_0 from V_1.

$$V_3 - V_2 = \frac{\pi h}{4}\ (4\ dr + 20\ r^2)$$

$$V_2 - V_1 = \frac{\pi h}{4}\ (4\ dr + 12\ r^2)$$

$$V_1 - V_0 = \frac{\pi h}{4}\ (4\ dr + 4\ r^2)$$

Then:

$$(V_3 - V_2) - (V_2 - V_1) = 2\ \pi\ h\ r^2 = \text{Constant}$$

and:

$$(V_2 - V_1) - (V_1 - V_0) = 2\ \pi\ h\ r_2 = \text{Constant}$$

The next succeeding volume may then be obtained directly by adding to the last known volume the difference between it and the next preceding one plus the constant as follows:

Given V_2 and V_3, to find V_4:

$$V_4 = V_3 + (V_3 - V_2) + 2\ \pi\ h\,r^2.$$

Leaky Subway Station Made Tight

A campaign of grouting has proved successful in stopping serious inflow of water into the new Canal St. subway section and station, New York City, according to a statement of the Public Service Commission. The section extends east from the new Broadway subway to the Centre St. loop subway, passing under the old subway in Lafayette St. In building it, connection had to be made with the existing subway structures in Lafayette St. and Centre St., after tunneling under them. Pumping down the ground-water by wells was resorted to during the construction, in order to facilitate the excavation work. After completion of the station, leakage developed at many points, and ultimately the total inflow reached the amount of 150 gal. per minute. It was necessary to cut channels for the water and provide gutters and pipes at various points, in order to permit the station to be kept in use as a means of transfer between the three subways. The leakage came through breaks at the connection of waterproofing laps on the outside of the structure. To stop them, grout was pumped through holes drilled in the wall of the station. These grouting operations have been carried on for a number of months, and they have been so successful that now the total flow of water into the station is reported at less than 2 gal. per minute. It is expected that when the grouting is completed the leakage will be eliminated.

Improving Concrete By Rodding

Tests Show That Strength Is Increased Materially by Continuous Agitation of Wet Concrete With Rods

By F. E. Giesecke
Head of Division of Engineering, Bureau of Economic Geology and Technology, University of Texas, Austin, Texas

"RODDING" concrete—that is, working a pointed rod of about ⅝-in. diameter into and around the soft mixture, adds considerably to its strength, according to tests made in the laboratories of the University of Texas. The tests were made to determine if this method would have any beneficial effect in removing the excess water which the necessity of a workable mix generally imposes on concrete placed in the field.

Eight groups of specimens, designated A to H, were prepared. Each group consisted of six 6 x 12-in. cylinders of the same concrete composed by weight of

Colorado River gravel P 1¼—R ¾	29.7%
Colorado River gravel P ¾—R ¼	29.5%
Colorado River sand P ¼—R 12	12.0%
Colorado River sand P 12—R 50	11.3%
Colorado River sand P 50	3.1%
Blend cement of two brands of Texas cement	14.4%
	100.0%

This mix corresponds very closely to the ordinary 1 : 2 : 4 mix; the resulting concrete contains about six sacks of cement per cubic yard of concrete. The lag of the tests is given in the accompanying table.

The A specimens were prepared with water amounting to 6.7% of the total weight of the other materials, or 46.5% of the weight of cement, or about 71% of the volume of the cement. They were of a very stiff consistency, and were thoroughly tamped while being placed in the molds. All other specimens were prepared with water amounting to 10% of the weight of the other materials, or 69.4% of the weight of the cement, or about 104.5 per cent. of the volume of the cement.

The concrete for the specimens was so thin that it flowed readily and was difficult to handle with shovels. It contained more water than need ever be used in practice to secure easy handling and a thorough filling of the forms.

Of these seven groups, the concrete for the B specimens was deposited in the molds, and as it settled more was added, so that the molds were well filled when the specimens were completed. The C specimens were tamped lightly with a wooden tamper. The D speci-

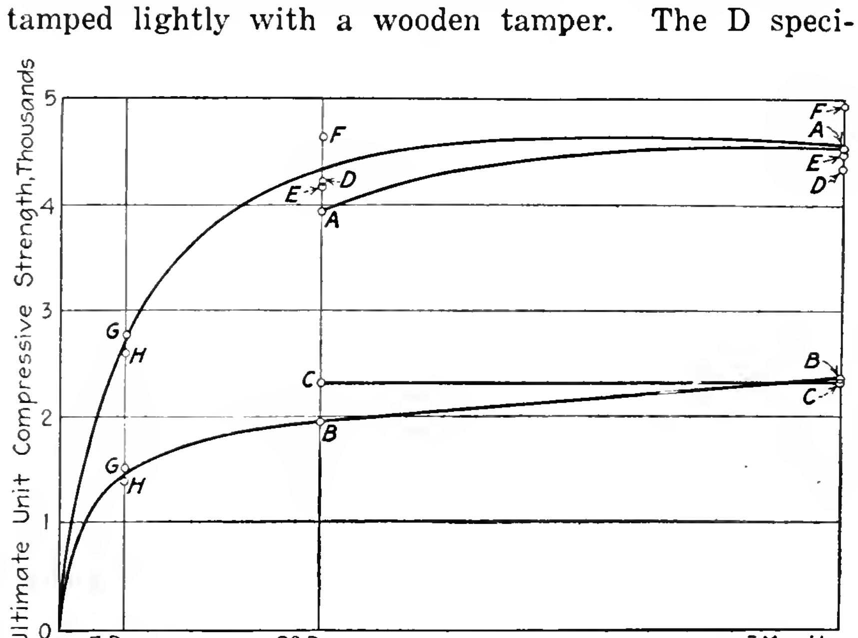


FIG. 1. TIME-STRENGTH CURVE OF RODDED CONCRETE CYLINDERS

mens were rodded every 15 to 30 minutes for four hours, when the concrete had set so firm that the rod would not penetrate more than 2½ in. The E specimens were rodded every 10 to 12 minutes for 2½ hours. The F specimens were rodded every 30 minutes for seven hours. Of the G and H specimens, one-half were rodded every 30 minutes for 7½ hours, and the other half were left untreated, like the B specimens; the G specimens were

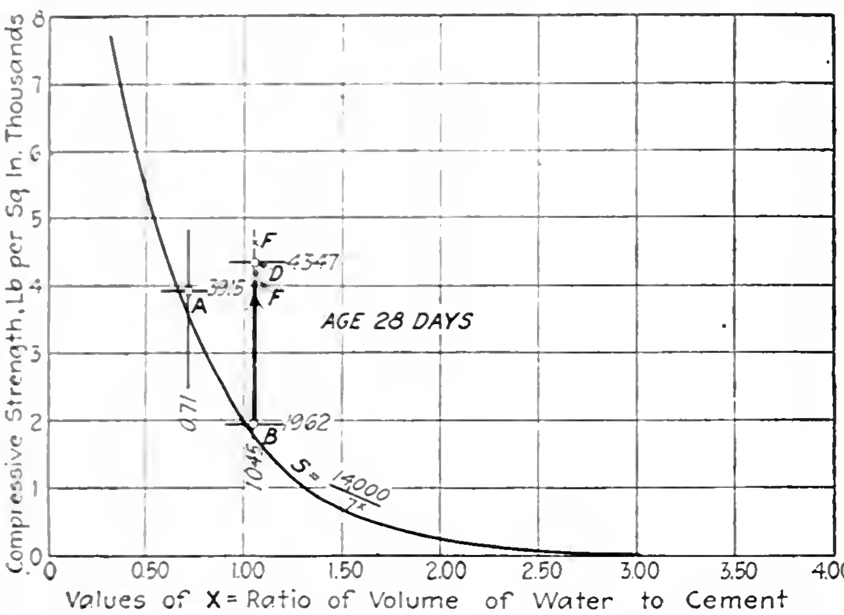

FIG. 2. WATER CONTENT OF SPECIMENS PLOTTED AGAINST STRENGTH

stored under usual laboratory conditions, and the H specimens were left in the molds and exposed to the weather and approximate working conditions.

These average values are shown graphically in Fig. 1. Comparing lines C-C and B-B shows that tamping the soft concrete increased the strength very little. Comparing lines DEF-DEF and B-B shows that rodding the soft concrete increased its strength about 100% at an age of 28 days and over, and about 80% at an age of seven days. Comparing lines DEF-DEF and A-A shows that the soft concrete prepared with a considerable excess water and rodded was stronger than the same concrete prepared with as little water as it was practicable to use.

A very thorough study of the effect of excess water on the strength of concrete by Prof. D. A. Abrams of Lewis Institute led to the value $14{,}000 \div 7^x$ as the ultimate unit strength of concrete at an age of 28 days, x representing the ratio of the volume of water to that of the cement, the latter being based on a weight of 94 lb. per cubic foot. (See *Engineering News-Record* of May 2, 1918, p. 873.) Fig. 2 shows the value $14{,}000 \div 7^x$ and the average 28-day strengths of the A, B, D, E, and F groups of specimens. An inspection of this figure shows that the strengths of the A and B groups, which were not rodded, agree very well with the value $14{,}000 \div 7^x$ and that the rodded groups, D, E, and F, are very much stronger.

TABLE SHOWING EFFECT OF RODDING CONCRETE

	Water Content in Per Cent. of Total Weight	Treatment	Compressive Strength Lb. 1 Sq. In. 28 Days	3 Months
A	6.7	Tamped	3,915	4,559
B	10	Slowly filled	1,962	2,386
C	10	Tamped lightly	2,313	2,343
D	10	Rodded every 15 to 30 min. for four hours	4,211	4,363
E	10	Rodded every 10 to 12 min. for 2½ hours	4,188	4,512
F	10	Rodded every 30 min. for seven hours	4,644	4,961
G (a)	10	Rodded every 30 min. for 7½ hours, stored in laboratory	2,770	
G (b)	10	Slowly filled, stored in laboratory	1,522	
H (a)	10	Rodded every 30 min. for 7½ hours; exposed to weather; slowly filled	2,611	
H (b)	10	Slowly filled; exposed to weather	1,409	

It seems very probable, from a study of Fig. 2, that the particular increase in strength, about 100%, due to rodding, found in these experiments, was caused by the particular percentage of excess of water used in preparing the specimens, and that the beneficial effect of rodding varies with the percentage of excess water used.

The increase in strength produced by the rodding is no doubt due to the removal of the excess water and the entrapped air and to the compacting of the aggregate. Specimens D, E and F, for example, had an average weight of 147.9 lb. per cubit foot and specimens B a weight of only 142.1 lb. To a certain extent, the excess water may act as a lubricant to permit a better compacting of the aggregate.

Strength Requirements for Manila Rope

SPECIFICATIONS for purchase and acceptance of manila rope recently drawn up for Government use by the Bureau of Standards give figures for required breaking strength according to the table reproduced below. Tests are to be made on pieces not less than 5 ft. long between end connections or splices; at least one coil of each size of rope in a given lot is to be tested, and if the lot includes a large number of a given size from 3 to 5% of the coils shall be tested. If the ends of the test specimens are fitted with eye-splices for test the inside diameter of the eye must be at least 7 in., and the splices must be strong enough to insure a break in the body of the specimen. An unusual clause of the specifications reads:

If not more than 30% of the coils tested fail, the lot, except the coils which have failed, shall be accepted. If more than 30% fail the manufacturer may request and shall be granted a retest of one or more lots of an equal number of specimens taken from the same coil or other coils of the lot. If not more than 30% of the entire number of tests fail, the lot, except those coils which have failed, shall be accepted. Any coil which has failed to

WEIGHT AND STRENGTH OF MANILA ROPE

New Government Specifications, Drawn by Bureau of Standards
Figures apply to three-strand rope, medium-laid. Four-strand rope may run up to 7% heavier and may show 95% of the tabulated strength.

Approximate Diameter in Inches		Circumference in Inches	Approx. Gross Weight of a 1200-Ft., Coil in Pounds	Maximum Net Weight per Foot Rope in Pounds	Minimum Breaking Strength in Pounds

	2 1/4	7	1,764	1.441	38,500
	2 1/2	7 1/2	2,016	1.646	4[illegible],500
	2 5/8	8	2,304	1.881	49,000
	2 7/8	8 1/2	2,580	2.107	55,000
	3	9	2,916	2.381	61,000
	3 1/8	9 1/2	3,240	2.645	67,000
	3 1/4	10	3,600	2.940	73,000

meet tensile requirements on the first test shall be accepted if two subsequent tests prove satisfactory.

The size and weight of the rope are to be determined while the rope is stressed by a load in pounds equal to 200 times the square of the diameter of the rope in inches. The weight per foot is also determined on the basis of the length of the rope when stretched under this load. A tolerance on circumferential measurement of size is allowed, ranging from $\frac{1}{8}$ in. for rope from $\frac{3}{4}$ to $1\frac{3}{4}$ in. in circumference, to $\frac{5}{8}$ in. for rope $9\frac{1}{2}$ in. and over in circumference. The weight tested is used, in case the rope overruns the tabulated weight, for reducing the billed weight in the same proportion as the overrun of the weight per foot.

It is specified that rope shall contain not less than 8% nor more than 12% of lubricant content. No non-manila fiber must be present in the rope, as indicated by the brown coloration of manila and red coloration of other fibers after treatment with acidified bleaching-powder solution followed by exposure (when dry) to strong ammonia fumes.

Concrete Mat and Columns Reduce Cost of Building

Heavy Foundation Work Avoided by Concrete Mat Over the Site—Columns Have Cast-Iron Core with Rods and Spirals

TO AVOID excavation in quicksand, and other expensive work in soft soil, a reinforced-concrete mat covering the entire area of the site was used for the foundation of the 10-story Blatt apartment building, which was erected in Chicago in 1917. Concrete columns of the Emperger type, with cast-iron pipe cores, were used in the same building. Street columns and reinforced-concrete floors were provided in the original design, but concrete construction was adopted on account of the high cost and uncertain supply of steel. The cost of the concrete columns and floors is said by the designer to have been only about 55% of that estimated for the steel work thus eliminated.

Situated near the lake shore, the site, about 106 x 160 ft., has the sidewalk elevation 14 ft. above lake level and only 6 ft. above ground water. The ground consisted of 20 ft. of fine sand over 30 ft. of soft clay.

Footings on wood piles were called for in the original design. Under the Chicago building code, however, the piles would have to be cut off 12 in. below lake level. This would have required 15 ft. of excavation, 9 ft. being in water-bearing sand or quicksand, necessitating the inclosure of the site with steel sheeting. The cost of such foundation work would have been prohibitive. Concrete piles also would have been expensive, as they would have had to be at least 40 ft. long.

A flat-slab raft or mat foundation which would give a load of not more than about 2000 lb. per square foot was then proposed. This was adopted, and the work was completed within six weeks. The slab is 24 and 20 in. thick, made of 1:2:4 concrete. Reinforcing bars are arranged as shown in the drawing. Special $\frac{3}{4}$-in. bottom bars in the spaces between the columns are provided for taking up the negative moment, and 1-in. bottom bars under the columns are provided for the same purpose. Both sets of rods are 10 ft. long.

To limit the shear to about 75 lb. per square inch, column footings or pedestals of 1:1:2 concrete were built on the slab. Each footing is 30 in. high, $5\frac{1}{2}$ ft. square at the base and $3\frac{1}{2}$ ft. at the top. It is reinforced with a 25-in. spiral of $\frac{1}{4}$-in. wire with 1-in. pitch, in order to allow the high compression load which the columns concentrate on the cast-iron base-plates.

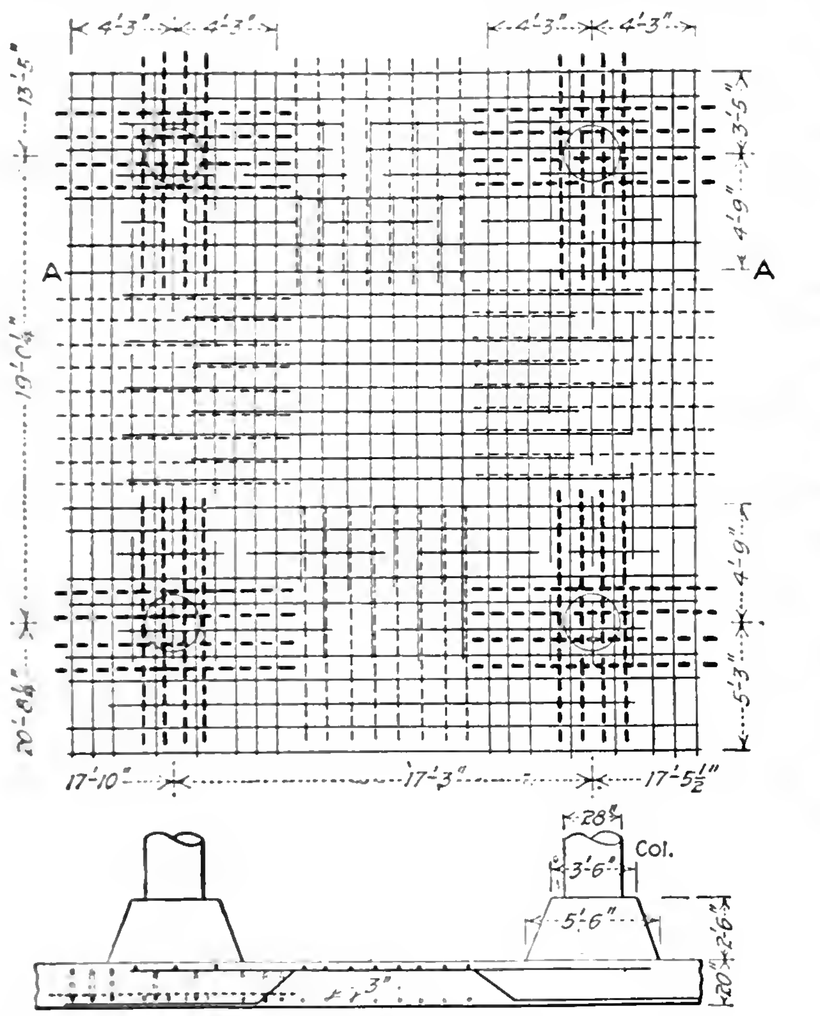
FOUNDATION SLAB AT BASEMENT IS READY FOR SUPERSTRUCTURE

Columns of the Emperger type, having cast-iron pipe cores, form one of the special features of the structure. The cores were plain cylindrical castings, poured vertically. They were mainly of 5- and $9\frac{1}{4}$-in. outside diameter, the thickness varying from $\frac{1}{2}$ to 1 in. for the former and $\frac{7}{8}$ to $1\frac{1}{2}$ in. for the latter. Butt joints were made about 2 ft. above each floor line, spliced with outside sleeves, as shown. Three 12-in. dowel rods were embedded in the concrete filling, in order to line up the columns and prevent lateral shifting. Cores for the basement and the first floor were cast in one piece, as the basement is only a 6-ft. pipe chamber, so that the height of these tall cores did not exceed 15 feet.

Dowel bars in the columns extend from the bottom of the concrete slab to about 30 in. above the first floor, as shown

in one of the drawings. There are 12 of these bars to each column. In the wall columns eight bars are on the outer side, with their horizontal bottom ends bent toward the inside of the building. The other four bars are on the inner side of the column, with their ends bent toward the outside of the building. All the rods lie within the spiral hooping of the column base and column.

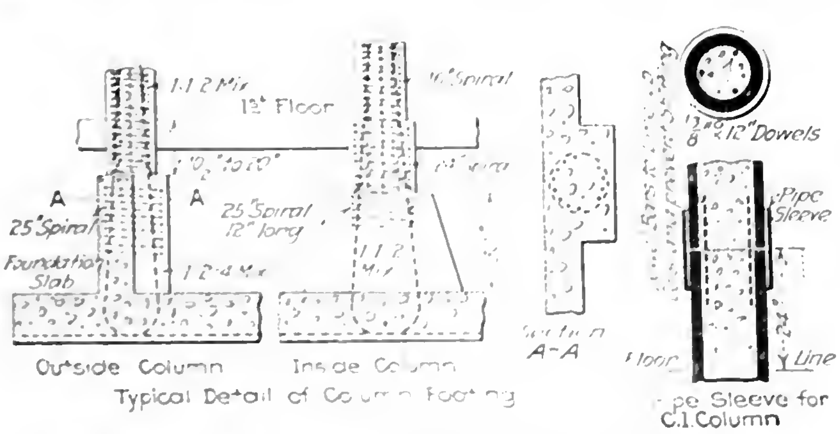
Above the first floor the columns were made of the same sizes as those originally provided for steel con-



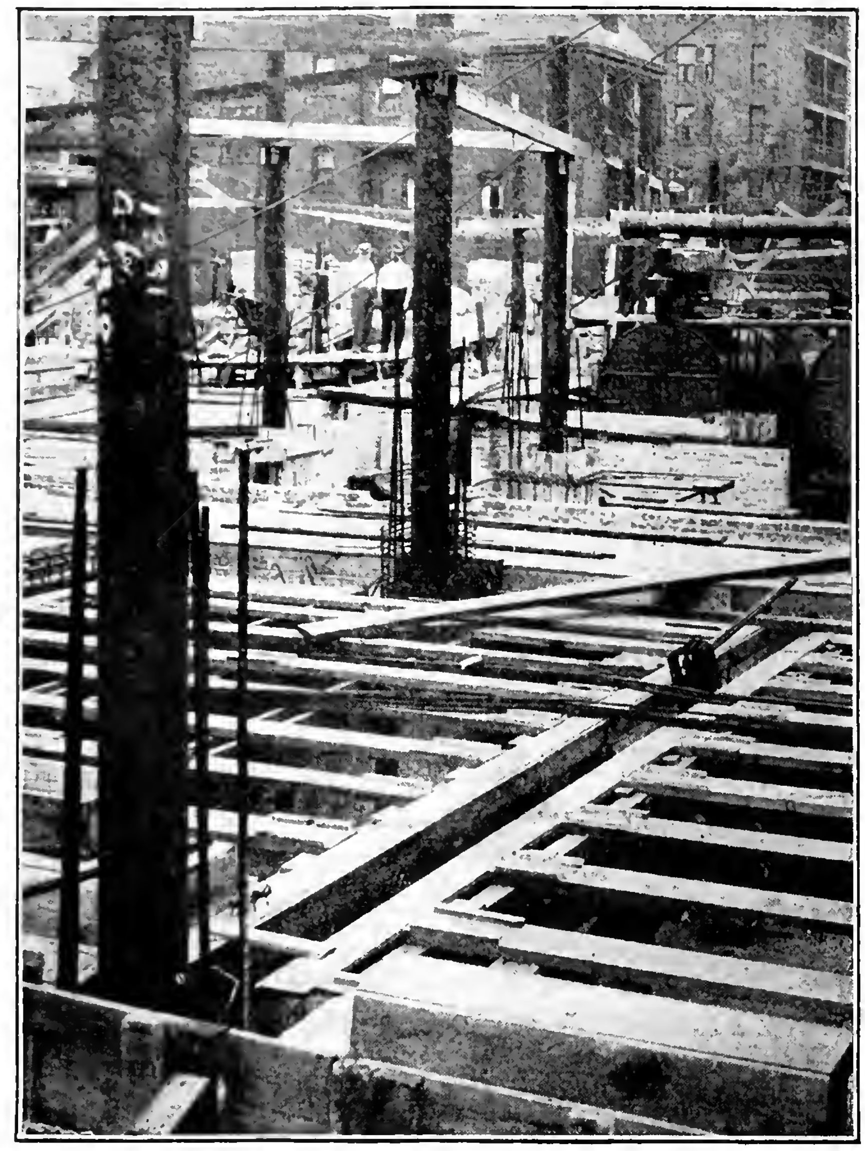
CONCRETE MAT IS FOUNDATION FOR 10-STORY BUILDING ON SOFT GROUND

struction with concrete fireproofing. The short stub columns in the basement were made larger than the original design and were provided with pyramidal concrete bases, as already described, in order to distribute the load and thus reduce the punching shear on the concrete mat which forms the foundation of the building.

Concrete of 1:1:2 mix was used for the interior filling and exterior casing of the core, the latter being 1½ in. thick outside of the steel spiral which surrounds the vertical reinforcing rods. To meet the safe-load requirement of the Chicago building department, the



CONCRETE COLUMNS HAVE CAST-IRON CORES—BENT BARS ANCHOR THEM TO THE FOUNDATION SLAB



CAST-IRON CORES READY FOR COLUMN FORMS—FLOOR FORMS IN PLACE

vertical reinforcement and spiral were each made 1% of the cross-sectional area of the iron core. Stress on concrete over full core area, inside spiral, was taken as 1120 lb. per square inch. Stress on cast iron was taken as 11,200 lb. less the 1120 lb., or 10,080 lb. per square inch.

R. W. Wilson & Co. were the architects. The adopted foundation and columns were designed and built by L. J. Mensch, contracting engineer. These plans were checked by the Westcott Engineering Co.. consulting engineers for the architects.

Decrease in Lumber Production in 1918

Recent tables compiled by the United States Forest Service show that the State of Washington, with a record of more than 3,250,000,000 ft. of lumber cut in 1918, Oregon with 2,000,000,000 cut and Louisiana with a cut of more than 1,500,000,000 ft. are still the great lumber-producing states of the country, with Mississippi, California and Nevada (the two in one division), Wisconsin, Arkansas, Texas and Idaho each cutting more than 500,000,000 ft. each. A total lumber production of 32,760,000,000 ft. is the estimated cut for 1918 on the basis of partial returns received by the Forest Service from 731 sawmills, each of which cut 5,000,000 or more feet in 1917 or 1918.

In 1917 the total production of lumber in this country amounted to 36,000,000,000 feet. The decrease in 1918 is not confined to any one region but is general. It is largest in the Southern and Eastern states and least in the Western states. Maine shows the greatest percentage of decrease.

Short-Circuiting Floods in the Big Sioux River

Two Thousand Second-Feet of Floodwater Dropped 110 Feet in Distance of 300 Feet Through Canal at Bend in River—Hydraulic Jump Takes Energy Out of Fall

By Francis C. Shenehon
Consulting Hydraulic Engineer, Minneapolis, Minn.

FLOODS in the Big Sioux River near Sioux Falls, S. D., are to be guarded against in the future by the Sioux Falls spillway, designed to pass 2000 cu.ft. of floodwater per second through a descent of 110 ft. in a distance of 300 ft. The spillway not only conducts the water but serves to absorb the destructiveness of its great energy. This absorbed energy is better comprehended by thinking of it as 25,000 theoretical horsepower.

The Big Sioux River, approaching Sioux Falls from the north, passes south tangent to the city, then makes a loop of 26 miles of meandering course, and returns through the city. The descent of the river over a bed of red jasper or quartzite rock creates a water power about which the city has centered and grown. The developed fall is 62 ft. The river departs northward again flowing in a deep gorge, and having a water surface level about 115 ft. below the surface level of its first tangential approach. From the upper river to the lower river across the neck of the loop is about 2½ miles, and this is the short cut for the diversion of floodwaters.

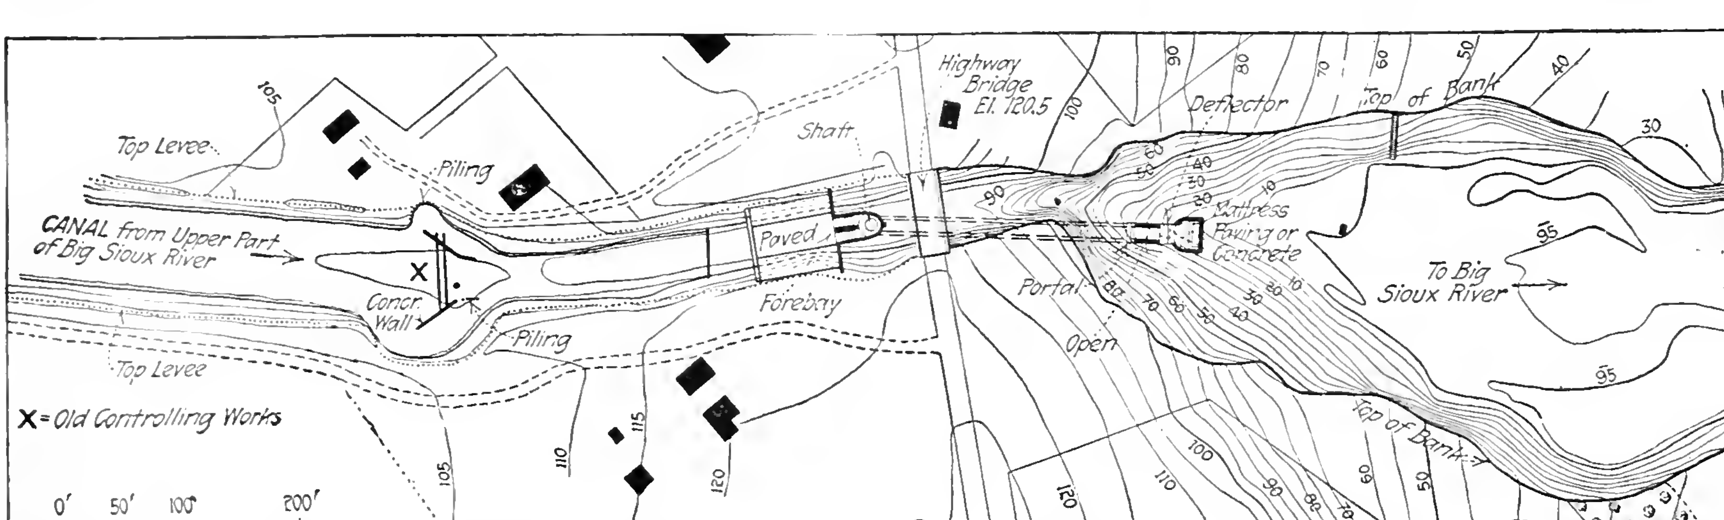
The river as it comes from the north has a drainage basin above Sioux Falls of 4450 square miles, the headwaters lying in the Heights of the Prairies in the northeastern part of the state. It has the characteristic devious, winding course of a stream flowing in banks little depressed below meadow lands. Its travel in reaching Sioux Falls appears as much as 300 miles with slopes not much exceeding 1 ft. to the mile. Between 1% and 2% of its drainage basin consists of lakes which have a slight tendency to detain the floodwaters and stabilize the flow. The normal annual rainfall is about 23 inches.

The southward flow of the river, with the ice disappearing downstream first and clearing the way for the later floodwaters from up-state, is not favorable for excessive flood volumes in the spring breakup. The corridor shape of the drainage basin, and its flat slopes, tend to the slow development of floods, and the lesser probability of synchronizing flood peaks. No records were available of flood flows. From high-water marks, channel dimensions and slope considerations, the writer's estimate of the bank-full flood flow was 6000 cu.ft. per second; or 1.35 cu.ft. per second per square mile of drainage basin. The spillway was designed to carry one-third of this normal flood flow, with some overload capacity.

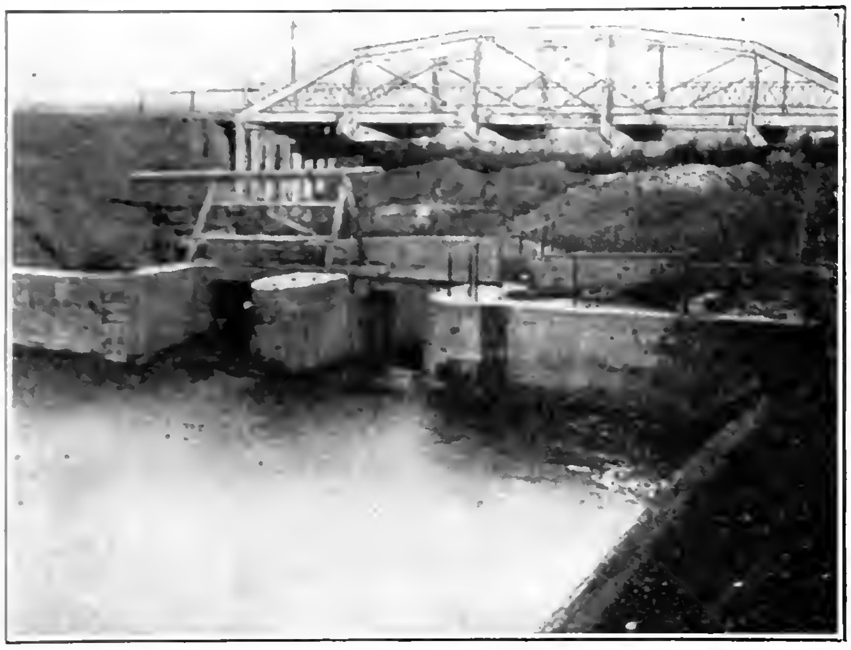
The upper river valley is flat, about two miles wide, and rimmed on either side with low boulder-clay ridges. The valley subsoil is fine sand easily eroded, and the top soil is a black clay loam enriched by centuries of overflow. The lands bear abundant crops and are valuable. The river channel is but slightly depressed in the valley floor, and in the past it has shifted to some extent.

WRECK OF OLD SPILLWAY, FLOOD OF MARCH, 1916

It was an obvious expedient to ditch this land for drainage purposes, and to give these ditches an outlet through the south rim of hills into the river of the gorge. These ditches were made large enough to divert water from the upper river across the neck to the lower river, and thus relieve the congestion of flood-time in



PLAN OF SPILLWAY TO TAKE FLOOD WATER ACROSS LOOP OF BIG SIOUX RIVER, NEAR SIOUX FALLS, S. D.



FOREBAY AND SLUICEWAYS AT HEAD OF SHAFT OF NEW SPILLWAY

the loop. One ditch taps the river 12 miles up the valley, and a second almost abreast the north edge of the city.

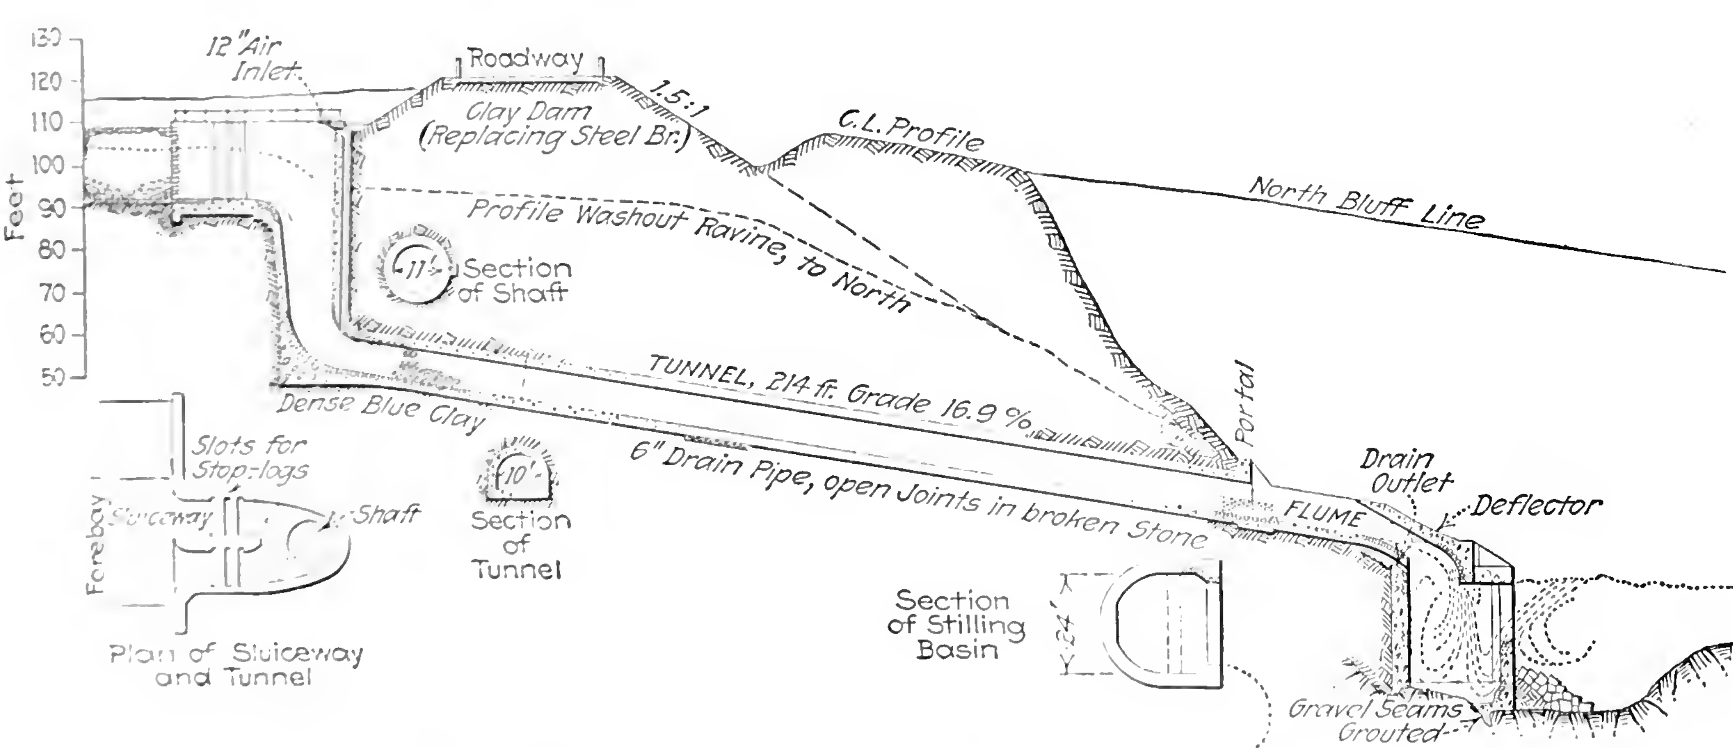
To bring these waters from the valley floor to the lower level, some ten years ago a cut was made through the valley rim and down the sloping river bank, and a reinforced-concrete trough lining was constructed. The destructive energy carried in the surcharged trough was perhaps not fully appreciated; and in the flood of March, 1916, the torrent cut out the protective works at the outlet end, and, by undercutting, tumbled the trough into a mass of broken concrete at the bottom of a gorge excavated 800 ft. back into the sloping hillside. One of the views shows the trough in process of destruction.

The writer was called by the board of county commissioners of Minnehaha County, in August, 1917, to design and construct a spillway of ample capacity.

As stated, the normal desirable capacity of the spillway (2000 cu.ft. per second) was taken as one-third the normal flood flow of the river, and somewhat in excess of the normal bank-full capacities of the ditches tributary to it. When an extreme flood overflows the ditches and brings water overland, increased depth in the spillway sluices will give an overload capacity of 2500 cu.ft. per second.

The geological formations and the topography determined the type of the spillway structure. The walls of the gorge cut at the time of the wrecking of the old trough spillway revealed an underlying stratum nearly 100 ft. thick of tough, rubber-like bluish-gray clay, which in the glacial epoch had been compacted by the enormous pressure coming from an ice sheet a mile or more in thickness. Above the blue clay was a cover of yellow clay of little tenacity. The blue clay at an unknown depth was underlain by the red quartzite rock. It was decided to penetrate the blue clay by shaft and tunnel and thus take the shortest route to the gorge, where a confined stilling basin at the outlet could be founded on rock and have a rock bottom.

The spillway as perfected was made up of simple elements. Controlling works were placed at the upper end, with sluiceways limiting the inflow to 2000 cu.ft. per second with water at El. 104. The sluiceways are provided with stop-logs to shut off the flow when desirable. Above the sluiceways the ditch is enlarged into a forebay and paved. A stilling basin is at the lower end, where the flood waters are made to plunge into a well, 25 ft. deep, U-shaped and equivalent in horizontal area to a circle 24 ft. in diameter. A conduit leads from the sluiceways to the stilling basin. It was designed to destroy energy, so the conduit first drops vertically in a circular shaft tapering to a diameter of 10 ft. at bottom. Then an elbow turns the water through an angle of 80° into a tunnel 10 ft. wide and 8 ft. high, with circular arch overhead. The tunnel is 214 ft. long and descends on a 16.9% grade. Then comes an open flume of the same width, with sidewalls 8 ft. high, bridged between the tunnel portal and the basin, so that the earth may settle from under its floor without endangering its stability.



SECTION THROUGH SPILLWAY CANAL AND TUNNEL SHOWING DETAILS OF STILLING BASIN

The flume leads to a curved deflector beam, where the flood stream is turned vertically down into the center of the well or stilling basin. As the water is turned downward on the deflector it spreads out laterally and strikes the water in the basin in a thin sheet perhaps 2 ft. thick and 20 ft. wide. Perhaps the well should be called a seething basin instead of a stilling basin, be-

FLOODWATER COMING FROM TUNNEL INTO STILLING BASIN CUTS ITS OWN CHANNEL

cause the water is not stilled when it issues from the basin in a stream 20 ft. wide and 15 ft. deep, but is alive with energy. The final absorption of the residual energy takes place in the open gorge downstream from the basin, where the rock bottom is at a depth of 30 ft., and the stream is free to cut out for itself a channel 100 ft. wide if it needs it. Sixty feet downstream from the basin the floodwater flows tamely away.

The original intention was to confine the secondary turbulence and expansion within concrete walls extending 80 ft. downstream. Since, however, this secondary turbulence could excavate in the gorge its own deep basin without cost and without danger to the stilling basin on its rock foundation, it appeared sound to regard the concrete extension as redundant, and to save its cost. This hydraulic excavation of the outer basin was successfully accomplished in an eight-day flood in March of this year. The flow was restricted by stoplogs to 1200 cu.ft. per second and the gorge walls were brought down in little landslides which did not endanger the structure. The lateral eddies were not allowed to advance unduly upstream. When the outside basin dimensions have been worked out by the floodwater itself, a fillet of heavy rock fragments will be made outside the basin and downstream from the sill, and a heavy cover of rock will be placed at the sides of the basin where the slow swing of the eddies tends to encroach upstream.

One geological feature is still to be explained. The rubber-like blue-gray clay rests on a stratum of fine quartz sand, which at the basin was 20 ft. in depth. This sand yields a small spring flow. It is not quicksand and does not flow, but where exposed to current wash it undermines the blue clay and causes the landslides mentioned above. When a condition of equilibrium is reached, the blue clay has formed a talus bank which confines and protects the sand from further wash. The clay itself does not scour readily.

The principle involved in the absorption of energy in the stilling basin is that of the hydraulic jump, or standing wave, in which a stream of high velocity and small section undergoes a transition to a stream of low velocity and large section. It has been much discussed of recent years in connection with the detaining reservoirs of the Ohio flood-relief projects.

The object of projecting the swift stream vertically downward into a deep well is to make the structure shorter and more compact. This feature was suggested by Adolph F. Meyer, associate professor of hydraulic engineering in the University of Minnesota, who at my request made experiments in the hydraulic laboratory to test the action of vertical jets in a confined pool. Desirable depths and basin dimensions were recommended by Mr. Meyer, but he is not chargeable with the final dimensions adopted or with the omission of the extended basin to contain the secondary turbulence and expansion.

By the Unwin equation a stream 2 ft. deep, with a velocity of 50 ft. per second will have, as its "alternate" after the hydraulic jump, a stream 16.7 ft. deep with a mean velocity of 6 ft. per second. A stream 2 ft. deep flowing at 60 ft. per second will have, after the transition, a depth of 20.2 ft. The velocity of the stream plunging into the well will be between these limits. The well is 25 ft. deep and the depth over the outlet sill is 15 feet.

All structures are of reinforced concrete of massive design. Perhaps the forces to be cared for may be more readily grasped when it is stated that at overload capacity 4700 tons of water per minute are speeding at 35 miles an hour vertically through the shaft, turned nearly to horizontal in the elbow, turned to vertical on the deflector; then flow out of the basin horizontally again. The reaction in the elbow and on the deflector is over 100 tons.

The two sluiceways, each 8 ft. wide and 12 ft. deep at normal flood flow, admit substantially 2000 cu.ft. per second. The duplicate sluices prevent vortex in the

shaft. When the flood is 2 ft. higher, some lands in the vicinity of the spillway are flooded, and some water passes overland back to the upper river further downstream. The sluices under this condition will admit 2500 cu.ft. of water per second. In extreme floods, coming at wide intervals, this depth is expected. When coming in March or April the temporary flooding of some lands will create no large damage. Such a flood means water coming overland from up the valley, the river and the ditches overflowing.

How the Shaft Was Built

The shaft was excavated through the tough blue clay 40 ft. deep and 15 ft. in mean diameter, without shoring. No forms were used, the facing wall of jasper and the clay surface forming the mold into which the concrete was poured. After the tube of reinforced concrete had set over a period of 10 summer days, the excavation was carried down to the base of the elbow, undermining the 120-ton tube. This tended to settle it, like a cork in a bottle, imperviously into the clay.

The tunnel heading was driven from both ends, the dense clay being blasted out with dynamite, and being carved into shape, 12 ft. high and 14 ft. wide, without timbering. One exception to this was over a length of 20 ft. where a pocket was encountered, which precipitated about 200 cu.yd. of wet sand and gravel into the heading. The jasper-faced floor and side walls to a height of 4 ft. needed no forms. The arch was carried on portable forms. All the rock facing was set integral with the concrete.

The basin presented the only really difficult problem. Suitable rock foundation lay at a depth of 25 ft. below water and through 20 ft. of sand. The site was hemmed in by clay bluffs, 100 ft. high, with slopes too steep for stability. Landslides were not uncommon. The basin construction is a story in itself. Pneumatic caisson was clearly indicated, but it was shoved through inside a circular ring of steel sheetpiling. The basin with the deflector and half the flume weighs nearly 700 tons. Its walls are locked to the rock, and it is anchored by the steel of the flume to the earth-bound tunnel against the heavy earth pressure and the water impact.

The spillway was built under the direction of the Board of Commissioners of Minnehaha County, South Dakota. The Sioux Falls Construction Co. executed the work. L. M. Norelius was resident engineer during the most difficult period.

Origin of English Weights and Measures

According to a letter formulated by the World Trade Club advocating universal adoption of the metric system, the present coinage of the British Isles, as well as the weights and measures of both the British Isles and of America, is German. The British pound, both sterling and avoirdupois, originated with the old German Osterling Hanseatic League, which for hundreds of years controlled the trade of England. What is still more remarkable is that America and Britannia continue to use these old German tools after Germany herself has forgotten them. The latter country adopted in 1871 the simplest decimal system of quantity expression known—the application of the decimal to weights and measures, the invention of that truly great Briton, James Watt, in 1783.

Frozen Concrete Thawed by Putting Warm Concrete on Surface

It Is Also Found That Chemical Changes in Setting Concrete Produced Enough Heat To Prevent Freezing

WARM concrete placed on the frozen surface of a previous layer was reported as thawing out the latter, in the construction of the Dead River dam, in northern Michigan, as described in an article in *Engineering News-Record* of Aug. 8, 1918, p. 260. Similar behavior is now recorded in the construction of the East Canyon Creek dam, near Ogden, Utah, described in a paper by A. E. Parker in the "Proceedings" of the American Society of Civil Engineers, March, 1919. In addition, the engineers on the Utah dam concluded that the chemical action by the setting concrete developed enough heat in itself to prevent damage from freezing. The particulars of the concreting work are recited by Mr. Parker as follows:

Most of the sand was in a large pile on the side hill above the two bins and, becoming wet from the autumn storms, it froze to a depth of 2 or 3 ft. The broken rock was coated with frozen earth, snow and ice. Although the bins were roofed, the materials often froze. The only thing done to overcome these conditions was to mix the concrete with hot water. The concrete as it came from the mixer was just above the freezing point, and to maintain it at this temperature it was necessary to keep the water hot and to throw out the larger, solidly frozen lumps. It was planned to use rock plums in the concrete, but cold weather prevented this, as it was too difficult to remove the snow, ice and dirt from the rock.

Rise in Temperature Prevented Damage

Experience soon showed that the rise of temperature due to chemical changes in setting prevented damage from frost when the concrete in the forms was covered at night. Canvas was spread over the forms, steam jets prevented surface freezing, and the temperature of the mass below the surface soon increased sufficiently to remove any frost occurring there, if not too great in quantity. As the steam caused heavy deposits of frozen moisture on the forms, which in melting made a very sloppy condition, salamanders burning coke were substituted for the steam jets, bringing about an improvement of conditions.

When concrete was placed on very cold days the surface of the fresh concrete often froze immediately to the depth of an inch or two. It was found that placing fresh concrete thickly over such a surface quickly thawed it out without harm, but when the freezing was too severe the frozen part was picked, broken up and thrown out. Steam jets were used freely to thaw out and remove the ice from the forms, concrete surfaces and rock walls immediately before concrete was placed against them.

The removal of the 1½-in. pipes in the contraction joints afforded a favorable means of testing the rise in temperature in the concrete when setting. Thermometers lowered into the holes showed in every case a considerable rise, a typical test showing a temperature of 70° F. at a depth of 15 ft. when the air was at 14° Fahrenheit.

A Map-Indexing System Adapted to Small Cities

Number Book, with Simple Classification Scheme Combined with Four-Color Card Index, Used at Riverside, California

By Frank J. Calkins
Riverside, California

NUMEROUS schemes for systematizing the filing of maps and other engineering data in large cities are on record, but very little information is to be found concerning indexing systems suitable for smaller cities, say of 10,000 to 50,000 population. The system developed by the writer for the City of Riverside, Calif., may be useful to others who have met the same difficulty. It is believed that the system will serve until a city has grown to such size that the city engineer's office is divided into several departments.

The objection to systems used by many small cities is that they leave too much to the memory of officials in charge. In developing a better system it was the purpose to eliminate this element. As finally revised, the plan includes a card index and a number record book. These two parts of the system are expected to afford so effective a means of cross-reference that there will never be delay or difficulty in locating the desired map.

The number record book was selected with a view to the strongest and most durable binding. Its page size is 9½ x 13½ inches, with ordinary record-book ruling.

Three numbers were placed on each page, the plan being to reserve one-third of the page for each entry and thus avoid the use of any subnumbers. The description of an article entered under each number is very brief; just enough to trace it in the card index. Thus the space allotted for each number is enough so that as old work is taken out of the files and replaced by new plans or maps the first record under any number can be canceled and the blank space below it used for later entries.

In the front of the book several pages were specially ruled for use as a chronological index of the numbers. In these pages the entries consist of date of entry and number, only. Their purpose is to facilitate finding the entry for a plan about which there may be some confusion in the index, or whose classification has been forgotten. If the approximate date of filing is known the chronological record makes it possible to turn immediately to the entries made about that time.

Another set of pages, with special ruling, in the front of the book is reserved for vacated numbers. That is, when articles are permanently removed from the files and the entries in the book are canceled, the numbers are listed in the vacated-number record, thereby indicating that these numbers are available for new entries. As these numbers are again used for new entries they are crossed off this list.

The index cards are 5 x 8 in. in size and are ruled and printed alike in four different colors—yellow, salmon, blue and white. Other colors, of course, could be added as further classifications were necessary. Yellow cards are used for all street work and alley work, and improvements such as bridges, culverts, profiles, cross-sections, surveys and lighting systems. Salmon cards are for sanitary-sewer records, including sewer farms, manholes, etc. Blue cards are for drainage work, including drainage sewers, ditches, manhole plans, etc. White cards are used for miscellaneous records, including plans, profiles, notes pertaining to parks, schools, public buildings, water systems, etc. The cards are always kept in the index case in the order of yellow, salmon, blue and white.

The column on the index card marked "Kind or Book" is used for describing the kind of paper upon which the map is drawn, or, when field notes are indexed, this column gives the field-book number, and in the "Map No." column following, the page number of the field book is given.

A key card kept in front of the index bears the following explanation of the system: (1) Maps are first indexed in the number-record book; next in the chronological record, and finally in the card index; (2) the heading typed on the index cards should begin over the letter "N" in the word 'Description"; (3) cards are placed in the file in the following order: yellow, salmon, blue and white; (4) all articles are to be cross-indexed as completely as possible; (5) the sign on the index cards shows that the article indexed covers more work than is shown on that particular card; (6) when a map or a plan is taken from the files permanently the number must be entered in the vacated-number list in the record book and note made in the record book and on the card index stating the date and the cause of removal; (7) when vacated numbers are used again such numbers must be crossed off the vacated-number list. As for the plans and maps themselves, they are kept in paper tubes riveted together with eye-rivets, in sections of 50 tubes each; each section just fitting into a space in a wooden rack built in a fire-resisting vault. The tubes are 2 in. in diameter and 36 in. long, and the rack can hold 900 tubes. The tubes are not fastened to the rack and can be removed whenever desired. This size has been found large enough for all practical purposes. The wall space occupied by the rack is approximately 5½ ft. square, while the floor space

Center Gutter Construction Used on Bituminous Street

Sidewalks With Unequal Exposure Utilized as Curbs on Narrow Streets—Plan Helped to Save Trees and Was Economical

By W. D. Johnston
City Engineer, Waterloo, Iowa

BITUMINOUS-surfaced pavement depressed at the center to form a gutter has been used with success in Cedar River Park Plat, Waterloo, Iowa. By utilizing the sidewalks as curbs, and building them with unequal exposures on opposite sides of the street to compensate for differences in elevation, many shade trees, rustic fences, etc., were saved, and a satisfactory and economical improvement was obtained. While streets with center gutters have been constructed elsewhere, it is not known that similar methods and materials were used.

Cedar River Park Plat, on a sandy ridge adjoining the river, was laid out, for the most part, following the rectangular system. The lots were 40 ft. front by

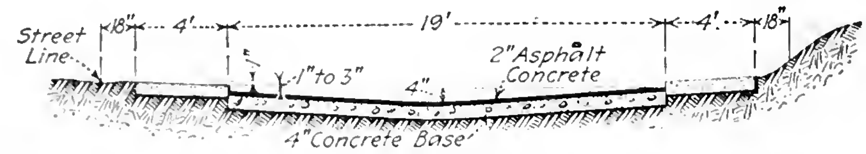
COMPLETED STREET SHOWING WALKS AND TREES

80 ft. in depth, and the streets were 30 ft. wide, with no alleys in the plat. The first stage of its development had been the building of a number of rather small, temporary cottages for summer occupation only; but as time went on additions were made to a considerable number of these and they were reconstructed into permanent homes. This led to a demand for permanent improvements such as sewers, sidewalks and pavements, for the small lots with the increasing number of outside toilets soon proved a nuisance, and the sloping, sandy streets washed away badly with each rain.

In the selection of a type of cross-section for the walks and pavement, the deciding factors were as follows: Rather low property values; sandy soil; fairly steep grades on most of the streets, and the presence of many shade trees, rustic fences, shrubbery, etc., on or near the street lines. After considerable study, the plan and cross-section shown were adopted.

Walks 4 ft. wide were constructed 1½ ft. outside the property line in an effort to leave the trees, shrubs and rustic fences undisturbed. The curves at intersections were built with 4-ft. radii on the inner side and an 8-ft. radius on the outer side. After the walks and sewers had been constructed bids were taken on several types of paving, and the contract was let in February, 1917, on 2-in. asphaltic-concrete surfacing with 4-in. concrete base, at $1.54 per square yard.

In carrying out the construction, a few places were encountered where the transverse slope was excessive and, to avoid throwing the center gutter too far toward



SIDEWALKS ABUT AGAINST CONCRETE BASE AND CONFINE BITUMINOUS SURFACING

the low side, an exposure of ½ to ¾ in. on the low walk, as against 3 to 3½ in. on the high walk, was resorted to, giving the desired result. A view of the completed street is shown.

The cost of the improvement to corner lots where both streets were paved was $190, while for interior lots it was $90, being a portion of the cost of side-street paving and a pro rata part of the total intersection cost. By the elimination of the side curbs a saving of approximately $38 to the corner lots and $26 to interior lots was effected.

Electrical Equipment for Movable Bridges

THE electrical equipment for various types of movable bridges—swing bridges, lift bridges and bascule bridges—is about the same, according to H. H. Vernon, of the power and engineering department of the General Electric Co., in the *General Electric Review.* Both alternating and direct current are used successfully. Standard practice for alternating curent, as illustrated in equipment for a double-leaf bascule bridge, adopts for the main operating power slip-ring motors with normal torque twice that required to overcome the friction of the bridge. Starting torque should be at least twice normal torque. This is necessary in order to provide sufficient torque to overcome static friction under adverse conditions, and to open and close the bridge when a high wind is blowing. The motors drive through a pinion which is either mounted on the motor shaft or on another shaft connected thereto by means of a coupling. Spring-set shoe-type solenoid brakes capable of holding 75 to 100% of the motor torque are mounted on the collector-ring end of the motor The spring-set brakes are used in order that they may be effective at any position of the motor when opening or closing the bridge. The brakes must be arranged so that they can be released by hand, because it is sometimes necessary to operate the bridge on failure of power. Emergency brakes of the spring-set type to hold from 100 to 125% of the normal torque of the motor are mounted on an extension of the motor shaft. Standard solenoid brakes can be obtained to hold 2800-lb. torque at 1-ft. radius.

Either drum controllers or panels containing magnetic switches are used. The lock motor is almost always of 5 hp., of the totally inclosed squirrel-cage type, arranged with metalline bearings and a spring-set shoe type solenoid brake so that it can be tilted at an angle of 90° in a direction at right angles to the shaft. A geared-type limit switch is used for each leaf of the bridge to shut off power from the motors when the leaves have reached their upper and lower limits, and, in addition, to show by means of lamps the open, nearly open, nearly closed and closed positions of the bridge. In order that the power

may not be applied to the lock motor until after the bridge has closed, a track-type limit switch is used that opens as soon as the bridge leaf opens.

In direct-current equipment, the main operating motors are of the series-wound totally inclosed crane or mill type, for which the normal torque should be about twice that required to overcome the friction of the bridge. The motors are arranged with either grease-cut or oil-waste lubrication, so that they will operate successfully when tilted to an angle of 90°. The solenoid brakes are of the same type as that used for alternating-current equipment.

Demobilizing Equipment of Spruce Production Division

System for Inspecting and Recording Keeps Order Among 4800 Classifications—Receipts up to 45 Carloads Per Day Soon Fill 50-Acre Tract of Yards and Warehouses

A WELL organized force of 50,000 men can operate a large amount of logging and sawmill equipment in these days of highly developed machinery. When the armistice was signed, the Spruce Production Division of the Army had great quantities of equipment in the Northwest to demobilize and an endeavor was made to collect it as quickly as possible during the rainy season, and then to dispose of it without disrupting local market conditions. This required also the classifying, inspecting, recording and labeling of each item as it was received, the provision of such weather protection and repairs as were necessary, and when the material was stored, marked and appraised, to find a buyer at a price which would not be unfair to the trade. That, in brief, was the final task set for the organization whose war-time achievements were reviewed in *Engineering News-Record* of Dec. 5, 1918, p. 1023.

STORAGE BAY IN ONE OF THE VANCOUVER WAREHOUSES

The point selected for the collection of the equipment was the cut-up plant at Vancouver Barracks, near Portland, Ore. To this center, shipments were made from about 160 subcenters of assembly at mills or camps in the woods. Each consignment contained a miscellaneous assortment, and, when coming in at the rate of 45 carloads per day, as occurred in January, a good deal of time and attention was required before each item could be delivered to the particular location assigned in the 50-acre tract of yards and warehouses.

There was no time to build new warehouses—in fact, shipments began to come in a full month before work stopped in the big cut-up mill for which the Vancouver tract was laid out. Therefore, as fast as the equipment arrived that required cover, storage space had to be found in the barracks, lumber sheds or kilns. By the time the mill could be shut down and its equipment dismantled, every foot of floor space under the many acres of roofs had been laid off in bays and sections and assigned for storage of classified materials.

For example, in one part of a shed something over 300 ft. square, long tiers of bins were built into which pipe fittings of several hundred varieties and sizes could be conveniently segregated. Across the aisle, racks were built up in which to lay pipe of various sizes that came in with every shipment. Other parts of the same shed were used for railway, blacksmith and grading tools, stoves, pumps, tanks and some 300 other classifications. The interior of one of these storage sheds is illustrated.

There were 4800 classifications on the list, all told. However, for convenience in handling records everything was included under one of 20 general headings, as shown in the table:

GENERAL CLASSIFICATIONS OF LOGGING AND SAWMILL EQUIPMENT

Letter	Number	Description
R.R.	1	Locomotive and repair parts and equipment
R.E.	2	Railroad cars, repair parts and equipment
L.	3	Logging engines, repair parts and equipment
L.E.	4	Cable, blocks and rope
B.	5	Boats and parts
G.	6	Grading tools and machinery
P.	7	Pile-driver and equipment
S.M.	8	Sawmill machinery supplies, etc.
E.	9	Electric equipment and supplies
P.L.	10	Plumbing supplies.
P.F.	11	Pipe and fittings
M.T.	12	Miscellaneous tools and machinery
M.S.	13	Miscellaneous supplies
O.S.	14	Office supplies
C.K.	15	Camp and kitchen ware
E.I.	16	Engineering instruments
F.P.	17	Fire-protection equipment
C.	18	Cranes
L.B.	19	Lumber
R.F.	20	Rails and fittings

Clerks at each shipping point numbered consecutively the consignments for Vancouver, and filled in a shipping tag for each. On these tags were entered quantities, sizes and the general classification numbers of all items included in the consignment. These shipping tags were checked on arrival at Vancouver, and a more complete record was made for the catalog files. The first or general record was made in duplicate on 4 x 8-in. cards, as shown in the accompanying illustration. A yellow copy was sent to Portland headquarters, while a salmon-colored copy was kept at Vancouver barracks. The entries on these cards give the classification number and indicate the storage location by warehouse and section numbers. The inventory number shows by letter the general classification of the article and the number of the item, as entered in that classification. The shipping number includes a letter to designate the camp from which the item came, and the number of the shipment from that camp.

COMPLETE CATALOG LOOSE-LEAF FILE SHEET USED AT VANCOUVER BARRACKS

The catalog files, on the other hand, contain a more detailed description, as shown, and where possible refer to specifications or other manufacturer's records. These catalog files, of which five copies are made, carry the same inventory number as the card index, thus providing a ready cross-index.

A policy was established of putting the current market price on new goods, and rating used equipment on a percentage of this price. To arrive at a fair appraisal value of used equipment such as cranes, locomotives and logging engines, a thorough examination was made, usually by three inspectors working together. One of these represented the catalog board, another the sales department, while the third was a civilian engineer employed as an independent. These three men looked over the equipment together and discussed and agreed upon a fair price for each engine before moving on to the next. Only the clothing and grocery stocks, being considered more or less perishable, were turned over to brokers. On all other classes the purchaser may deal direct with the Spruce Division officers, no matter how small the purchase.

GENERAL-RECORD CARD FOR ALL EQUIPMENT RECEIVED

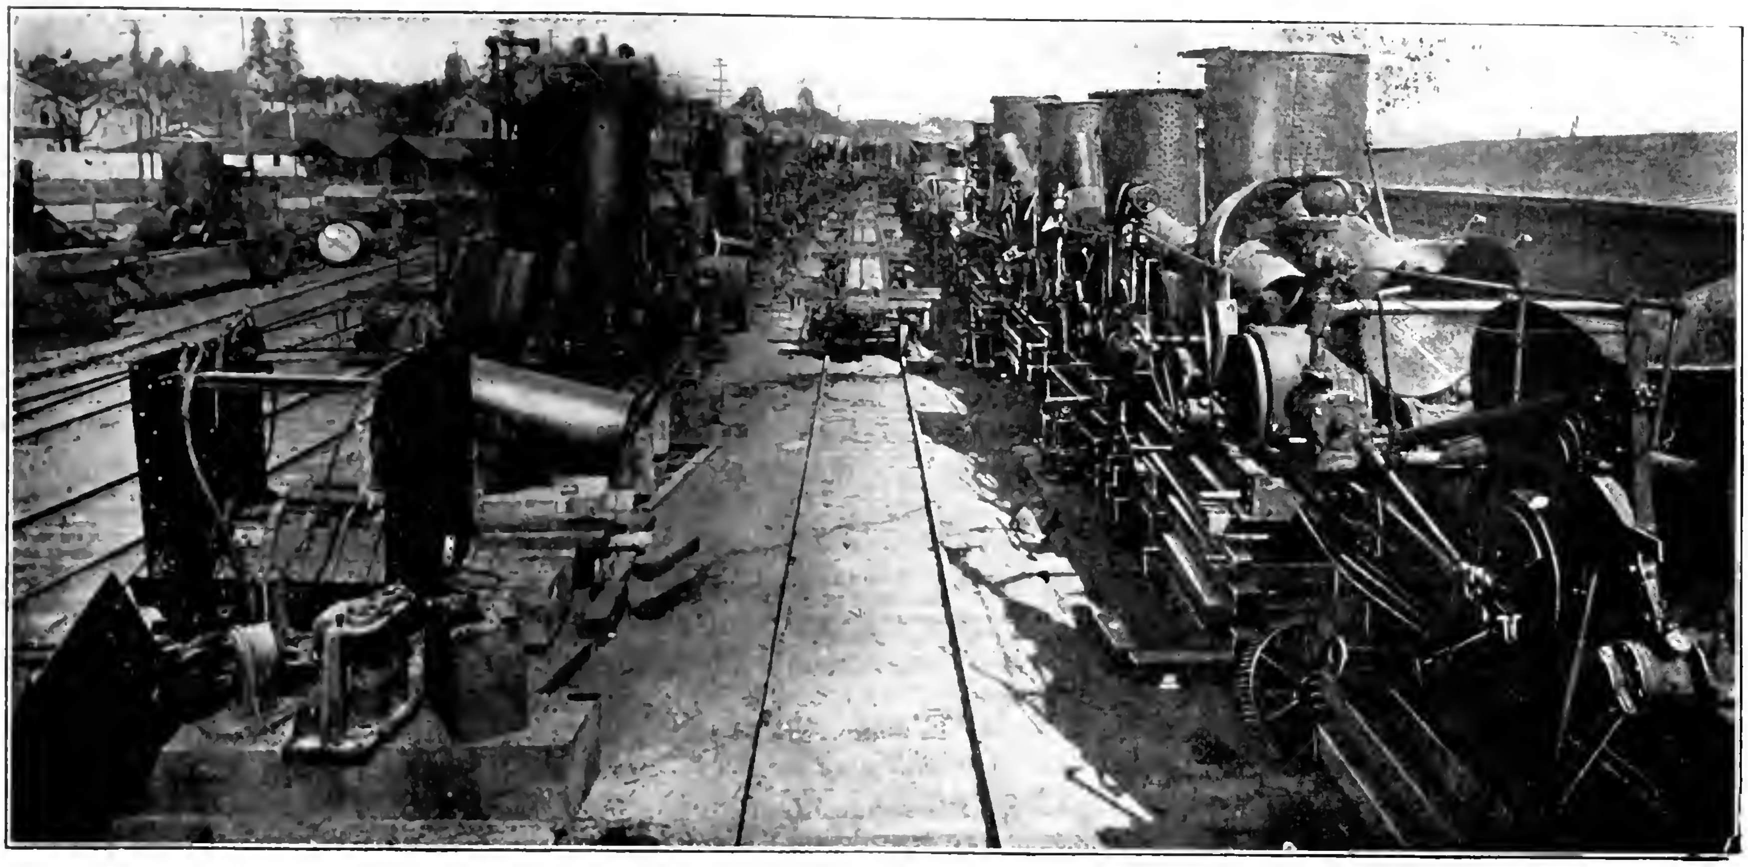
The classification and inventory work was assigned to a catalog board of Spruce Division officers appointed immediately after the armistice was signed. A sales board was also organized and charged with the advertisement and disposal of the property. As soon as the more important items could be classified a list was published, giving a month's notice that bids would be opened Feb. 15. Some 1500 bids were received, but in most of these the bidders had ignored the announcement that bids far below market values would not be considered. Therefore comparatively few bids could be accepted.

Equipment began to come in rapidly by Nov. 25, and the steady stream continued until about Feb. 1. A total of 1324 carloads was received. Without actually seeing the Vancouver storage yards it is difficult to visualize the great quantity and variety of equipment collected there. For example, there were 274 donkey engines, most of which were of large size (11 x 13- and 12 x 14-in. cylinders), 26 locomotives, equipment for three complete lumber mills, 260 pairs of car trucks, a million-dollar stock of groceries, 11,700 tons of rails and 600 motors with electrical equipment complete. Absolutely nothing was left in the woods. Even scrap was brought in to avoid the possible criticisms that might be aroused should it be found there in later years.

Much of the equipment was loaded in the rain, and all of it was more or less hastily taken down, so that, as it arrived at Vancouver, each consignment received such attention as it required. Wet tents were dried out in the kilns; broken parts on machines were replaced; gears and moving parts were greased, and bright parts were coated with white lead. To prevent rusting of the machine as a whole, most of the larger pieces, such as cranes, donkey engines and car trucks, received a light coat of black paint.

At first, logging engines were stored on their sleds, just as they came in. These sleds are made of large timbers about 60 ft. long, and had to be placed parallel to the spur tracks between which they were stored. This required so much space that it was decided to dismount the engines and pile the sleds. The engines were then set on cribs of railroad ties built up to flat-car height, as shown, so they could be easily loaded or unloaded over skids.

The steel cable required more attention at Vancouver, perhaps, than any other one item on the lists. Up to Apr. 15 a total of 629,678 ft. of it had been received in sizes of ⅜ to 1½ in. All of this except the unused reels was rewound so it could be measured, oiled, inspected and appraised. To facilitate this work, two frames, on which reels could be conveniently turned by hand, were set up in the cable warehouse, about 50 ft. apart. A long, narrow trough, from frame to frame, was filled with crude oil, and a snatch block at either end oiled the cable as it passed from reel to reel.



LOGGING ENGINES DISMOUNTED ON TIMBER CRIBS

After being rewound, the cable length was marked on each reel, and the appraised value was entered on the records. Cable was unwound from engine drums in the yard by use of a locomotive crane. To save rewinding this cable again in the warehouse, it was drawn over a measured length of track by means of a snatch block attached to the rail. Thus it passed under the inspector's eye and through a small oil tank on the crane tender, so that when delivered to the warehouse the cable had been oiled, measured and appraised and its length had been marked on the reel.

On the 13 railroads built last year by the Spruce Division nine were considered to have no future as commercial logging projects; therefore, their equipment and rails were brought to Vancouver. The Lewis and Clark line was taken over by the lumbering company with which an agreement on this point had been made before construction. The other three lines are being offered for sale complete as commercial logging properties. These include the 36-mile line on the Olympic peninsula in Washington (Railroad No. 1), 40 miles of track on the Yaquina lines (Railroads Nos. 10, 11 & 12) along the Oregon Coast and the North Nemah line (Railroad No. 5) 7¾ miles long near Willapa Bay, Washington.

A total of 143,000,000 ft. of airplane stock was shipped out by the Spruce Division, the rate of production having been increased from something over 2,000,000 ft. per month in October, 1917, to about 22,000,000 ft. in October, 1918. The 29,000,000 ft. of commercial lumber stored at Vancouver has been sold. All told, about $10,000,000 worth of equipment was centralized at Vancouver Barracks; about $2,000,000 worth of this has already been disposed of.

Shortly before the signing of the armistice the production activities of the Spruce Production Division were taken over by the United States Spruce Production Corporation, and the personnel of the latter has been reduced steadily since that time. Those who remain in important positions are those who were identified with and are proud of its war-time activities. Some are still in the service and some are retained in a civil capacity. The War Department desires that the corporation liquidate its own affairs, and this is being done under the direction of Lieut. Col. C. P. Stearns as successor to General Disque. The fixed policy of the corporation is "to go out of business with as little disruption as possible in the industries and business of the Northwest, with the hope that when the corporation and its activities have passed into history it may be said of it that it helped rather than hindered the community in which it operated."

Motor Sweepers and Trucks Show Economy

HAULAGE of street material by motor trucks, and operation of motor-driven street sweepers and sprinklers have proved economical in Denver, Colo., according to a statement made by F. J. Altvater, highway commissioner, in the April number of *Municipal Facts*, published by the city. At the present charge for teams, the trucks hauling slag and gravel will pay for themselves in one year.

Motor trucks for hauling slag and gravel for street work show a material saving in cost, owing to the high prices and slow work with teams. In 1918, the daily cost for a team was $6 per day, which this year has been increased to $7. A team will average three 1½-cu.yd. loads per day, making a cost of $1.33 per yard or $1.55 at the 1919 rate. Last year three motor trucks hauled from 5540 to 5930 cu.yd. each at an average cost of $0.766 per yard. This cost included repair, oil, gasoline, chauffeur, interest at 6% and depreciation. The depreciation charge was computed at 33.3% for the first year and 25, 20, 15 and 6.3% for succeeding years. Five motor-driven street-sweepers and a motor-driven flushing machine also effected a considerable saving over horse-drawn apparatus; but the sweepers were rather light for the service and their repair cost was very high. Two 2-ton trucks were purchased later to do the heavier sweeping, and as they are separate from the sweepers they can be attached to wagons and other apparatus and thus are kept in use for about 16 hours daily. The two new machines have displaced 10 teams.

Construction Firm Finds Personnel Work Profitable

Group Insurance, Shareholding, Accident Prevention and Medical Care Repaid By Increased Efficiency

(Editorial Interview)

ACCIDENT prevention is an important part, but it is only a part, of the "personnel" service which contractors owe their employees. If reduction of accidents in construction operations pays (and it certainly does pay) so do group insurance, medical supervision and social and personal service of many sorts. Combine these activities with some arrangement by which directing employees become shareholders in the firm's business, and an organization is knit together with which a contractor can face unstable construction conditions with reasonable assurance. "These assertions are not theory," stated L. D. Woedke, manager of the protection and safety department of Fred T. Ley & Co., contractors; "they are facts demonstrated by our own experience."

About every kind of construction has been performed by the company, its work has been widely distributed and its force on different jobs has averaged from ten to ten thousand. If personnel work is impracticable in contracting it would seem that it should fail under these conditions. But the company has proved to its own satisfaction and to that of its clients and its employees that it can take so good care of its men that "they follow the company's operations everywhere and repay, in efficiency, loyalty, reduction in labor turnover, economy and speed, every dollar spent in their interests."

Accident prevention as it is practised by the firm has already been described in *Engineering News-Record* of Mar. 14, 1918, p. 523, and all that need be said in addition is that the results become more favorable with increased experience. Medical service goes beyond caring for injuries. On large jobs complete field hospitals are installed and equipped with medical and surgical supplies, and a regular staff of doctors and nurses and attendants is placed in charge. All kinds of illness are treated in these hospitals, not merely injuries received on the job.

As an illustration of this policy, when influenza threatened to overcrowd the regular hospital accommodations on one job last autumn, an additional field hospital with 40 beds was built and placed in service, with doctors and nurses, in 12 hours. When work on this hospital was begun mechanics and laborers were packing their kits for a general exodus. The sight of the new hospital at once relieved the crisis. Grips were unpacked, the panic subsided and not a man left the job.

The establishment of hospitals is not practicable on small operations, but no job is too small to be without a first-aid cabinet. If the work is near a settlement where physicians are available, arangements are made whereby they will be on call if needed.

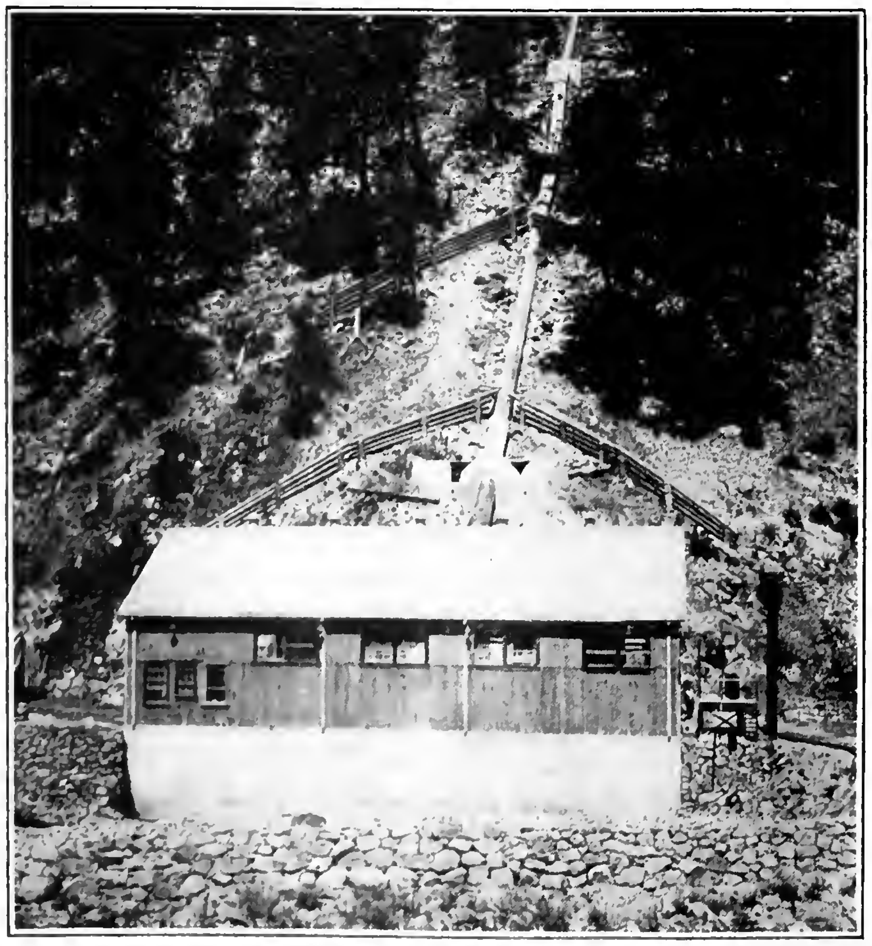
Good wishes and prudent advice are not the limit of service toward making employees financially independent. The firm gives its permanent or regular employees life insurance in amounts of $1000, $1500 and $2000, depending on length of service. In addition, these permanent employees, department heads, superintendents, engineers, etc., have, during the last few years, received preferred stock in amounts determined by length of service, position held and record for good service. A record in detail of every employee enables the firm to shift men to better positions and to place employees who have finished or are about to finish their work on various operations. All these measures combine to make the employee feel that he is an integral part of the business, and he repays the company by loyalty and better work.

The employees themselves have organized for mutual service. The Leyers Club at the home office has branches on all large jobs. Through the activities of this club athletics, dances, field days, lectures, etc., are fostered, the sick are visited, and assistance is given to anyone in trouble. Weekly news bulletins edited by the club are issued to all jobs, offices and departments. The club is now considering a sick-benefit and relief plan.

Annually the company gathers at the home office in Springfield, Mass., all its superintendents, foremen, timekeepers, engineers, department heads, office managers and executives, for a discussion of all phases and details of the business. At this time all complaints, difficulties or troubles of the respective departments or field offices are discussed, with Mr. Ley sitting as chairman. Full stenographic reports are made of these meetings. From the various discussions changes in policies, rules, instructions and agreements have resulted, with improvements in organization and in methods of doing work. All in all, the interest the company has shown in its men has been a substantial factor in the company's rapid and substantial development. C. S. H.

Timber Walls to Divert Rolling Rock From Power House

IN THE cañon of the Tuolumne River, where water will enter an 18-mile tunnel on the Hetch Hetchy project, the slopes are quite steep, with a cliff here and there. Early in the construction work a small wooden tool house near the site of the temporary power house



POWER HOUSE WITH PROTECTION OF TIMBER WALLS

was practically demolished by a rock which was loosened by the road excavation above and rolled down the hill. This accident was taken as a warning of possible damage that might result if a boulder rolled down onto the roof of the temporary power house. Timber wing walls were therefore built along the penstock for the purpose of stopping or diverting rocks that might roll toward the power house.

The power is supplied by a 42-in. steel pipe, 530 ft. long, running from the end of the ditch line on the hillside above. Each of the wing walls consists of two parts flanking the penstock at an angle above the power house. The supports are 14 to 20-in. round posts set 8 ft. in the ground. On the uphill side of the posts a facing of rough logs has been built up and lashed to them with pieces of old cable. Thus far the power house has sustained no damage from rolling rock.

This work is being carried out by the City of San Francisco under the direction of M. M. O'Shaughnessy, city engineer.

Economics of Transportation in the Mississippi Valley

Southern Ports Can Well Be Developed to Take Care of Some of Our Foreign Trade if Interior Transportation Is Revised and Improved—Existing Rates Limit Interior Zones for Foreign Shipment

By J. R. Bibbins
Engineer, Associated with Bion J. Arnold, Chicago

TRANSPORTATION economics in the United States today has to be considered in relation not only to domestic trade but to foreign trade. Future development must take into account easy and cheap transport of goods to and from the great interior of this country to the centers of production and consumption the world over. No longer should it be proper, in the planning for trade, to be bound by the great East-West railroad lines, built up in the past by readily seen causes, but the strategic and economic position of the Mississippi Valley should be studied with a view to its logical connection to world routes. A start on such a study has been made. Its elements indicate some radical revisions in the transportation routes and methods of the United States.

A physical examination of the Mississippi drainage basin leads one to wonder why the lines of economic gravitation cannot be developed along the same lines as hydraulic flow, and then to inquire what forces and tendencies so altered this natural gravitation in the early history of the United States as to result today in the elevation, over the passes of the Appalachian range to north Atlantic tidewater, of by far the greatest proportion of the production of this valley, with all the increased expense incident to such elevation. No student can overlook for one moment the fact that the urge of commerce originated in Europe and has continued in effect throughout the century-old commercial independence of America. However, it must be patent that the study of the "vector diagram" of commerce with reference to Europe and South America, respectively, will reveal the fact that the relative value of abscissa and ordinate are changing, with the result that the force of commerce is gradually shifting toward Panama. New Orleans and Galveston have grown as southern gateways of the United States largely by virtue of the fact that other nations needed our cotton. New Orleans has profited by a triangular trade to Europe, to South America, and back to New Orleans in British bottoms. But still the great transcontinental gateways of Chicago, St. Louis, Pittsburgh, etc., have witnessed the overflowing production from the vast Western plain headed for north Atlantic ports directly in contravention of the natural outlet for this territory through the southern water gates.

The answer must lie in the brains of the inhabitants of the Mississippi Valley, who represent the majority of the voting population of the United States. Their vast waterways lie idle. While dozens of freight trunks radiate from the crowded East-West tunnels of Chicago and St. Louis, not one radial trunk reaches into the Northwest from the second port of the United States. The country seemingly has been educated to think east and west, and the prevailing rate system is conceived on its east and west economic base line. What will be the result when the people of the Mississippi Valley fully conceive of a different economic base line—Chicago to the Gulf?

The Mississippi Valley Association, recently convened in Chicago, showed itself to be alive to the necessities of this situation. At this convention standing committees reported upon numerous matters of fundamental importance. One of these committees, a subcommittee on the economic development of waterways, terminals and electric and highway feeders in relation to transportation, presented a report prepared by Bion J. Arnold, consulting engineer, Chicago. Colonel Arnold's report was based on instructions to investigate the now existing facilities for foreign trade; that is, the existing physical plan of the railroads, terminals and steamship lines and their capacity and adequacy for the contemplated freight movement of the valley. It also dealt with the economic policy under which these transportation facilities are used and should be used.

As a preliminary to the study, Colonel Arnold prepared a statement of principles and policies which is as follows:

1. Methods of securing actual commodity movement along natural economic lines of transit.
2. What are these natural economic lines of transit?
3. Natural and artificial barriers, preventing logical movement.
4. Necessity of curtailing man-handling of freight.
5. Economic median lines of rail transit for overseas movements.
6. Function of low-grade lines in controlling mass movement; their ultimate dependence on shipping.
7. Midcontinental gateways and their effect on commodity movement.
8. Shall the cost-of-service-plus-profit basis be allowed to control the transit movement in the valley?
9. Should overseas traffic movement be adjusted to a least-ton mileage basis—that is, shortest route, taking the relative cost of water and rail into consideration?
10. Function of storage in absorbing heavy seasonal movement and securing much desired two-way loading for steamship lines—i.e., a "balanced port."

11. Effect of policy of national waterway development upon transcontinental movement.

12. Lessons to be drawn from past waterway experience.

13. Proper economic field for railroads and waterways with respect to different classes of freight.

14. Comparative possibilities of Mississippi River and rail routes between specific points.

15. Should waterways develop as through freight carriers—i.e., largely as a full-cargo trunk line, rather than as packet lines?

16. Special terminal facilities required for: (a) Freight originating at main terminal; (b) transshipped freight.

17. Desirability of the "sailing day plan" as a terminal policy for both rail and barge lines.

18. Type of floating equipment and economic units best suited for handling different classes of cargo.

19. Can the electric railways function individually or collectively to any extent as freight carriers to and from points of rail interchange or transshipment to water lines?

20. Is there any necessity of extensive motor-highway development as a means of accelerating interior production and thus tending to guide this movement through properly designed channels or terminals?

21. Immediate steps to be taken to secure a sound development program.

General Consideration of Principles

Having put these general questions, Colonel Arnold continued with the following general consideration of the policy to be pursued and the conclusions which are to be drawn therefrom:

The Mississippi Valley should be considered as a great *drainage basin* favoring natural rather than artificial outlets. Up to the present time, the laws of economic gravitation within this drainage basin have been artificially upset to a large degree. The question now is to reëstablish economic equilibrium, which involves four essential elements: (1) Rails; (2) waterways; (3) terminals, and (4) shipping.

It is contended that commerce needs *both* rail and inland water transportation, especially where a vast bulk of commodity movement runs in seasons. Railroads are expensive transportation systems when they have to be built largely for short-seasonal use. Therefore, on general principles, the capacity of the natural waterways should be drawn upon to their fullest extent where possible to relieve railroad operation of this expensive peak-load traffic.

Successful business adjusts the character of its facilities to the requirements and profits of each particular branch; that is, classifies its operation. So should the waterways be used intelligently as a coördinate agency to railroad transportation, rather than as a competitive agency.

But a clear definition and understanding of advantages and limitations is very desirable. To attempt to handle bulk cargo in little bottoms with no terminal facilities is manifestly wrong policy. The great waterways are trunk lines primarily, and transportation should be provided and sold *wholesale* rather than retail. Further, something more than a paved levee or even a simple wharf is required for economic handling, especially with rising wages. Frequent *man-handling* will destroy both the profits and the practical success of waterways movement. For this reason, the "*original-package*" idea is being actively worked out, by means of which transshipment from rail to barge and vice versa may take place, without breaking bulk, through mechanical handling in original packages.

Over 30% of Chicago's freight passes *through* the city, carload freight being rehandled in original cars, less-than-carload freight being handled in parcels. For carload freight, man-handling has been reduced to a minimum by the terminal yards at clearing. The railroads are still wrestling with the problem of reducing the cost of man-handling less-than-carload freight.

In the Mississippi Valley's largest port, nearly 30% of the incoming freight passes over the wharves *direct* and this would probably be increased to 50% if all *freight held in transit* were included; i.e., seasonal freight held over season in storage warehouses for later transshipment. Chicago's freight has to pass on promptly, as every hour's delay means increased congestion. Overseas freight, on the other hand, must have waiting time, hence the vital importance of warehousing, storage and methods of prompt handling to clear the wharves for incoming and outgoing boats. It would be idle to build railroads without vast city terminals. It is equally idle to develop waterways without equivalent terminals; for terminals are only reservoirs in which to permit freight to "slow up" in its general movement to destination. The faster the main-line movement, the more terminal capacity is required to avoid congestion.

Conclusions as to Policy

In order that the Mississippi Valley Association may have a tangible basis upon which to organize, promote and finance the advanced policies, physical improvements and desired changes in established methods of transportation, it should undertake a transportation survey to be conducted with as little delay as possible for the purpose of argument and defense of the following program:

1. Encourage the construction of more direct trunk-line transportation from the Northwest to Gulf ports, particularly via the Alexandria-Shreveport gateway.

2. Ascertain the maximum possibilities of classification and freight handling by means of which slow and fast freight may be routed on lines best adapted thereto, with rates gaged accordingly.

3. Endeavor to secure a freer interchange between steam and electric lines than at present, in order that the latter may become more useful in the general transportation scheme than at present.

4. Consider fully the economics of motor-truck transportation in all its aspects, prior to commitments for vast expenditures in expensive motor highways, so that both motor equipment and highway expenditures may be kept within their proper economic limits.

5. Study carefully every possible means of encouraging a balanced two-way vessel movement through Gulf ports which will be perhaps the most important factor in attracting additional shipping facilites.

6. Support the Government program for inland waterway development assisted by state contributions where necessary to prevent excessive lockage time and delays on canalized routes.

7. Ascertain the reasonable *base cost of service* per ton-mile of transportation within the valley:
   - (a) By rail;
   - (b) By water;
   - (c) By rail and water;
   - (d) Cost of transshipment:
     - (1) By handling or trucking,
     - (2) By mechanical means

   for typical commodities and points of origin.

8. Ascertain similar base cost of service per ton-mile of both waterway and overseas haul, disregarding existing arbitraries and differentials.

9. Determine how far the cost-of-service-plus-profit basis may be allowed to control the transit movement within the valley, without too great disturbance of the existing economic structure upon which the commerce of the country is based.

10. Determine what readjustment of shipping schedules and capacity, as between various ports, is reasonably called for in order to meet this cost-of-service basis of interior transit.

11. Ascertain the desirable economic section which should be built for the Illinois waterway, the rock cuts and for locks in this and in other waterways, in order to minimize the delays in breaking up fleets of barges in transit.

12. Consider with care the economic size of barge units.

13. Consider the maximum application of the "original-package" idea for rail-river transportation, in order that a fair trial may be had.

14. Encourage the construction of barge terminals for originating or transshipped freight, and especially the pro-

vision of mechanical methods of freight handling to the maximum extent.

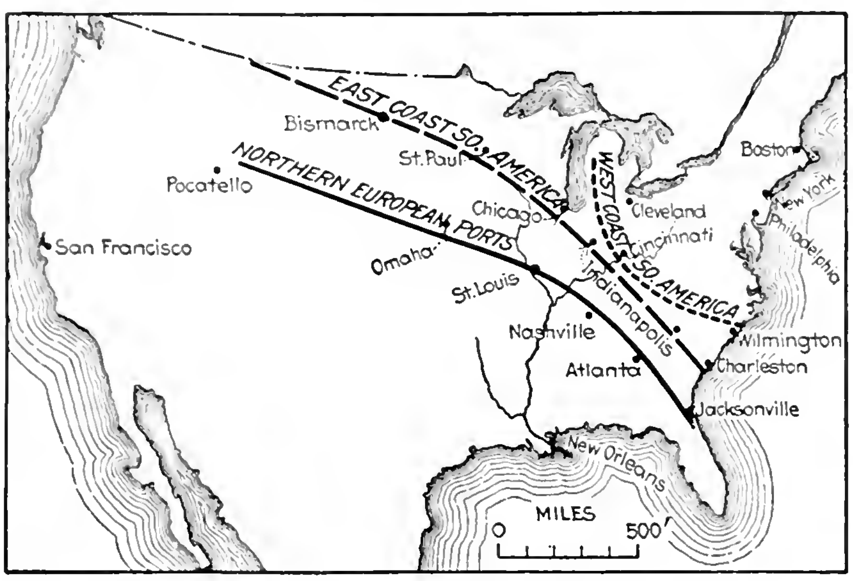
15. Impress upon municipalities the vital necessity of doing their full share in providing the required terminal facilities.

Delays in transit will be the greatest enemy of inland water transportation.

Economic Median Lines Explained

A definite conception of what is involved in the great economic questions analyzed in the foregoing statement is illustrated in the accompanying diagram, which is presented through the courtesy of the Public Belt R. R. of New Orleans, being a part of a technical study of the transportation development of that city.

This diagram shows which territory is properly tributary to the Gulf and North Atlantic ports of the United States (specifically in the diagram New Orleans and New York), disregarding all other considerations except those of rail and overseas transportation. The territory north and east of each of the lines, for instance, should



ECONOMIC MEDIAN LINES SHOW ZONES FROM WHICH OVERSEAS FREIGHT SHOULD BE SHIPPED

Goods to and from territory north and east of lines should pass through New York; zones south and west are tributary to New Orleans; based on average prevailing tariffs, assuming one mile rail haul equals four miles water haul.

ship goods to the foreign districts attached to those lines, through the north Atlantic ports. The territory south and west of each of the lines should ship and receive goods through the Gulf ports. These lines, which for the purpose are called economic media lines, are worked out on the only basis now available; that is, cost-of-service-plus-profit average rail haul in the United States and average water haul overseas with such controlling rate points as Gibraltar, Pernambuco and Panama. In other words, these lines reflect what the rail and water carriers actually charged to the shippers for transportation.

Considering Panama as the water-gate to the Pacific and the west coast of South America, it will be seen that almost the entire Mississippi Valley is logically tributary to Gulf ports. For the east coast of South America and South Africa, the Chicago gateway marks in general the dividing line between Gulf and Atlantic ports. If we consider northern European ports, it appears that almost half of the Mississippi Valley should in fact be tributary to the Gulf ports.

Is this allocation carried out in practice, even under present rates? The answer will be found partly in the great preponderance of east-west transportation lines, incidentally in the comparative absence of the trunk lines from the mouth of the Mississippi into the great Northwest.

It may be contended that these lines are not properly conceived, as they must be drawn for specific cases. Theoretically, this is quite true, and yet the diagram illustrates forcefully the general situation. It is fundamentally based upon the assumption of one-mile rail-haul equals four miles of water-haul. Considering the fact that transcontinental rates are constructed upon a New York-Chicago base line with its extensive detours or mountain climbs, it is plain that if such a diagram were reconstructed on the basis of a water-grade base line of Chicago to the Gulf, all three median lines would move eastwardly, and the result would be still more conclusively in favor of the development of Mississippi Valley transit through the Gulf ports.

In view of these conditions, should not the United States of America, with the largest systems of transportation on the face of the globe, awaken to the necessity of a deeper consideration of this vital subject of internal transportation and lift this question out of the domain of legal and political controversy, and place it squarely upon the basis of scientific analysis and uncontrovertible fact—so that uncoördinated state legislation and ill considered action by both labor and Congress may not culminate in retarding rather than developing this great agency of transportation, which has been chiefly instrumental in the development of our commerce as it is today?

Water-Softening Sludge Repumped Eliminates After-Reactions

THE re-use of sludge in the lime softening of water at Grand Rapids, Mich., to intensify the removal of colloids, to save alum and accelerate the "curing" of water so as to stabilize the effluent, thereby eliminating after-reaction difficulties, has been tried in a large-scale experiment. The results were told recently by W. A. Sperry, chemist in charge, in a paper read before the Illinois Section of the American Water-Works Association. The experiment was suggested by what is being done with the use of air and sludge in the treatment of sewage.

Preliminary laboratory experiments indicated that the time of contact was not a factor beyond the period required for thorough intermixing; that the volume was of exceeding importance; that the sludge was most effective when applied just after the addition of alum or when the normal lime reactions were most nearly completed; that it seemed most effective in removing the products of the reaction rather than to hasten it; and that it worked better under winter conditions than under summer conditions. The amount of air applied was such as to keep the sludge well up in suspension, with the result that it formed into large, ragged, feathery flocs that seemed to fall from suspension like sand.

For the working-scale experiment a motor-driven, 6-in. centrifugal pump was connected with a 100-ft. section of pipe with 1-in. holes bored 1 ft. apart on alternate sides of the horizontal diameter. This pipe was located at a point in the settling basin where the sludge accumulated deepest.

The several runs confirmed the laboratory tests as to the greater effectiveness in the winter and the importance of a sufficient volume. Alkalinity was reduced

to 33 ppm., 10 parts lower than the average for five years. A negligible drop in alkalinity and normal carbonate was noted in the going through the filters. Ordinarily, the loss, causing incrustation, was 13 parts in alkalinity and 11 in normal carbonate.

The unfavorable considerations were: (1) Difficulty in getting a sufficient amount of sludge, due to the fact that it would not flow, and (2) the production of a finely divided suspended matter difficult and expensive to remove by alum. To eliminate the first difficulty Mr. Sperry suggests the use of a Dorr thickener to bring the sludge to the suction, or some type of traveling or flexible suction to follow up the sludge. The second difficulty was contrary to the laboratory experiment and hard to explain, unless due to mechanical agitation in the pump. No agitation was used other than that afforded by the normal baffling. As an explanation of the results, which Mr. Sperry considers of enough value to warrant further study, he stated that they are largely mechanical in that the sludge contains no residual chemical activity but apparently acts to "scour out" the colloidal matter, the many crystals of calcium carbonate acting as foci for the more rapid formation of such crystals than normally takes place.

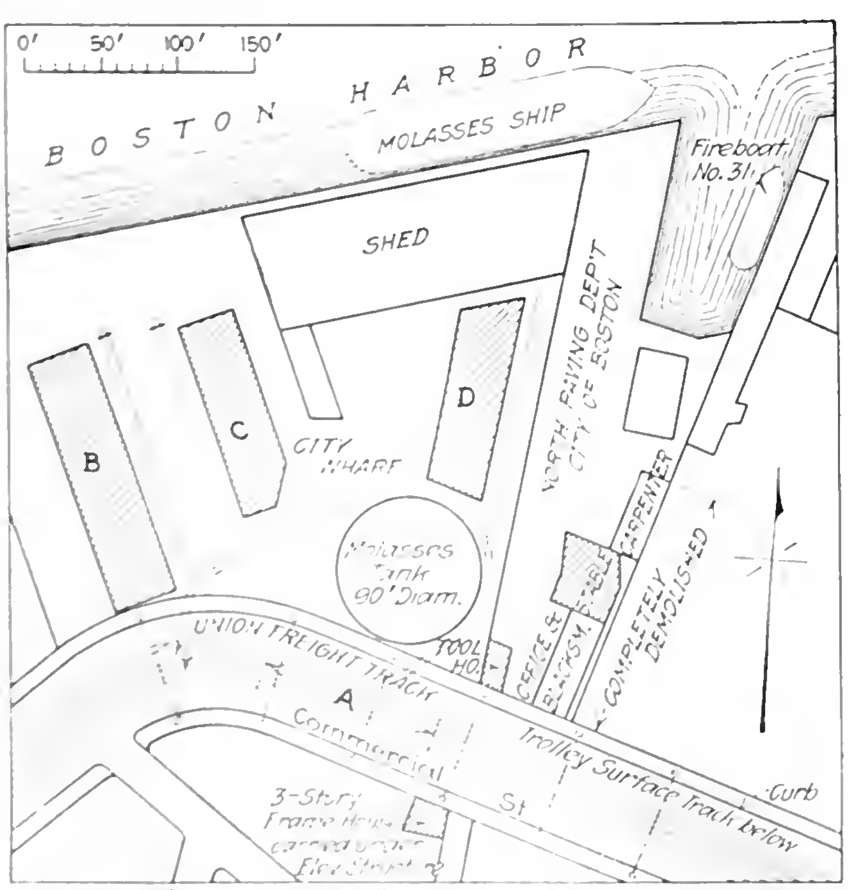
Details of the Failure of a 90-Foot Molasses Tank

Steel Shell Used in Wrecked Boston Structure Highly Overstressed—Designed and Built by Construction Company

BY BURTIS S. BROWN
Consulting Engineer, Boston, Mass.

THE peculiar accident of serious magnitude which occurred in Boston during the noon hour, Jan. 15, as described in a news note in *Engineering News-Record* of Feb. 13, 1919, p. 353, was the result of the collapse of a 90-ft. riveted steel tank used for storing molasses by the Purity Distilling Co., a subsidiary of the United States Industrial Alcohol Co. A flood of 2,300,000 gal. of molasses spread over Commercial St. and the adjoining lots, and filled the cellars of nearby houses. The steel plates of the tank wrapped themselves around the columns of the elevated-railway structure, shearing one of them completely near its base.

This tank, 90 ft. in diameter and about 50 ft. high, was built in 1915-16. The treasurer of the distilling company accepted a noncompetitive bid from the Hammond Iron Works, a construction company which had built smaller tanks in Cambridge for the same company.



Portion "A" of Elevated Structure ... to be removed and New Members built
B-C-D - Trolley Freight Sheds

FIG. 1. LAYOUT OF DEVASTATED REGION NEAR MOLASSES TANK

It "was thought" that a factor of safety of 3 was used. Details were left to the construction company, and the tank was formally accepted by the purchasers on Feb. 1, 1916, and put into use for storing molasses.

The court finding, announced after investigation, that this tank design was wholly insufficient in structural strength, is borne out by stress computations submitted herewith, showing a highly overstressed condition of the steel shell and rivets. Among other causes which have been suggested are: (1) An explosion; (2) a collision by a trolley freight car—it is reported that

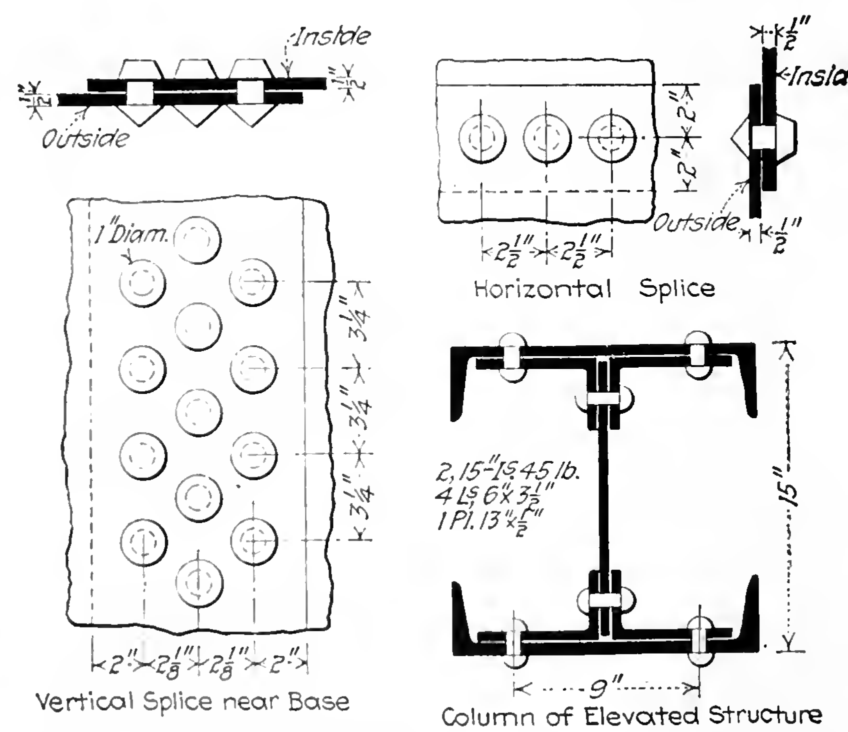


FIG. 2. RIVETED JOINTS OF TANK AND SECTION OF ELEVATED COLUMNS

twice before such cars had split a switch and run into the tank; (3) vibrations from elevated trains. The day of the accident was cloudy, the wind was blowing from the west about 13 miles per hour, and the temperature was 44° Fahrenheit.

Location—The accompanying plan (Fig. 1) shows the surrounding buildings before the collapse; the tank, located on Commercial St., adjoined the North End playground and recreation pier and other buildings belonging to the City of Boston, including the headquarters of Fire Boat No. 31, and the office, stable and storage yard of the North End division of the paving department. To the west are the trolley freight yard and sheds on land owned by the Boston Elevated Railway Company.

The tank was about 300 ft. from the harbor line, and molasses was brought by steamers and pumped into it for storage. Thence it was drawn into trolley tank cars and transported to the Cambridge plant of the distilling company and used to make alcohol for the

FIG. 3. ELEVATED-RAILWAY COLUMN SHEARED OFF NEAR BASE AND BENT UP UNDER GIRDERS

manufacture of munitions. The Boston Navy Yard is located just across the harbor.

Results of the Accident—Twelve persons lost their lives either by drowning in molasses, smothering, or by wreckage. Forty more were injured. Many horses belonging to the paving department were drowned, and others had to be shot. The elevated structure of the Boston Elevated Railway Co. was put out of use for several weeks. Occupied houses were demolished. Motor trucks passing along Commercial St. were marooned and in some cases the truck bodies were floated away several hundred feet, and in general the vicinity looked as if a small cyclone had struck the place.

Calculations—The weight of molasses is taken as 11.75 lb. per gallon, or 90 lb. per cubic foot, which is 44% heavier than water. From data obtained just after the collapse, the depth of molasses in the tank was 48 ft. 10 in. The steel plates in this tank near the bottom, as measured by calipers, varied from $\frac{1}{2}$ in. to $\frac{5}{8}$ in. in thickness. Ordinary lap joints were used. The rivets were of 1-in. diameter, with flat-topped heads on the inside and conical heads on the outside. The tension in the side of the tank at the bottom

FIG. 4. VIEW OF WRECKAGE, SHOWING ROOF AND BASE OF COLLAPSED TANK

would therefore be $90 \times 48.83 \times 90/2 = 198{,}000$ lb. in 1-ft. height. Hence the unit stress on a solid $\frac{1}{2}$-in. plate, $12 \times \frac{1}{2} = 6$ sq.in., is 36,000 lb. per square inch, or on $\frac{5}{8}$-in. plate, $12 \times \frac{5}{8} = 7.5$ sq.in., is 26,400 lb. per square inch. If the riveted-joint efficiency is assumed to be 66%, the unit stress on the net section would be 50,000 and 40,000 lb. per square inch, respectively. These values approach the ultimate strength of steel plates.

The spacing of the rivets in the vertical joints near the base is shown in Fig. 2. There are 11 rivets in 1-ft. height, so that each rivet carries $198{,}000 \text{ lb.} \div 11 = 18{,}000$ lb. Comparing this value with the allowable stresses for 1-in. rivets bearing on $\frac{1}{2}$-in. plates permitted by the Boston building law (10,000 lb. per square inch shear and 18,000 lb. per square inch bearing) it is found that the rivets are overstressed about 2.2 times in shear and 1.92 times in bearing.

An examination of the wreckage shows that part of the vertical joints failed by shearing off the rivets, while at other points the plates were torn apart between rivets. Many of the rivets dropped out of the holes after shearing off, indicating that possibly the rivets were driven cold.

Effect on the Elevated Structure—On collapsing, a side of the tank was carried against one of the columns

FIG. 5. STEEL SHELL AND ELEVATED RAILWAY WRECKED

supporting the elevated structure. This column was completely sheared off as shown in Fig. 3, and forced back under the structure. These columns are built up, as shown in section, Fig. 2, and are spaced between 50 and 60 ft. apart longitudinally at this point, where the structure is on a curve. Fig. 5 shows how the track was pushed out of alignment and the superstructure dropped several feet. It has been necessary to remove completely two entire bents, as noted on the plan, where the collapsing side of the tank was carried against the outer face of the curve.

The tank was built on a concrete mat, supported by concrete piles. After the débris was cleared away, the concrete appeared to be in excellent condition. Not a crack or defect of any kind could be noted anywhere.

Approval of Plans—The plans for this structure

FIG. 6. STEEL PLATES WRAPPED AROUND COLUMN

were filed Sept. 30, 1915, with the Boston building department, as required by law, and after the examination by the plan division a permit was issued. The plan examiner who was supposed to check the plans admitted in the municipal court investigation that the problem was beyond him. He approved the plans as filed for construction because they bore the stamp of C. H. Gannett, a civil engineer, who filed the plans for the distillery company. The latter did not check over the steel design, but simply laid out the foundations. The building department now requires that all calculations of the designer shall be filed with the plans and that the sheet be signed.

From the foregoing investigation it would appear that this tank was erected near a busy city street, where hundreds of lives were endangered, with practically no factor of safety and without competent check of the design by the building department of the city.

Macadam Stone Treated With Deliquescent Salts

Roads at Detroit Naval Training Station Surfaced With This Material Have Noiseless and Dustless Surface

By Harlan H. Edwards
Highway Engineer, Chicago, Illinois

During the past few years a new type of macadam road surfacing has been developed in and near Detroit, Mich., and its use is spreading to other parts of the country as road engineers and municipal officials become acquainted with its merits. It is a combination of crushed stone and deliquescent salts, the latter being used for their water-collecting and retaining feature. This type of road-surfacing material was used during the past summer at the River Rouge Naval Training Camp, Detroit, Mich., and because of its low cost, ease of construction and maintenance, noiselessness and dustlessness, it was placed on most of the roads. Since this work was done, it is reported that contracts have been let to put trial stretches in the road systems of Wayne and Ottawa Counties.

Character of the Material

The stone used is a dolomite or limestone which, before impregnation, is crushed and graded into a well-proportioned mixture, varying in size from ½ in. down. When treated and placed on the road it has the appearance of wet, coarse, limestone screenings, and packs down under the roller to a smooth, compact mass. The chemicals used—a mixture of calcium, magnesium, and other chlorides obtained as a byproduct from salt wells—supply a property, the lack of which has made the purely water-bound macadam road a failure for motor traffic. Heretofore the water bond has failed because it could not be kept uniform. This resulted in a road that was either too wet or too dry. If too wet, the road softened and cut; if too dry, it crushed, ground, and disintegrated. The wind completed the job by blowing off the fine cementing material, leaving the large, sharp stones exposed. The result was the raveling and rutting of the surface.

In this mixture, on the other hand, the deliquescent salts act as a stabilizer, maintaining approximately an even degree of dampness throughout the entire mass. They do not easily wash off, waste or evaporate, but gather moisture from the air, dew, rains, and from the soil below the roadbed. This keeps the surface constantly damp—making practically a dustless roadway having enough elasticity to prevent crushing of the surface even under heavy loads. There is just enough moisture, so that automobile tires serve as a *constructive* instead of a *destructive* medium. The tires have a tendency to pack and "iron out" the road, rather than to suck up the fine particles. It has been found necessary to maintain a thickness of 4 or 5 in. of surfacing in order to hold enough moisture to insure this condition.

Method of Construction

In the construction of the roads at the Detroit Naval Training Camp it was necessary first to provide a firm foundation upon which to place the surfacing material, for the soil was originally a marshy river deposit, subject to inundation each spring. It had been drained recently to permit construction work to begin on the camp, and at the start was of such a consistency that at times it took four horses to pull an empty wagon through it. This necessitated delivering the first building materials at the camp by water.

A base of from 6 to 12 in. of brickbats, slag and cinders was placed and rolled on all the roads originally laid out, and over this foundation most of the heavy hauling for the camp was done. This consisted of heavy motor-truck loads of crushed stone, cement, lumber, cast-iron pipe, etc. The surfacing mixture was then hauled from town, a distance of about six miles, in large trucks carrying from six to eight tons per load. It was spread upon the subgrade to such depth that, when struck off to the proper crown and rolled, a thickness of at least 4 in. would result. This required from 5 to 5½ in. of the loose material. Before this was placed, however, an earth shoulder was thrown up and tamped to the proper line and grade on each side of the road.

Traffic need not be shut off the roadway during the placing of the surfacing, except between the time when the final crown has been given by the templet and the time when the roller is applied. In fact, it is well if wagons do travel over the road, for they help consolidate the loose spots which may not be reached by the heavy wide wheels of the roller. If a roller cannot be obtained, this packing can be left entirely to the traffic, with the only added expense of a man with a rake to smooth out the wheel and hoof marks.

At this camp a 10-ton roller was used. The surface formed was hard, yet, if a depression occurred, that part of the road bed could be loosened easily with a stiff rake or pick, and new material could be added to bring it up to a level surface, and packed down again with a tamp or by traffic. About six to ten times over with the roller was usually sufficient for the original compaction.

In order to provide adequate subdrainage in part of

this soil, a 4- or 6-in. farm tile was laid about 1 ft. off the edge of the road, and to a depth of from 2 to 4 ft. The trench was backfilled partly with cinders, and the remainder with loose stone, brickbats, earth, etc., to permit the surface water to escape rapidly to the tile.

The organization was usually small, consisting of one man and a helper to set line and grade stakes from the engineer's offset stakes, two men to build up and pack the earth shoulders, three men to spread the surfacing material, two men to strike it off to the proper crown with a wooden templet and one foreman—a total of 10. With this organization some 400 to 600 lin.ft. of 12-ft. pavement, crowned 1½ in., can be laid in a day. One cubic yard of the material covered approximately 7 sq.yd. of finished road, costing in all about $1.25 per square yard. This was under war conditions and prices, and the long haul by truck raised the price considerably. Under normal conditions, with a good organization and the source of materials nearer at hand, this price should be reduced nearly one-half.

This impregnated stone road-surfacing has many advantages for medium traffic roads and residence streets, and for walks and drives in cemeteries, large estates, etc., where a permanent, noiseless, and medium-priced road is desired. It matters little how many times it is torn up and relaid, as it will always knit again. One man with a horse and wagon or a small truck and a stock pile of the material should be able to keep from 12 to 16 miles of 20 ft. roadway in perfect condition. It is claimed that a satisfactory road can be obtained from dolomite, gravel, slag or cinders treated with these deliquescent salts, the degree of excellence being in the order given.

Standard Precast Concrete Frames Make Up Flume Trestles

Sections Cast Along Line Put Together To Carry Conduit Over Gullies Up To 180 Feet Long and 36 Feet Deep

TRESTLES UP TO 36 FEET IN HEIGHT BUILT UP OF PRECAST CONCRETE FRAMES

X ONCRETE trestles, made up of standardized trap-E ezoidal frames set one on top of the other in bents and tied together with longitudinal stringers grouted into place, have been built to carry the conduit of the San Dieguito Mutual Water Co. from the Lake Hodges reservoir in southern California. The five-mile conduit consists in the main of a concrete-lined canal, but over depressions up to 36 ft. in depth the line was carried in iron flume or siphon pipe on the trestles.

In all, 27 trestles were required, of which 23 carried open flume and four were used to carry the 42-in. reinforced-concrete siphons at the low point where there would have been danger to the pipe from floods. In the construction of all these trestles the precast method was adopted, partly because of the difficulty anticipated in handling and pouring concrete in small monolithic structures which would each be a separate job, and partly because of a serious labor shortage that existed when the work was planned. It was believed that the precast sections could be erected with a smaller crew than monolithic construction would require.

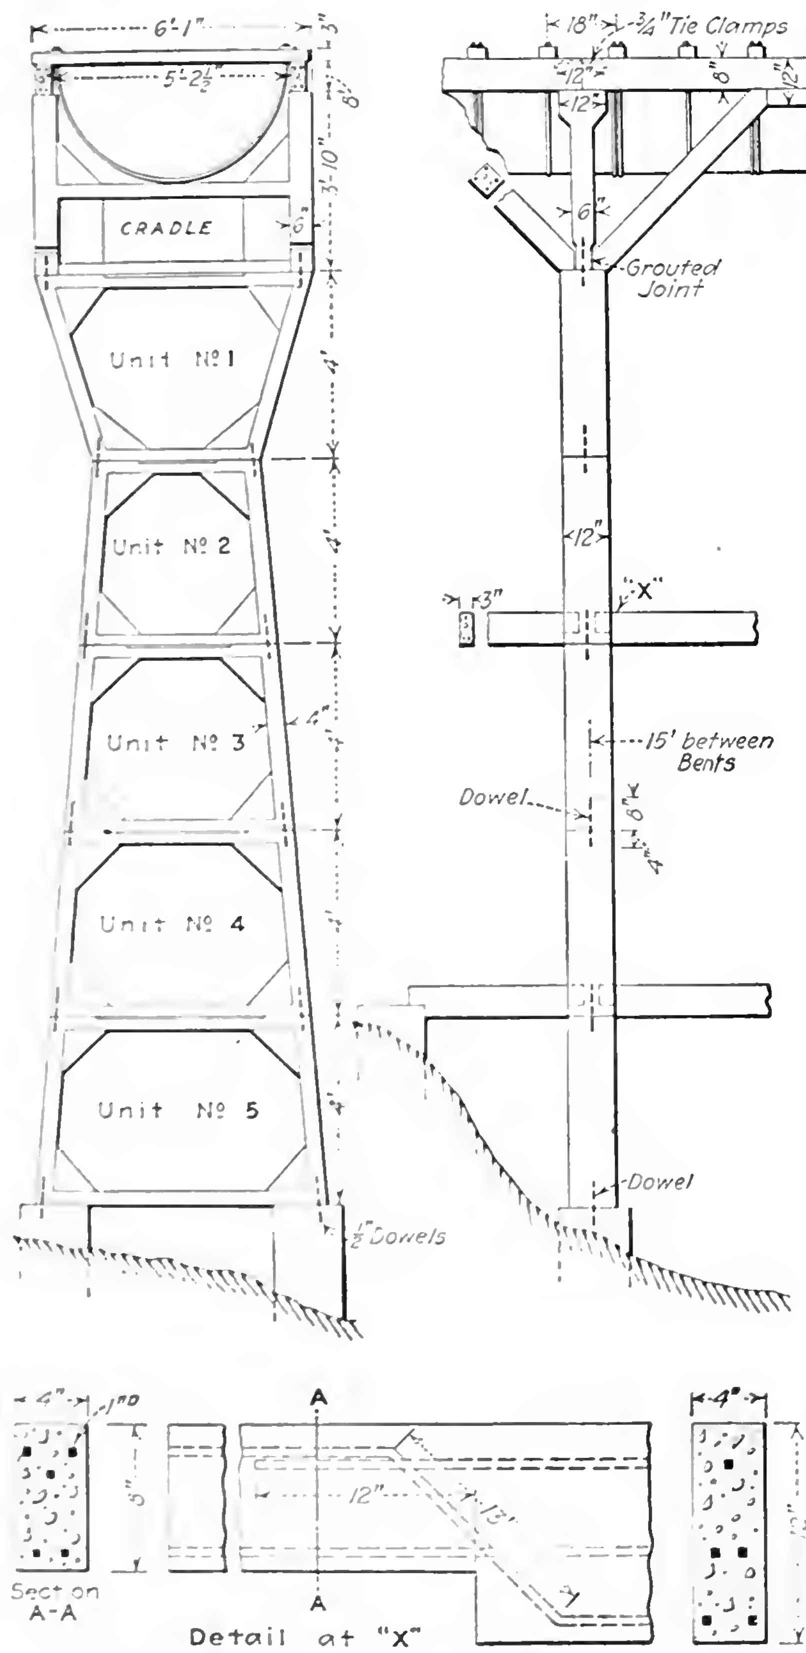
Although the trestles varied from 15 to 180 ft. in length and from a few feet to 36 ft. in height, the precast sections were standardized so that the upper units on all trestles were the same. All bent sections were 4 ft. in height, gradually increasing in width from the top downward. The only variation in design of the trestles was to replace the cross-ties used as supports for the open flumes with slabs on those trestles which were to carry the 42-in. siphons.

The units forming the trestles were cast in nearby yards in forms laid flat. The forms were built up of 2-in. lumber surfaced on one side. By thoroughly scraping and oiling them between pourings, some were used 20 times. The method of procedure was to build first the forms required for the highest trestle on the line. There was then on hand a set of forms suitable for building any other trestle, and the bottom sections not needed after the larger trestles had been built were available for repairing other forms. Casting yards were located at points central to several trestle sites. Care was taken in placing the concrete around the steel, and it is believed that more accurate location of steel was obtained than would have been possible if monolithic construction had been used. After the concrete had been poured into the forms the top surface was finished by hand with a trowel.

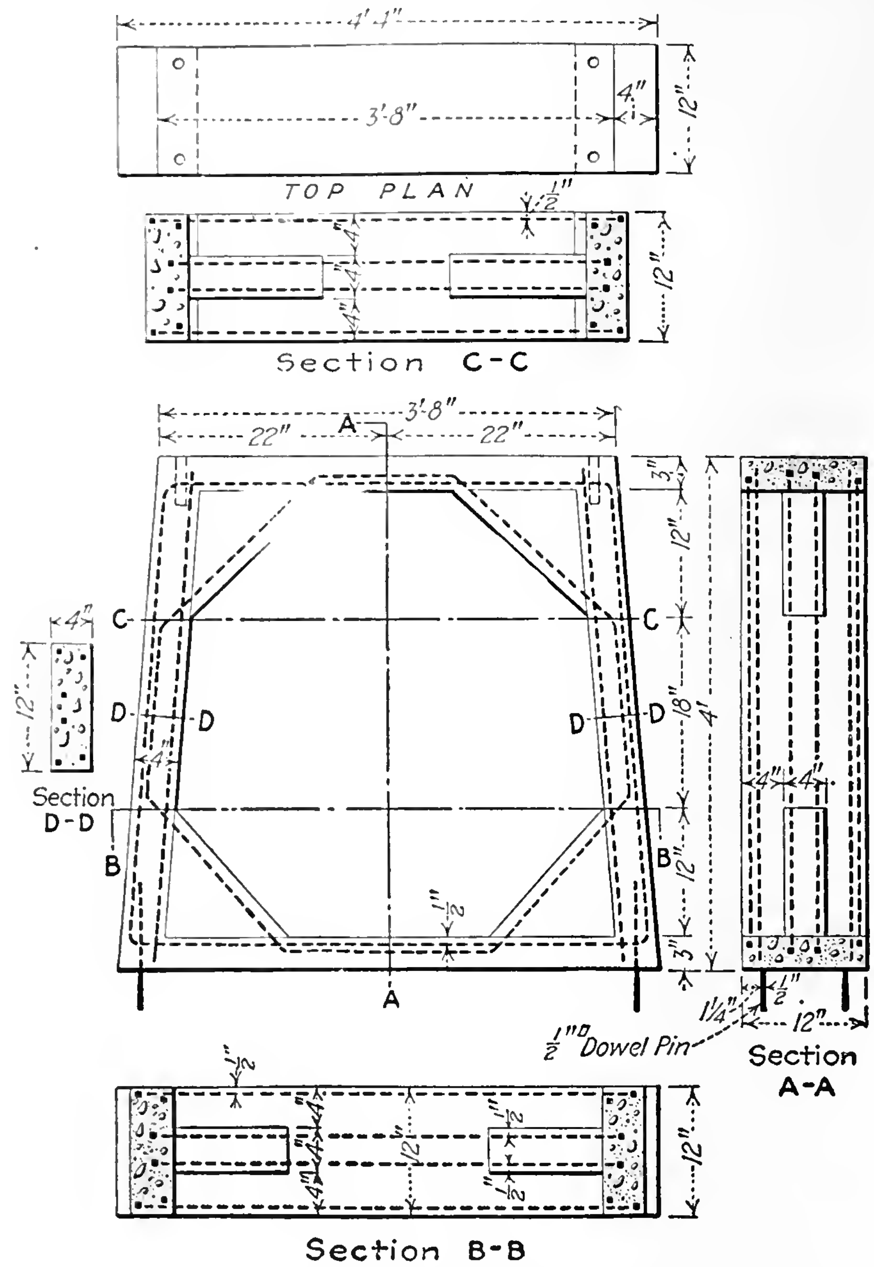
Cableways were used for the erection of the trestles

in all cases. The largest pieces to be handled were the girders for the siphon trestle which weighed about 1000 lb. each. In the higher trestles—the maximum being about 36 ft. from foundation to flume top—the sections placed at the footings weighed about 900 lb. Concrete piers were provided as foundation for each bent, and as each section was superimposed on its predecessor the dowel pins of ½-in. steel projecting 4 in. into the lower section were carefully grouted in place.

A feature of design is the dap used in the middle of the top of each section so that the sections bear one upon another only above the struts. This was done to avoid the possibility of any roughness on the surface at the center of the section causing a tendency to "rock." Even in the highest trestle the bents were erected independently and without guys. After the placing of the cradle on top of each bent the pair of girders connecting adjoining bents were placed, and the tie clamps were grouted into place to fasten together abutting girders.



DETAILS OF PRECAST PIECE TRESTLE CARRYING FRAME OF FLUME



DETAILS OF THE PRECAST SECTION LOCATED NEXT TO THE TOP OF THE TRESTLE

Dap along the top chord of section is not shown in this drawing

Originally, it was planned to grout only the angle braces running from bent to girder, but during construction it was found desirable to use grout between sections at various points, particularly in placing the cradles.

On the higher trestles, horizontal braces running the full length of the structure longitudinally were placed 8 ft. apart vertically. These braces consisted of 15-ft. beams spanning from bent to bent and resting upon the horizontal members of the sections. These were held in place by their own weight, any lateral thrust being taken by the shoulders provided on each beam end. Concrete abutments were provided where the ends of these longitudinal beams reached the ground line.

The trestles were designed by Thomas H. King, office engineer for the San Dieguito Mutual Water Co., and were erected under the direction of E. W. Case, chief engineer. Bent Brothers of Los Angeles were the contractors.

Correction

Through a typographical error, the letter L was omitted from the numerator of the expression for D in Equation (4), *Engineering News-Record* of May 8, 1919, p. 921, in the article "Computation of the Time Required to Fill a Graving Dock," by Eugene E. Halmos. The expression should read $\frac{2lmL}{K\Sigma a\sqrt{2g}} = D$.

ENGINEERING LITERATURE

A REVIEW OF BOOKS AND A LISTING OF NEW PUBLICATIONS

New Edition of Structural Handbook

STRUCTURAL ENGINEERS' HANDBOOK: Data for the Design and Construction of Steel Bridges and Buildings—By Milo S. Ketchum, C. E., M. Am. Soc. C. E., Dean of the College of Engineering and Professor of Civil Engineering, University of Colorado; Consulting Engineer. Second Edition. New York: McGraw-Hill Book Co., Inc. Flexible Cover, 6 x 9 in.; pp. 896; illustrated. $5.

In the second edition of this widely used structural engineers' handbook, the first edition of which was reviewed in *Engineering Record* of Nov. 28, 1914, p. 598, and *Engineering News* of Mar. 18, 1915, p. 530, no attempt has been made by the author to carry out the complete and thorough revision which had been planned, chiefly owing to performance of war duties as the assistant director in charge of construction, United States Government Explosives Plant at Nitro, W. Va. Errors have been corrected and 16 pages added in Chapter I illustrating standard details for steel windows and doors, giving data on cement and gypsum tile roofs, and presenting methods and formulas for computing stresses in mill-building columns and in rigid frames.

Chapter III, treating of steel highway bridges, has been largely rewritten and enlarged by the addition of 16 pages of new matter. The added data include the bridge standards of the Wisconsin and Iowa highway commissions, results of various tests on floor-slabs, a complete discussion of the distribution of concentrated loads to stringers in bridge floors, a treatment of wearing surfaces, useful tables and diagrams to assist in the design of floors for various motor-truck concentrations, and reproductions of standard details of the later highway-bridge designs issued by various highway commissions.

In typography and general appearance the new edition is an improvement over the old.

Revision of "Irrigation Engineering"

REVIEWED BY F. H. NEWELL

Professor of Civil Engineering, University of Illinois, Urbana

IRRIGATION ENGINEERING—By Arthur Powell Davis, D.Sc., M. Am. Soc. C. E., Director and Chief Engineer U. S. Reclamation Service, Author of "Irrigation Works Constructed by the United States," etc.; and Herbert M. Wilson, C. E., M. Am. Soc. C. E.; Former Chief Engineer and Irrigation Engineer, U. S. Geological Survey; Author of "Topographic Surveying," etc. Seventh Edition, Revised and Enlarged. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd. Cloth; 6 x 9 in.; pp. 640; illustrated. $4.50.

New data and general conclusions based on recent practice are offered to students and to engineers engaged in irrigation investigation, construction and management, in the Davis or seventh edition of Wilson's "Irrigation." The original work, long regarded as the *vade mecum* on water control and its application to dry lands, revised from time to time by the original author, has been rearranged and brought up to date to such an extent as to justify considering this as practically a new book; the added facts and deductions are adequate to form in themselves a valuable treatise.

The older data, acquired by Mr. Wilson during his visits to India, Egypt and other irrigated lands, serve, while forming the essential background, to emphasize the rapid developments which have taken place on this continent in response to the demands imposed by American conditions, where, as pointed out, the high cost of labor as contrasted with that abroad requires entirely different methods of building and operation.

The more striking of the new facts, as might be supposed, are those which have come from the long experience of Mr. Davis who, as chief engineer of the United States Reclamation Service, has had intimate connection with a larger number and a greater variety of irrigation projects, under American conditions, than any other person. He has given especial consideration in his revision to the larger structural features, such as canal headgates, linings, spillways, drops, flumes and pipes—all well illustrated—and has also introduced a wealth of information on reservior construction, including the design and building of large dams.

Waterproofing Engineering

WATERPROOFING ENGINEERING: For Engineers, Architects, Builders, Roofers and Waterproofers—By Joseph Ross, B.S., C. E., Waterproofing Engineer. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd. Cloth; 6 x 9 in.; pp. 442. $5.

Waterproofing is too often considered one of the minor details of engineering, something which can be left for odd moments of design and which requires little thought or effort in construction. It happens, however, that when there is need at all for waterproofing there is very great need, and instances are far too common when repairs required by faulty waterproofing greatly exceed any preliminary expense which should have been put into original waterproofing design. For these special cases, then, a book on waterproofing engineering practice will be useful, although there must be much that is elementary in any exhaustive treatment of the subject. This would seem to be the main criticism of Mr. Ross' book. It treats fully the subject of waterproofing, but in an effort to make a complete exposition he has entered into so many of the elements of the subject as to make it somewhat difficult to follow the treatment throughout the whole volume. If the book is used purely for reference, picking out as required the details of construction which apply to any case in hand, it is valuable. Considering it as a students' manual or as a book to be read by the engineer, much will have to be passed over.

Rigid Concrete Frame Analysis

ANALYSIS AND TESTS OF RIGIDLY CONNECTED REINFORCED-CONCRETE FRAMES—By Mikishi Abe, Formerly Student in the Graduate School of the University of Illinois. Urbana, Ill.: Engineering Experiment Station. Paper; 6 x 9 in.; pp. 106; illustrated.

Reinforced-concrete frames are peculiarly adaptable to analysis as a rigid system. Such a method of analysis has been common in continental European practice for some years, and has had a fairly wide application in this country recently. The exact determination of the stresses and the consequent close designing make the method attractive, although its application has been

somewhat complicated. In this bulletin the author goes very thoroughly into the theory of design and checks this theory by a rather limited set of tests on large-size rigidly connected concrete frames. All concrete designers who are interested in the development of their art would do well to study this exposition of the tests.

Mathematics for Engineers

MATHEMATICS FOR ENGINEERS, PART I: Including Elementary and Higher Algebra, Mensuration and Graphs, and Plane Trigonometry—By W. N. Rose, B.Sc. Eng. (London), Lecturer in Engineering Mathematics at the University of London Goldsmiths' College. New York: E. P. Dutton & Co. Cloth; 6 x 9 in.; pp. 510; illustrated. $5.

This first volume of two planned as a systematic and complete treatment of the subject includes proof of rules, etc., with practical illustrations well chosen from engineering practice. Methods of calculation, algebraic processes, mensuration of simple areas and solids, including conic sections, graphs and charts, earthwork problems, slide rule and planimeter work, are all well handled. This is one of "The Directly-Useful Technical Series" (D. U. Series) of which Wilfrid J. Lineham is editor.

Relation of Land Slides and Glacial Deposits to Reservoir Sites

RELATION OF LANDSLIDES AND GLACIAL DEPOSITS TO RESERVOIR SITES IN THE SAN JUAN MOUNTAINS, COLORADO—By Wallace W. Atwood. Washington, D. C.: U. S. Geological Survey. Paper; 6 x 9 in.; pp. 38; illustrated.

Geology as an allied science has little interest to a number of engineers, but to those concerned with the construction of dams it is, perhaps, the principal minor study which they must pursue. The United States Geological Survey Bulletin noted here should be of great aid to all dam builders. While it describes the formations of a limited area of this country, it is an area which contains a great number of dams and one in which subsurface conditions have been particularly difficult. The analysis of the geological formation and the consequent infiltration of the water through strata beneath the dam has application to other locations.

Two New Books on Shipbuilding

THE ELEMENTS OF WOOD-SHIP CONSTRUCTION—By W. H Curtis, Naval Architect and Marine Engineer. New York: McGraw-Hill Co., Inc. London: Hill Publishing Co., Ltd. Cloth; 6 x 9 in.; pp. 223; illustrated. $2.50.

THE SHIPBUILDING INDUSTRY—By Roy Willmarth Kelly, Director, Harvard Bureau of Vocational Guidance, Author of "Hiring the Worker," and Frederick J. Allen, Assistant Director, Harvard Bureau of Vocational Guidance, Author of "The Shoe Industry." With an Introduction by Charles M. Schwab. Boston and New York: Houghton Mifflin Co. Cloth; 6 x 9 in.; pp. 303; illustrated. $3.

Two new publications dealing with shipbuilding prove to be of radically different character. Curtis' "Elements of Wood-Ship Construction" is an excellent technical monograph, logically arranged, concise, clear and judiciously illustrated. On the other hand, the reader is entitled to a warning against "The Shipbuilding Industry," which is not a technical book at all, but may from its title be thought to be in part scientific or scholarly. It is a piece of "popular," or, more accurately, Sunday-magazine, writing, consisting of a confused mass of heterogeneous statements in which there is much gross misinformation. The reason for the preparation and publication of the book, say the authors, is that many more men must become shipyard artisans, and the book may "help them to decide for themselves whether or not they are qualified to undertake any of the work which it describes." That is, it is intended as a recruiting device, though it does not seem likely to show very high efficiency in this service.

Our critical shortage of shipworkers also led to the writing of Curtis' book, which is based on an instruction text prepared by the author for the Emergency Fleet Corporation. But in this instance a product of lasting value resulted. The steps in building a wooden ship are described sequentially, and the mechanical interrelation of the successive steps as well as the character of workmanship required are made apparent to the student in remarkably clear manner. Design, or the why of shaping the parts of a ship as the drawings show them, is not touched directly, but the reader can hardly fail to acquire much inferential knowledge concerning it. An unusual number of illustrations, which show excellent judgment on the author's part in deciding on scope, scale and detail of explanatory drawings, support the text.

Designing Concrete Mixtures

DESIGN OF CONCRETE MIXTURES—By Duff A. Abrams, Professor in Charge of Laboratory, Lewis Institute. Chicago, Ill.: The Institute. Paper; 6 x 9 in.; pp. 20; illustrated.

Extensive extracts from this bulletin were given in *Engineering News-Record* of Apr. 17, 1919, p. 758, but every concrete engineer, or contractor working in concrete, should get a copy of the full report, for study. Professor Abrams has been conducting a monumental series of tests on the properties of concrete, and has announced some very definite views, backed up with laboratory facts. Some of these views are going to be subjected to searching inquiry in the next few months, and the controversies which will arise will undoubtedly be among the most alive of any that have stirred the concrete industry. It behooves every one interested to be well informed, therefore, on the basic tests reported here.

Packing Engineering Material for Export

An instruction book for packing engineering material for exportation to foreign countries has been issued by the Engineer Corps, U. S. A. This book should be interesting to all those who have problems in packing similar material for export. Seven subjects are treated in the book. The first four are from standard specifications of the War Department and are as follows: Crating, boxing, wire-bound boxes, and baling. Two subjects are taken from the specifications of the General Engineering Depot. The first one discusses "The Problem," the second, "Packing Specifications." The last division covers "Marking of Packages." The book is 5 x 7¾ inches in size, contains 63 pages, and is illustrated.

Helping Disabled Soldiers to a Vocation

Among the "Opportunity Monographs" in the Rehabilitation Series designed to aid disabled soldiers, sailors and marines in choosing a vocation are No. 6, "Safety and Fire-Protection Engineering"; No. 9, "Oxy-acetylene Welding," and No. 13, "Concrete Construction and Cement Manufacture: Engineer or Architect, Inspector, Contractor, Superintendent, Foreman, Machine Operators, Modelers, Pattern Makers." (Federal Board for Vocational Education, Washington, D. C.)

Book List for Disabled Soldiers

As one of the many aids toward putting disabled soldiers in the way of earning their living to the best advantage of themselves and of the country, the American Library Association, through its library war service, which has its headquarters in the Library of Congress, Washington, D. C., has issued a "Reconstruction Hospital List; Books on Subjects Taught in Reconstruction Hospitals." No less than 150 subjects are covered, ranging alphabetically from advertising and agricultural engineering to wiring and wood finishing. Other subjects that may be mentioned are chemistry, farm machinery, forestry, irrigation farming, landscape gardening, railroad engineering, sanitation, and steam engineering. Various occupations are also included, as well as a wide range of science, art and literature.

Dining Rooms for Industrial Plants

More and more industrial plants are building dining rooms of one sort or another for the accommodation of their workers. Very little literature on the subject is available for those engineers who are called upon to lay out such accommodations. Therefore, a recent pamphlet issued by the William Disston Co., of Tacony, Penn., describing the new cafeteria which has been built at its manufacturing plant outside of Philadelphia, should be valuable. This plant was designed under the direction of A. S. Blum, chief engineer of the company, and the pamphlet, which can be obtained from the Disston company, was prepared by Mr. Blum.

PUBLICATIONS RECEIVED

[So far as possible the name of each publisher of books or pamphlets listed in these columns is given in each entry. If the book or pamphlet is for sale and the price is known by the editor the price is stated in each entry. Where no price is given it does not necessarily follow that the book or pamphlet can be obtained without cost. Many, but not all, of the pamphlets, however, can be obtained without cost, at least by inclosing postage. Persons who are in doubt as to the means to be pursued to obtain copies of the publications listed in these columns should apply for information to the stated publisher, or, in case of books or papers privately printed, then to the author or other persons indicated.]

AMERICAN CONCRETE PIPE ASSOCIATION CONVENTION: Official Proceedings, Feb. 14-15, 1919. Chicago, Ill.: The Association. Paper; 6 x 9 in.; pp. 93; illustrated.

CALIFORNIA STATE ENGINEERING DEPARTMENT, Sixth Biennial Report, Dec. 1, 1916 to Nov. 20, 1918. Sacramento, Calif.: California State Printing Office. Paper; 6 x 9 in.; pp. 93; illustrated.
Reports on various phases of the California water problem—irrigation development, water conservation, flood control and land reclamation, river navigation and the mining débris problem; San Francisco's harbor-front improvements; snow studies.

CHICAGO BOARD OF LOCAL IMPROVEMENTS: Quadrennial Report to the Mayor and City Council, for 1915-18. Chicago, Ill.: The Board. Paper; 6 x 9 in.; pp. 100; illustrated.
Outlines the history of this board from its inception in 1897, and reviews the work of its paving, sewer, civil and other divisions. The board has charge of the initiation and execution of public improvements paid for in whole or in part by special assessments. Certain acts of the board are subject to approval by the City Council and others by the courts.

COMMUNITY LEADERSHIP: The New Profession—By Lucius E. Wilson, Vice-President of the American City Bureau. New York: The Bureau. Cloth; 5 x 7 in.; pp. 137. $1.50.

EXPERTS IN CITY GOVERNMENT—By Edward A. Fitzpatrick, Ph.D., Director, Society for the Promotion of Training for Public Service; Editor, "The Public Servant." National Municipal League Series. New York and London: D. Appleton & Co. Cloth; 5 x 8 in.; pp. 363; illustrated. $2.25.

FLORIDA STATE ROAD DEPARTMENT: Second Biennial Report, Oct. 1, 1916, to Sept. 30, 1918. Tallahassee, Fla. The Department. Paper; 6 x 9 in.; pp. 47; illustrated.

THE GOVERNMENT OF THE UNITED STATES, NATIONAL, STATE AND LOCAL—By William Bennett Munro, Ph.D., LL.B., Professor of Municipal Government in Harvard University. New York: The Macmillan Co. Cloth; 6 x 9 in.; pp. 648. $2.75.

HOW AMERICAN MANUFACTURERS VIEW EMPLOYMENT RELATIONS—By Stephen C. Mason, President of the National Association of Manufacturers. New York City: The Association, 30 Church St. Paper; 6 x 9 in.; pp. 11.

HOW FRANCE IS GOVERNED—By Raymond Poincaré of the French Academy and President of the Republic; Translated by Bernard Miall. New York: Robert M. McBride & Co. Cloth; 5 x 8 in.; pp. 336. $2.

INDUSTRIAL GOODWILL—By John R. Commons, University of Wisconsin. New York: McGraw-Hill Book Co., Inc. London: Hill Publishing Co., Ltd. Cloth; 6 x 9 in.; pp. 213. $2.

INFLUENCE OF THE GREAT WAR UPON SHIPPING—By J. Russell Smith, Professor of Geography and Industry, University of Pennsylvania; Carnegie Endowment for International Peace; Preliminary Economic Studies of the War, Edited by David Kinley, Professor of Political Economy, University of Illinois; Member of Committee of Research of the Endowment. Washington, D. C.: Carnegie Endowment for International Peace. Paper; 7 x 10 in.; pp. 357.

LABOR TURNOVER, LOYALTY AND OUTPUT: A Consideration of the Trend of the Times as Shown by the Results of War Activities in the Machine Shops and Elsewhere—By Fred H. Colvin, Associate Editor *American Machinist;* M. Am. Soc. M. E., and Franklin Institute. New York: McGraw-Hill Book Co., Inc. Cloth; 5 x 8 in.; pp. 152; illustrated. $1.50.

MAINE STATE HIGHWAY COMMISSION: Fifth Annual Report, Jan. to Dec., 1917. Augusta, Me. The Commission. Paper; 6 x 9 in.; pp. 61.

MANUAL OF GURLEY HYDRAULIC ENGINEERING INSTRUMENTS. Troy, N. Y.: W. & L. E. Gurley. Cloth; 6 x 9 in.; pp. 139; illustrated. 50c.
Although primarily a trade catalog, this volume has a broader scope. Besides describing the current meters and water-stage recorders made by the publishers, the book contains a considerable amount of general information on hydraulic measurements, including some tables.

NEW YORK STATE COMMISSIONER OF HIGHWAYS: Report Transmitted to the Legislature Feb. 15, 1918. Albany, N. Y.: The Commissioner. Cloth; 6 x 9 in.; pp. 592.

OFFICE ADMINISTRATION—By J. William Schultze, B.C.S., C.P.A., with William Demuth & Co.; Formerly Controller, Robert H. Ingersoll & Bros., Etc.; Author of "The American Office," "Production Records," Etc. New York: McGraw-Hill Book Co., Inc. London: Hill Publishing Co., Ltd. Cloth; 6 x 9 in.; pp. 295; illustrated. $3.
A book written to meet the requirements of the business executive and business student by discussion of the principles and methods which underlie efficient and economical office management, including office layout.

OREGON STATE ENGINEER, SEVENTH BIENNIAL REPORT TO THE GOVERNOR: For the Period Beginning Dec. 1, 1916, ending Nov. 30, 1918—By Percy A. Cupper, State Engineer, Salem, Ore.: The Author. Paper; 6 x 9 in.; pp. 30; illustrated.

PHYSICAL PROPERTIES OF DENSE CONCRETE AS DETERMINED BY THE RELATIVE QUANTITY OF CEMENT—By F. E. Giesecke and S. P. Finch. Bureau of Economic Geology and Technology, J. A. Udden, Director Division of Engineering, F. E. Giesecke, Head of the Division. University of Texas Bulletin. Austin, Texas: The University. Paper; 6 x 9 in.; pp. 85; illustrated.

THE REDEMPTION OF THE DISABLED: A Study of Programs of Rehabilitation for the Disabled of War and of Industry—By Garrard Harris, Research Division, Federal Board for Vocational Education; With an Introductory Chapter by Frank Billings, Colonel, Medical Corps, U. S. A.; and a Foreword by Charles A. Prosser, Director of the Federal Board for Vocational Education. New York and London: D. Appleton & Co. Cloth; 5 x 8 in.; pp. 318; illustrated. $2.

REST PERIODS FOR INDUSTRIAL WORKERS: Research Report No. 13, January, 1919. Boston, Mass.: National Industrial Conference Board. Paper; 6 x 9 in.; pp. 55.

SAND AND GRAVEL IN 1917—By R. W. Stone. Washington, D. C.: U. S. Geological Survey. Paper; 6 x 9 in.; pp. 15.

STANDARD SPECIFICATIONS FOR WROUGHT-IRON PLATES: Spanish Text as Adopted by the American Society for Testing Materials. Washington, D. C.: Bureau of Foreign and Domestic Commerce. Paper; 6 x 9 in.; pp. 13. 5c. from Superintendent of Documents.

TIDE TABLES FOR THE EASTERN COASTS OF CANADA, 1919: Including the River and Gulf of St. Lawrence, the Bay of Fundy, Northumberland and Cabot Straits; and Information on Currents. The Tidal and Current Survey in the Department of the Naval Service of the Dominion of Canada, W. Bell Dawson, M.A., D.Sc., M. Inst. C. E., F.R.S.C., Superintendent. Ottawa, Can.: The Department. Paper; 7 x 10 in.; pp. 64.

TRAUTWINE'S CIVIL ENGINEER'S POCKET-BOOK—By John C. Trautwine, Civil Engineer; Revised by John C. Trautwine, Jr., and John C. Trautwine, 3d., Civil Engineers. 20th Edition. Philadelphia, Penn.: Trautwine Co. London: Chapman & Hall, Ltd. Montreal: Renouf Publishing Co. Flexible Cover; 4 x 7 in.; pp. 1528; illustrated. $6.

VITAL STATISTICS: An Introduction to the Science of Demography—By George Chandler Whipple, Professor of Sanitary Engineering in Harvard University, Member of the Public Health Council, Massachusetts State Department of Health. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd. Flexible Cover; 5 x 7 in.; pp. 517; illustrated. $4.

WASHINGTON STATE, FIRST BIENNIAL REPORT OF THE STATE HYDRAULIC ENGINEER TO THE GOVERNOR: June 15, 1917, to Nov. 30, 1918—By Marvin Chase, State Hydraulic Engineer. Olympia, Wash.: The Author. Paper; 6 x 9 in.; pp. 50.

WASHINGTON STATE WATER CODE AND ITS ADMINISTRATION—By Marvin Chase, State Hydraulic Engineer. Olympia, Wash.: The Author. Paper; 6 x 9 in.; pp. 53; illustrated.

WHY OUR SHIPS WILL NOW STAY ON THE OCEAN—By Edward N. Hurley, Chairman, U. S. Shipping Board, Philadelphia, Penn.: U. S. Shiping Board, Emergency Fleet Corporation. Paper; 6 x 9 in.; pp. 14.

Society Service

A Section Dealing with the Results of Teamwork by Technical Men

Questionnaire by Oregon Society

The following questionnaire is being sent to members of the Oregon Society of Engineers, in order to draw out their opinions and develop suggestions:

1. Are you satisfied to have the Oregon Society continue in its past course?
2. What do you consider the proper activities to make the society a vital moving force among engineers?
3. Do you favor the society looking more actively to the business interests of engineers?
4. Shall we establish an effective employment department?
5. Do you favor the establishment of a scale of minimum salaries and fees?
6. Do you favor taking an active and aggressive part in legislation affecting engineers?
7. Do you favor affiliation in any way with existing trade unions?
8. Are you familiar with the aims of the American Association of Engineers?
9. Do you favor affiliation with the American Association?
10. Do you favor coöperation with local chapters of the national societies and other local engineering bodies?
11. What form of such local coöperation do you suggest?
12. Shall we establish a downtown office headquarters?
13. Shall we acquire clubroom facilities?
14. Would you advocate the increase of our present annual dues if clubroom and library facilities were provided?
15. Would you support a luncheon conducted in connection with clubrooms?
16. Would you support weekly or biweekly engineers' luncheons such as we have had in the past?
17. Do you favor increased attention by the society to social activities among engineers?
18. Would you attend an engineers' dance?
19. Make us a helpful suggestion. Answer in as much detail as you like. Paper is cheap and ideas are wanted.
20. What can the society do to better serve out-of-town members?

Engineers' Club Plans Larger Activities

The Engineers' Club of the Youngstown district, Youngstown, Ohio, is making a drive for greatly increased membership. At its April meeting, with an attendance of 347, it was announced that 625 applications had been received. The club covers the territory within a radius of 25 miles, including several other cities, and it is estimated that there are 1500 men eligible for membership. It is planned to have the club active in coöperation with civic bodies and such commercial organizations as boards of trade and chambers of commerce in regard to problems of an engineering character. The membership is of five classes, admitting those in all branches of engineering, architecture, chemistry and applied science, and also those interested in the advancement of engineering. It has been voted to lease a floor of the Park Theater Bldg. for headquarters. The president is F. W. Funk; the vice-president is W. H. Ramage, and the secretary is E. R. Rose, Republic Iron & Steel Co., Youngstown, Ohio.

Publicity by Engineering Societies Promises Good Results

Passage of the Iowa engineers' registration law was helped materially by the hard work of the Iowa Engineering Society and of engineers who took time for nearly a month to make members of the legislature realize the public benefit of the measure. It is considered evident that engineers can exert considerable influence in public affairs if their efforts are properly coördinated, and that state engineering societies may be powerful agencies in securing proper appreciation of the engineering profession by the public. Educational publicity work of this kind will do much to make clear to the legislator and the average citizen the scope and importance of the engineer's work.

Societies Submit Names for Board of Engineer Examiners

At a dinner to representatives of various technical societies given by Calvin W. Rice, secretary of the American Society of Mechanical Engineers, at the University Club, Denver, Colo., the license law recently passed in Colorado was discussed, and the question of the appointment of members for the board of engineer examiners was raised. It was resolved that each society represented at the dinner should choose three of its members for candidates, and that these names should be submitted to the Governor.

As a result the following list of names has been forwarded to the Governor: For the Colorado Association of Members of the American Society of Civil Engineers, Prof. Milo S. Ketchum, C. W. Comstock, and J. C. Ulrich; for the American Institute of Mining and Metallurgical Engineers, Richard A. Parker, R. J. Grant and John T. Milliken; for the American Institute of Electrical Engineers, Prof. H. S. Evans, Franklin D. Wood and C. W. Comstock; for the American Society of Mechanical Engineers, J. B. McKennan, W. J. Reilly and Prof. J. A. Hunter; for the Colorado Scientific Society, D. W. Brunton, George O. Argall and H. S. Sands; for the Teknik Club, M. S. MacCarthy and L. L. Davis; for the Colorado Society of Engineers, R. M. Hosea, F. W. Whiteside and V. A. Kauffman.

Sanitary Engineers Condemn Shallow Wells

At a recent meeting of the Indiana Sanitary and Water-Supply Association shallow wells and privy vaults were condemned by resolution, as were dual water-supplies (one of which may be contaminated) and physical connections to industrial-plant supplies. Of the 500,000 wells in the state more than 2% have been tested in the past 12 years and 61% of these found to be bad. The privy vault and the back-yard well are both of vital concern to the sanitary engineers in Indiana, for water is easy to obtain and equally easy to contaminate.

LETTERS TO THE EDITOR

Comment on Matters of Interest to Engineers and Contractors Will Be Welcome

Draftsman's and Shoemaker's Salaries

Sir—With reference to the letter from C. H. McGarry, in your issue of Apr. 24, 1919, p. 835, quoting from the April bulletin of the Civil Service Commission of Ohio announcing the examinations for positions of architectural draftsman and of shoemaker, I wish to make the following statement:

In so far as Mr. McGarry's letter might be interpreted by some readers as being a criticism of the Ohio Civil Service Commission, a brief description of the method in which the salaries for the positions in question are fixed is pertinent. The state department (in this case the Ohio Board of Administration) submits its request for salaries of its employees to the Budget Commissioner, who passes upon the request and forwards it, with his recommendations, to the Governor. The Governor transmits his recommendations, based upon the reports of the Budget Commissioner, to the legislature. The legislature, after making any changes it may deem advisable, makes a direct appropriation for salaries. The Civil Service Commission is not consulted in regard to the salaries, but is required to fix the grades and qualifications for the positions.

A careful consideration of the salaries paid, in connection with the nature of the two positions in question, would disclose the following points: The entrance salary of the architectural draftsman is $1500 per annum with no maximum limit designated. That of the shoemaker is $1200 with maximum limit of $1400 per annum.

The position of architectural draftsman affords excellent experience, which can be used by the incumbent as a means for future advancement. The position of shoemaker is "Grade 1" in the skilled labor service, and is practically without further possibilities to the shoemaker incumbent.

In connection with tnese examinations, it might be interesting to know that there were five applicants for architectural draftsman, and one applicant for shoemaker. G. F. SCHLESINGER.

Assistant Chief Examiner, The State Civil Service Commission of Ohio.
Columbus, Ohio.

Interpretation of Overhaul Specification

Sir—A letter from R. G. Williams in *Engineering News-Record* of Apr. 24, 1919, p. 835, asks for interpretations of a certain specification for overhaul.

This specification states that "payment for overhaul . . . . shall be the product of . . . . tons of material . . . . by its distance in miles (and fractions thereof) less one mile, of its *center of mass* from the points of locations. . . . (The italics are mine.)

Thus, in the first overhaul mile, i.e., the space covered between, say, mile post 1 and mile post 2 from the pit: If there be 100 tons of material, assumed to be uniformly distributed, the location of its center of mass will be at mile post 1½, and the overhaul paid should be 100 tons multiplied by ½ mile or 50 ton-miles, which, at 25c., unit price, amounts to $12.50, as claimed by the engineer. F. T. HOWES,

Resident Engineer, Northern Pacific Railroad.
Emigrant, Mont.

Sir—In your issue of Apr. 24, 1919, p. 835, R. G. Williams asks what is the correct interpretation of an overhaul specification.

In analyzing the specification I believe the following points should be taken into consideration:

1. The first sentence plainly says that the free haul shall be one mile from the pit or loading point. There is no uncertainty in this statement.

2. The second sentence says that for each mile or fraction thereof in excess of the one-mile free haul the contractor shall be paid for overhaul at the rate bid per ton-mile, which is 25c. This clearly means that the contractor shall receive 25c. per ton-mile for every ton of material hauled beyond the first mile, whether the material is hauled one foot past the first mile post or whether the material is hauled to any other point within the one- to two-mile zone.

3. The third sentence says that payment for overhaul shall be the product of the tons of material hauled times its distance in miles and fractions thereof less one mile, of its center of mass from the points of locations. The grammatical construction of this sentence is faulty and admits of two interpretations. The first part of the sentence which says payment of overhaul shall be "the product of tons of material hauled times its distance in miles and fractions thereof less one mile" is clear and must be construed as outlined in paragraph 2 above. The second part of the sentence goes on to say "of its center of mass from the points of location," and indicates that the engineer probably had some idea of paying for an average haul. However, he does not say so in good English.

The contractor in this case should have asked the engineer for his interpretation of this sentence before submitting his bid. This evidently was not done. On the other hand, the engineer has failed to write a clear specification.

A reasonable interpretation of the specification would be for the engineer to pay the contractor on the same basis, using the ton-mile unit of 25c., as other contractors are being paid on similar work in that state or that section of the state. NEWMAN B. GREGORY.
Walnut Ridge, Ark. General Contractor.

Joints in Concrete-Road Work

Sir—The lively interest in and discussion on transverse expansion joints in the construction of concrete highways will lead to a logical and proper solution. There is a significant tendency to abandon all joints, and, in some localities and under certain conditions this seems to be a sane departure from the theoretical idea of their importance. However, it will be best to act with caution, owing to the fact that concrete laid at or near freezing temperatures will, under summer heat, show expansion and may buckle or crush. Again, there is danger of expansion from moisture during rainy seasons, especially if the coarse aggregate used is absorbent or if the binder of cement and sand is not rich and dense enough to avoid penetration of moisture.

The blind joint is, in my judgment, the best type. This style of joint is most easily produced by placing a 4-in. weatherboarding, thin edge up, across between the forms and resting it on the subgrade. This will cut the slab from the bottom to about the center for standard work. As the work shrinks in curing, the cleavage will be over this board. The future behavior of the work will determine whether any treatment of the crack is advisable. We place this joint at the end of each day's work, or about every 400 feet.

If bituminous expansion strips are used for joints, the maximum thickness should not exceed $\frac{1}{4}$ in., and my present judgment and experience tend to condemn them entirely. They do not properly support and protect the edges of the concrete. In all cases where joints are inserted, either blind wood or bituminous, they ought not to cross the slab at right angles, but should cross as the segment of a circle.

This "rainbow" type is easily produced by using a strip of joint material of such length as will, when sprung into place between the forms, give the desired radius or curve. If the roadway be 18 ft. wide and we use a strip of joint material 18 ft. 4 in. in length, we shall produce a bow of 18 in. at the center of the roadway.

In case the specifications are old and the engineer in charge is ultra-conservative, thus forcing the elastic joint on the contractor and into the work, it is best to use a light metal templet not over $\frac{3}{16}$ in. thick sprung into position for placing the joint material. The strips of material may then be placed against the outer or convex surface of the templet and be held in place by driving light, wooden stakes into the subgrade, so as to hold the strips against the metal. Lifting out the templet is made easy by drilling two small holes near the top, say 4 in. from each end, and using small lifting hooks. In case wooden strips are used as mentioned above and left in, there is a total elimination of all labor after placing.

The "rainbow" type has many features of preference and should supersede the straight line in future work, whenever it is required to place joints of any description. Its appearance is more pleasing to the eye, and the wheel contact with the joint is better for both the driver and the vehicle. As in crossing car tracks at variance from a right angle, the thrust is only on one wheel at a time, as one passes over before the other reaches the curved line. The chug of both wheels at once gradually ravels the road at the crossing of the joint, and this is minimized by crossing the "rainbow" instead of a straight line. C. O. FRYE.

Tulsa, Okla.

Concrete Road with Bituminous Carpet Wrongly Classified

Sir—In the Apr. 3 issue of *Engineering News-Record*, p. 670, data were given on the cost of maintenance of different types of highways in the City of Philadelphia. In this table 1:3:6 concrete was listed under "foundation" when placed under vitrified brick and Bicomac. When thin bituminous carpet was placed on the concrete base, the concrete was listed under "type of surfacing."

A 1:3:6 mix of concrete is not the proper mixture for concrete surface. Under modern specifications the weakest mix being used for concrete surfacing is 1:2:4. In the majority of cases the mixture is even stronger. Where concrete base was placed with bituminous carpet, the concrete should have been carried under "type of foundation," as in the case of brick, and the surfacing should have been noted as "bituminous carpet."

I am calling this to your attention in the hope that you may correct in the minds of the readers of *Engineering News-Record* any wrong impression that they may have obtained in regard to the cost of maintenance on concrete highways. The average cost of maintenance on a properly constructed concrete highway is as low as on any other type of pavement, and the cost of maintaining a large mileage for this class of pavement surface for several years shows that it does not average over $\frac{1}{2}$c. per square yard per year. A 1:3:6 foundation with a bituminous carpet coat is not a concrete surface, and should not be classed as such. B. H. WAIT,

District Engineer, Portland Cement Association.

New York City.

Union of British Women Engineers

Sir—In regard to the item on this subject in *Engineering News-Record* of May 1, 1919, p. 863, it might have been well to point out that in England the term "engineer" is used as synonymous with our term "machinist," and that the Amalgamated Society of Engineers is a machinists' labor organization. However, it appears that the women also want to become members of technical societies, but it is not clear that membership in a trade union will help them in this respect.

Chicago. ENGINEER.

Control of Fires in Cinder Fills

Sir—For those who are experiencing difficulty in the control of fires in cinder fills, as described in your issue of Apr. 10, 1919, p. 711, the method which has been used with success at the Rensselaer Polytechnic Institute may be of some interest and help.

For a number of years the cinders have been dumped into a natural ravine close to the boiler house, and the fill probably reaches a depth at present of about thirty feet.

Considerable difficulty had been experienced from time to time with fires. Attempts were made to quench these by applying a large volume of water from a hose, but the attempts met with indifferent success. On one of these occasions there was danger that the fire might spread to soft coal stored near by, and the necessity for some more certain means of fighting it led to the adoption of the following plan:

A gridiron was constructed of several $\frac{3}{4}$-in. pipes, with tees spaced about 8 ft. apart. Into these tees were screwed other pipes about 6 ft. high, and upon the top end of each of these was screwed an automatic sprinkler head from which the disc had been removed. The whole arrangement was placed on top of the cinder fill over the place where the fire seemed to be, and connected by a rubber hose to the water supply. The water thus applied was distributed uniformly over the location of the fire and was very effective in its action. Usually not more than four sprinkler heads were required to quench the fire completely in a few days' time.

LE ROY W. CLARK,
Assistant Professor of Mechanics, Rensselaer Polytechnic Institute.

Troy, N. Y.

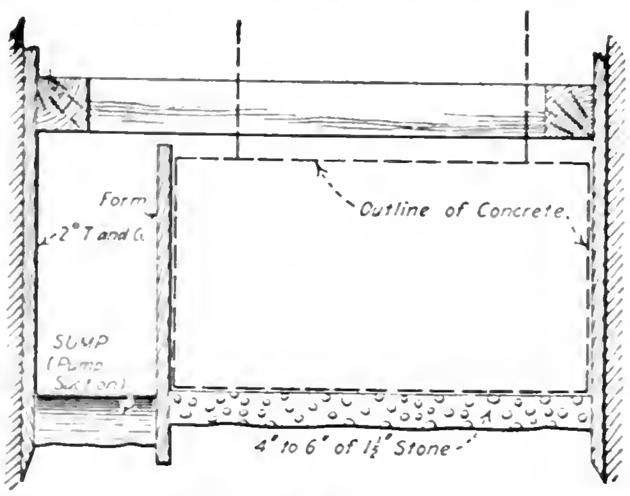
HINTS FOR THE CONTRACTOR

DETAILS WHICH SAVE TIME AND LABOR ON CONSTRUCTION WORK

Sump and Drain Keep Footing Pit Dry

By A. P. Roscoe
Ozone Park, N. Y.

USING the arrangement depicted by the accompanying drawing, concrete was placed without trouble from water in constructing elevated-railway column footings in New York City. The pits varied from



SUMP KEEPS FOUNDATION PITS DRY FOR CONCRETING

7 x 7 x 10 ft. to 9½ x 9½ x 12 ft., and ground-water level ranged from 2 ft. to 9 ft. above the pit bottoms. Tongue-and-groove sheeting was driven by hand and by steam hammer, and the water was kept down by steam pumps and gasoline-driven diaphragm pumps. As the drawing indicates, the sheeting was driven to the neat lines of the concrete on three sides, but on the fourth side it was driven 2 ft. outside the neat line. This gave a 2-ft. space for a sump which was excavated 6 in. deeper than the pit itself. A side form for the footing on the sump side was then set up, and the pit bottom was covered with 4 in. to 6 in. of 1½-in. broken stone. Water seeping into the pit drained through the broken stone into the sump and left practically dry the bottom on which the footing concrete was deposited. An open-joint tile drain embedded in the stone was laid across the pit bottom to the sump in the first few pits, but was afterward omitted as unnecessary.

Simple Device Decreases Loading Costs

By Max Miller
Engineer, M. Shapiro & Son, New York City

AN INEXPENSIVE device successfully used on concrete work resulted in a saving of a considerable percentage of loading and carting costs. As indicated by the illustration, it consists of a simple box made of old lumber and measuring about 5 x 7 ft. in plan by 1 ft. 6 in. deep. It holds about 2 cu. yd. of material and loads a motor truck by one operation in a few minutes. The box is arranged to rest on the side of the open railroad car in which the material is received, is slightly overbalanced outward, and is dumped by the release of a rope at the end of a lever at its back, which is fastened to the opposite side of the car.

On the job where this was used it took as long to fill the truck by the ordinary hand shoveling as was required for the truck to make a complete round trip. The device, therefore, practically doubled the number of trips per day for each truck. Furthermore, the loading laborers were continually busy filling the box and did not lose time waiting for the truck to come alongside of the car.

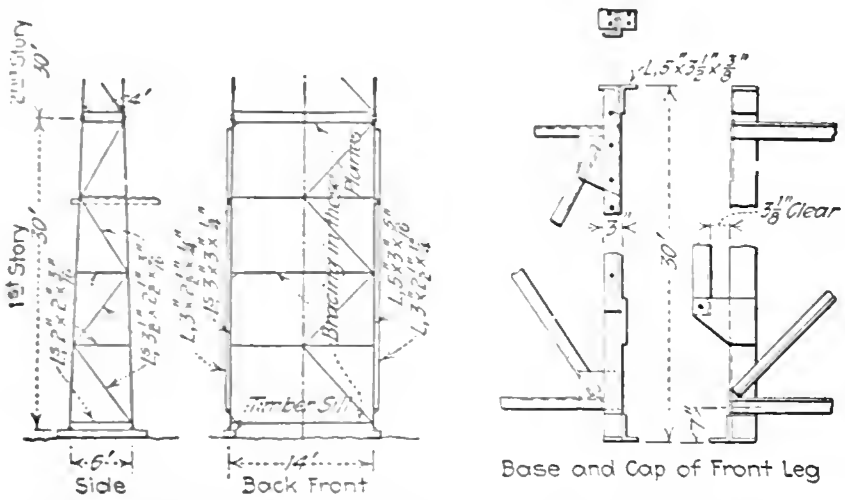
Other Articles in This Issue of Interest to Contractors:

BOX ON SIDE OF RAILROAD CAR DUMPED BY RELEASE OF LEVER

The device was used by M. Shapiro & Son, for whom the writer is engineer in charge of construction on the masonry, foundations and concrete work for the new Strand Theatre at Far Rockaway, N. Y.

Steel Scaffold Towers Reduce Handling at Fore River Shipyard

A DISTINCT simplification in ship-erection scaffolding is found at the Fore River shipyard of the Bethlehem Shipbuilding Corporation, Ltd., at Quincy, Mass. The supports are steel towers 6 x 14 ft. at the base, built in heights of 30 ft. and so detailed that a second story can be set on top of the first without trouble, and attached by a few bolts to keep it from shifting. Placing ledger planks to support the scaffold runways involves no more trouble than with wooden scaffolding. As shown in the detail sketches, an angle is attached to each of the tower leg angles by outstanding gusset plates in



STEEL SCAFFOLD UNITS AT FORE RIVER SHIPYARD

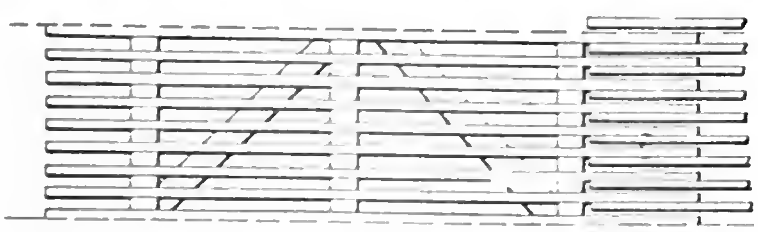
such position as to leave a clear space 3 in. wide between the two angles. The ledger boards are passed through this space, and are held by steel pins passed through holes in the two angles above and below the board.

Timber sills are attached to the foot of the tower, and thus the tower becomes a self-contained unit, which the shipbuilding cranes can easily pick up and place anywhere along the ship. As soon as it is set on the ground it is stable without bracing, and the ledgers and runways can be put in position. Because of the absence of timber bracing, the working space around the bottom of the ship is much clearer of obstructions than with the ordinary scaffolding made of independent bents.

The idea of self-contained scaffold units is credited to S. W. Wakeman, former general manager of the yard and now general manager of the eastern district of the Bethlehem Shipbuilding Corporation, Ltd., which embraces a number of yards and manufacturing plants. The towers were built by the New England Structural Co., of Everett, Mass. They have been in service about two years, and in that period little expense for repairs has been incurred. Compared with timber scaffolding they are regarded as virtually free from deterioration.

Timber Grid Floor Forms With Sheet Iron Covering

FLOOR-FORMS consisting of wood grids over which sheet iron was tacked were an important factor in the unusually rapid concreting operations in constructing the Boston Army supply base described in *Engineering News-Record* of Sept. 19, 1918, p. 522. The grids, as shown by the sketch, consist of 2 x 3-in. sticks set parallel on edge 3 in. apart and cleated together to form mats 3½ x 12 ft. in size. As shown, the ends of abutting mats can be telescoped to provide longitudinal adjustment. A succession of these mats was laid over the floor area, being supported on 4 x 6-in. stringers spaced 5 ft. apart and carried on 3 x 4-in. posts set about 5 ft. apart. Over the tops of the mats thus assembled was tacked No. 22-gage sheet iron which could be lapped in any direction to cover a given space without cutting. The grids, when sturdily built, could be used at least 10 times, and the sheet metal, which was rolled after each usage, was good for re-use from 12 to 15 times. Maj. Charles R. Gow was constructing quartermaster and the W. F. Kearns Co., Boston, Mass., was the general contractor for the base.



GRID AND SHEET-IRON COVERING CAPABLE OF REPEATED RE-USE

Check Bidding Prices Against List of Possible Cost Items

THERE are so many items of cost in road construction that memory alone is a feeble guarantee that all have been included when the contractor submits his sealed bids. To prevent errors or omission the Prendergast-Clark Construction Co., of St. Louis, Mo., general contractors, with extensive experience in road building has compiled a list of items to be considered in estimating the cost of 1 sq.yd. of pavement on concrete highway, as follows: (1) Surety bond; (2) liability insurance; (3) installing railway sidings; (4) freight on equipment; (5) equipment; (6) installing equipment, building bins and cement shed; (7) laying and taking up track (industrial-railway outfit); (8) cement, sand, gravel or stone on railway siding; (9) unloading cement, sand, gravel or stone; (10) hauling cement, sand, gravel or stone to roadway; (11) pumping water; (12) operating mixer; (13) charging mixer; (14) spreading concrete; (15) finishing concrete; (16) sprinkling concrete; (17) canvas covering for concrete and cement; (18) earth covering for concrete; (19) form setting for concrete; (20) subgrade for concrete; (21) rolling subgrade; (22) bundling cement sacks and return freight to mill; (23) lost and damaged sacks; (24) oil, gasoline and coal; (25) interest; (26) depreciation, and (27) overhead. In appraising these items, careful scrutiny of the specifications is made vital by the changes in requirements which are constantly being introduced. The requirements for dry concrete, for example, introduce tamping and tamping machines which must be appraised under items 5 and 14. Many other of the items can be subitemized to advantage, but the list furnishes a fairly complete skeleton on which to build up a schedule of costs that will be reasonably complete. No schedule to be devised will obviate the necessity of a final allowance for contingencies.

C. S. H.

Tractor Operators Trained for Road Work

In view of the probable shortage of tractor operators to handle the machines which will be required on the extensive road work planned in Nebraska for this year, Prof. L. W. Chase, head of the agricultural engineering department of the University of Nebraska, organized a special short course in tractor instruction, similar to the course for tractor operators on agricultural work. The time was short, but posters were hurriedly prepared and distributed Apr. 3 announcing that this special course would begin Apr. 14. The newspapers also gave publicity to the new course. Instead of 15 to 25 attendants as expected, there were over 80, so that three sections were necessary, and for five days the lecture periods had to be doubled. The course consisted of two lectures and six hours' laboratory work each day for 20 days. The innovation was suggested by George E. Johnson, state engineer.

NEWS OF THE WEEK

New York, May 15, 1919

Price Stabilization Board Resigns

Following the failure of the Railroad Administration, the steel producers and the Industrial Board of the Department of Commerce to agree on steel prices, the members of the latter board May 8 presented their resignations to Secretary Redfield, who accepted them. This marks the end of the attempt to stabilize prices on the part of a Government bureau by announcement of a fair price.

New Record of Ship Production

April figures for shipbuilding in the United States establish a new high mark for deliveries of completed ships: Ninety-three vessels, of 320,280 gross tons, which is 57,000 tons higher than the previous record figure, made in October, 1918. With this month's report the Shipping Board has abandoned the use of dead-weight carrying capacity tonnage, and has gone over to gross tonnage.

Rapid-Transit Construction Under a Single Commissioner

Direction of subway and elevated-railway building in New York City will hereafter be in the hands of a single commissioner, under a law signed by Governor Smith of New York State during the past week. This law completes the replacement of the five-member Public Service Commission for the First District (New York City) by two independent commissioners, one in charge of utility regulation and the other in charge of rapid-transit construction. As noted in these columns last week, Lewis Nixon, who was appointed regulative public service commissioner, is administering the duties of both offices pending the appointment of a construction commissioner.

Government Scientists Organize Union at Washington

Scientific and technical employees of the Government, at a meeting held in Washington, May 10, organized a union which is to become a branch of the present Federal Employees' Union. There was a long discussion on the formation of an independent organization, which would in no way be connected with the present union of Federal employees, but this was decided against, by a vote of 185 to 132.

Dr. Edward B. Rosa, chief physicist of the Bureau of Standards, said that the work of the joint Congressional reclassification commission had brought to the forefront the question of an organization of scientific and technical workers more acutely than ever before. He also spoke in opposition to the plan for an independent organization, declaring that it would be practically without influence, but that in a union allied with other Federal employees the scientific and technical employees would be heard and recognized, and the desired results would follow.

P. G. Agnew, secretary of the new organization, pointed out accomplishments of the Federal Employees' Union, accrediting it with increasing the wages of Government employees and securing the appointment of the reclassification commission.

Employment Bureaus

Engineering Societies' Employment Bureau, 29 W. 39th St., New York City.

American Association of Engineers, 29 S. La Salle St., Chicago. Service to members only, but Army or Navy Engineers in uniform who are eligible to certified membership may join without payment of entrance fees or dues while in uniform and for six months after discharge.

Engineers' Service Bureau, 57 Post St., San Francisco. Only applications by mail or wire will be considered.

Professional and Special Section, United States Employment Service, 469 Fifth Ave., New York City.

Reëmployment Committee of New York City for Soldiers, Sailors and Marines, 233 Broadway, New York City.

Building War Department Concrete Steamers

Concrete river steamers for the use of the Army are to be built by the Newport Shipbuilding Corporation, Ltd., at its yard at Newbern, N. C. These ships, which were noted in *Engineering News-Record* of Jan 2, 1919, p. 65, are 130 ft. long and will be used as short-trip transports. Nine of them are contracted for.

More Harbor Bonds for Portland, Oregon

On June 3 the voters of Portland, Ore., will be asked to approve an additional bond issue of $1,000,000 to take care of any emergencies in the current improvement of the harbor and municipal port works. No definite use is indicated for the additional funds, but the port commission asks for the money to provide for contingencies.

Minnesota Drainage Control Reorganized by New Law

Complete reorganization of the state administration of land drainage in Minnesota is provided by a bill which has just become law through Governor Burnquist's approval. The original house bill was amended in the senate to provide an engineer commissioner, and in this form was passed and approved. The State Drainage Commission existing hitherto consisted of the Governor, the state auditor, and the secretary of state. The new law creates a Department of Drainage and Waters, to be headed by a commissioner ($4000 per year) appointed by the Governor for a term of four years. He is assisted by a deputy commissioner ($3000). The commissioner must be a practical drainage and hydraulic engineer.

In addition to the duties assigned to the old commission, the new department receives power to investigate the topographical features of the watersheds of the state; to ascertain the work necessary for securing proper drainage outlet for the lands in each basin and for preventing and controlling floods; to measure stream discharge; to determine drainage run-off coefficients; to establish rules and regulations governing the work of drainage engineers; to survey and establish the boundary lines of drainage basins or of organized drainage and conservancy districts; and to keep a record of all drainage improvements.

An important auxiliary feature of the law is a new schedule of maximum allowable compensation to be paid to engineers engaged in public drainage proceedings. The principal increases are: Engineers, from $10 to $12.50 per day; rodmen, from $3 to $4 per day; viewers, from $4 to $5 per day; chainmen, axemen, etc., from $2.50 to $4, the pay including necessary expenses in each case. It is further provided that referees must be qualified consulting civil engineers.

Government to Give 20,000 Motor Trucks to States

About 20,000 motor trucks, valued at more than $45,000,000 are to be distributed by the Secretary of Agriculture, through the Bureau of Public Roads, to the state highway departments. These trucks have been declared surplus by the War Department, and are being distributed to the states under the provisions of Section 7 of the Post-office appropriation bill. They must be used by the states on roads constructed in full or in part by Federal aid. All that the states are required to do to

obtain these trucks, which range in capacity from 2 to 5 tons, is to pay the loading and freight charges.

Of the total number of vehicles to be acquired, 11,000 are new and 9000 have been used, but all are reported to be in serviceable condition. They will be apportioned to the states only upon request of the state highway department and on the basis of the total number of requests received from the various states. The requirements of the Federal-aid law, under which these trucks must be apportioned, do not allow the Bureau of Public Roads to distribute trucks to counties or to individuals.

Army Camps Are Sold Cheap

Twelve Army camps, eight of them of the more or less temporary type used for National Guard concentration sites and four used for miscellaneous camps, have been sold for a total of $548,194.

Bids on these camps were noted in the "Business News" section of this journal, May 1, 1919. No statement has been given out as to the original costs of the camps, but they must have been forty or fifty times the selling price. Contracts awarded for the sale of the camps are shown in tabulated form on p. 292 of the Construction News Section of this issue.

The City of Montgomery, Ala., obtained Camp Sheridan; the State of North Carolina takes over Camp Polk. Other camps went to individuals and firms, except Camp Kendrick, New Jersey, which was withdrawn from auction, and is to be retained for the Navy. In the case of Camp Beauregard, Louisiana, the successful bidder must guarantee to the state without cost buildings and improvements sufficient for one regimental camping area for the use of the state troops. At Camp Hancock, near Augusta, Ga., the underground improvements must be left intact for the benefit of the community. At Camp Polk, North Carolina, the buildings were sold to the state for use in connection with the state penitentiary. To the City of Spartanburg, S. C., will be given the sewerage and water systems at Camp Wadsworth.

All of these camps had comparatively few buildings, the cost of construction going mostly into underground and ground work.

New Piers for Staten Island

Twelve new steamship piers for Staten Island are being designed in the Department of Wharves, Docks and Ferries of the City of New York. Two of the piers are ready for the contract advertisement and await only the appropriation of the Board of Estimate, having been authorized by the Sinking Fund Commission. The development is located on the eastern shore of the island, just inside the Narrows and between Clifton and Tompkinsville. Each pier will be 125 ft. wide and 1000 ft. long, with 300-ft. slips.

Program of Water-Works Association Meeting

Discussion of the present trend of prices and other economic subjects of current interest will engage an entire session of the annual meeting of the American Water-Works Association to be held in Buffalo, June 9-13, 1919, according to preliminary announcement of the program. In addition to papers on technical water-works subjects, a series of papers by United States Government officials and by manufacturers on the price situation will be read.

The first day of the meeting will be devoted largely to registration and to committee meetings. In the evening the Water-Works Manufacturers' Association will hold a reception at the Iroquois Hotel.

A. W. Kreinheder, commissioner of the Buffalo Board of Public Works, will deliver the address of welcome at the opening session on the second day of the meeting. He will be followed by John E. Teeple and John A. Kienle, who will speak on "The Relation of the Chemical Industry of Niagara Falls to the Water-Works." After this paper a round-table meeting will be held for the discussion of problems relating to operation and maintenance of water-works. Among the topics to be discussed will be "Damage to Fire Hydrants by Motor Vehicles, and Remedies Therefor." The afternoon session will include the report of the Private Fire Protection Service Committee, Nicholas S. Hill, Jr., chairman. In the evening the following papers will be presented: "Buffalo Water-Supply, With Special Reference to the Filtration Problem"; "Reduction of Water Consumption by Means of Survey and Constant Inspection," and "The Uniflow Pumping Engine," by D. A. Decrow.

The morning session June 11 will be given over to a discussion of economic and business subjects, and will be addressed by Government officials and manufacturers.

Other papers to be presented at the meeting are: "Purification of Water for the Army and Field Purification Plants," by William J. Orchard; "Air Lift and Water Purification," by John Oliphant; "The Effect of the War Period, 1914-1918, and Public Control Upon Water-Works of the United States," by Leonard Metcalf.

Minnesota Water-Works Meeting

Fire-supply connections as dangerous features of public water-supplies, sewage pollution, centrifugal pumps and aëration for water softening were the principal subjects presented at the semi-annual meeting of the Minnesota Section of the American Water-Works Association, held at the University of Minnesota, Minneapolis, May 3.

Papers relating to the first two subjects included "Water-Works for Fire Protection," by H. F. Blomquist, of St. Paul; "Features of Design in Small Water-Works," by F. H. Bass, of Minneapolis, and "Legal Responsibility for a Pure Water-Supply," by John Wilson, of Duluth. Resolutions were adopted opposing cross-connections between a polluted fire supply and a pure or purified public supply, and commending the state Board of Health for its work along these lines; also requesting the American Water-Works Association to appoint a committee to secure coöperation and standardization in the design of fire and domestic supplies, with a view to local or state control.

The remarkable results of a 30,000,000-gal. centrifugal pump at Minneapolis, with the economy of this large unit in regard to installation and operation, were the subject of a paper by F. W. Cappelen, city engineer. Water softening and removal of iron by aëration were discussed by J. A. Childs and L. I. Birdsall, who showed drawings of plants for removing iron from well supplies. Mr. Childs explained the need for this, as in small towns the people are apt to use a soft water readily available (but possibly polluted) in preference to a hard, iron-laden water supplied by the municipality.

Officers for 1919 were elected as follows: Chairman, H. F. Blomquist, of St. Paul; vice chairman, D. A. Reed, of Duluth. An invitation was extended to hold the fall meeting at Rochester, Minn.

Indiana State Highway Commission Selects Chief Engineer

Under the state highway law enacted by the last Indiana legislature the reorganized state highway commission has appointed H. K. Bishop, formerly district engineer of the Bureau of Public Roads, chief engineer. Mr. Bishop has had extensive experience in highway engineering, and in his position with the Bureau of Public Roads supervised all Federal-aid road work in Ohio, Pennsylvania, Maryland, Virginia, West Virginia, North Carolina and New Jersey. He was graduated from Cornell University, Ithaca, N. Y., in 1893, and after considerable experience in municipal, New York State Barge Canal and other public work, became one of the first deputy engineers of the New York State Highway Commission when it was formed in 1909. He continued in this position until 1911. Following this he went to Honolulu, Hawaii, where he laid out the boulevard system and became commissioner of the Honolulu board of public works. Shortly after returning to the United States he became district engineer in the Bureau of Public Roads. The salary of his new position will be $7000 per year.

Milwaukee to Develop Harbor

Municipal docks and freight terminals on Jones Island, in Milwaukee harbor, are under consideration by the city. The harbor commission has just retained H. McL. Harding, consulting engineer, New York, to have charge of the project.

Campaign on Foot to Organize Auxiliary Engineer Corps

Letters have been sent to a number of the civilian members of the United States Engineer Department urging upon them the advocacy of an Auxiliary Engineer Corps, which will apparently be a part of the Corps of Engineers of the Army. The letter states that a bill for this purpose has recently been placed in the hands of Senator Ransdell of Louisiana, with a view to having it introduced at the coming session of Congress. This bill provides for a complete organization of the engineers doing public work in the United States, but placing the new department under the Chief of Engineers, U. S. A., and providing military status for all of the members thereof. The head of the department would be the Chief of Engineers, with the rank he now has of major general, and the division engineers would have the rank of brigadier general, and district engineers the rank of colonel, with provision for military rank for all subordinate assistants. It is the intention, according to the letter, that the corps be mobilized from the experienced men now in the United States Engineer Department. It is also stated that the duties of the corps will be the control of the river and harbor work of the United States as well as the construction, care and maintenance of all public works, particularly highways and bridges.

The last paragraph of the letter says: "Strong influence is working to turn public works over to the Quartermaster Corps, because they have already so many of our men in the service, and there is talk of a waterways commission and a construction-engineer branch in the quartermaster service, but it is not believed that either the people or Congress are ready for a change of engineers. The Auxiliary Engineer Corps will meet any public necessity, if there is one, for a waterways commission. There is a chance for any engineer who knows anything about river and harbor work to get in, as it calls for men having this special qualification."

Lieutenant Stuart Missing Since January 18

The American Red Cross is making every effort to locate Lieut. William H. Stuart, son of Duncan C. Stuart, of 12 Maple St., Oneonta, N. Y., who has been missing since Jan. 18, when he was last seen in New York City.

Any information that may be obtained is requested by the Red Cross.

Lieutenant Stuart is 27 years of age. He arrived from overseas service in January, and went to Washington Jan. 13, and received his discharge. He returned to New York and was last seen in that city Jan. 18 at 7:30 p.m. He is a graduate of Colgate University, class of 1914, and did two years' post-graduate work at the Brooklyn Polytechnic Institute. He is 5 ft. 8 in. tall, has dark brown hair and blue eyes and a ruddy complexion. He has a brown mole on the left side of his nose. If in uniform he has three gold service chevrons on his sleeve, indicating 18 months' service overseas. He was wearing, when last seen, spiral puttees, and not the customary leather ones for officers. Information relative to him may also be sent to D. C. Stuart, at the address given above, or Thomas Blizard, chief of police of Oneonta, N. Y.

British Columbia Technical Union Formed at Vancouver

An organization was recently formed in Vancouver, B. C., for "professional technical men and their technical assistants." It is called the British Columbia Technical Union. It is in nowise to be classed with the labor trades unions, the founders assert, nor will it affiliate with the labor organizations. The membership, which includes many members of the Engineering Institute of Canada and other national engineering organizations, rose above 100 within a few weeks. About 60 are classified as civil engineers.

The general purposes of the union are: (1) To obtain adequate public recognition of technical work; (2) to establish scales of standard fees for consultants and obtain recognition of the same; (3) to obtain equitable remuneration for salaried technical men and their salaried technical assistants; (4) to secure the consultation and employment of local members of the technical professions for work in British Columbia and to discourage the importation of men for technical work when duly qualified men are available in the province; (5) to protect members of this society when handicapped by extraneous influence in the execution of their professional duties; (6) to coöperate with existing professional societies in furtherance of the above objects, and, while not interfering with their usual activities, to assist them in every legitimate manner which will tend to maintain or improve the efficiency, status and remuneration of the technical professions; (7) to protect the public by encouraging the employment of qualified technical men.

The secretary-treasurer for the coming year is Charles T. Hamilton, 510 Hastings St. West, Vancouver, B. C.

Cities to Save Colorado Railway

Mayors of several Colorado cities recently organized the Northwestern Colorado Tunnel Association, for the main purpose of preventing the threatened abandonment of the Denver & Salt Lake R.R. It will endeavor also to secure the carrying out of the project for the six-mile James Peak tunnel which will eliminate the high altitude, steep grades and snow troubles of the present high-level line through the Corona Pass. R. E. Norval, of Hayden, Colo., was elected chairman.

Civil Service Examinations

New York.—Junior assistant engineer, State Engineer and Highway Department, \$1200-\$1440 per year, May 24. Apply to State Civil Service Commission, Albany, N. Y. File applications before May 24.

New York.—Bridge designer, Public Service Commission, First District, \$1501 to \$2100 per year. Apply to State Civil Service Commission, Albany, N. Y. File application before May 24.

United States

For United States civil service examinations listed below, apply to United States Civil Service Commission, Washington, D. C., or to any local office of the commission, for form 1312.

Highway bridge engineer, \$1800 to \$2100 per year, junior highway bridge engineer, \$1200 to \$1600 per year, Bureau of Public Roads and Rural Engineering, May 21. File applications in time to arrange for examination at place selected by applicant.

Engineer in forest products, \$1860-\$3000 per year; assistant engineer in forest products, \$1200-\$1800 per year, Forest Products Laboratory, Madison, Wis., May 27. File applications before May 27.

Chief of road survey party, \$1800 to \$2100 per year, transitman for road surveys, \$1200 to \$1800 per year, highway draftsman, \$1200 to \$1800 per year, Bureau of Public Roads and Rural Engineering, May 29. File applications before May 29.

Senior engineer and senior architect, Interstate Commerce Commission, \$1800-\$2700 per year, June 10. File application before June 10.

Valuation engineer, \$3600-\$4800 per year, and assistant valuation engineer, \$2500-\$3600 per year; technical staff, income-tax unit, Bureau of Internal Revenue, Treasury Department. No date specified.

ENGINEERING SOCIETIES

The Master Builders' Association of Central Washington was formed recently with the following officers: President, D. L. Thacker; vice-president, Edward McWilliams; secretary, J. H. Corbett, and treasurer, Harry Boyer. The headquarters are at Yakima.

The Logansport, Ind., Chapter of the American Association of Engineers was recently organized, with the following officers: President, C. T. McGreevy; vice-president, Carl Lux; secretary-treasurer, Ralph Newcomer.

The Canadian Good Roads Congress will hold its annual meeting at Quebec May 20-22, at the time of the informal conference of the provincial ministers of public works and their deputies. In

Calendar

Annual Meetings

NATIONAL CONFERENCE ON CITY PLANNING: 19 Congress St., Boston; May 26-28, Niagara Falls and Buffalo.

AMERICAN WATER-WORKS ASSOCIATION; 47 State St., Troy, N. Y.; June 9-13, Buffalo, N. Y.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS, 29 W. 39th St., New York; June 16-19, Detroit.

AMERICAN SOCIETY OF CIVIL ENGINEERS; 29 W. 39th St., New York; June 17-20, St. Paul-Minneapolis.

AMERICAN SOCIETY FOR TESTING MATERIALS; University of Pennsylvania, Philadelphia; June 24-27, Atlantic City, N. J.

AMERICAN CONCRETE INSTITUTE; 6 Beacon St., Boston; June 27-28, Atlantic City, N. J.

addition to technical papers there will be an exhibit of materials and road-building methods. The conference of provincial ministers is called to discuss the Federal-aid highway bill.

The Colorado Association of Members of the American Society of Civil Engineers held a regular meeting May 10 at which Milo S. Ketchum, dean of the College of Engineering, University of Colorado, spoke on "The Construction of the United States Government Explosives Plant at Nitro, W. Va."

The Engineering Society of Tulsa, Okla., was organized at a meeting May 1. The following officers were elected: President, J. C. Hughes; vice-president, E. H. Cornelius; secretary-treasurer, S. W. Mitchell.

The Savannah, Ga., Chapter of the American Association of Engineers recently elected the following officers: President, George O. Haskell; vice-presidents, W. J. Kehoe and Percy Sugden; secretary, G. A. Beldan; treasurer, W. A. Whitfield.

The Rochester, N. Y., Engineering Society will be addressed May 16 by E. A. Fisher on "Old Surveys of Rochester." A meeting will be held May 23, at which E. Blough, chief chemist of the Aluminum Co. of America, Pittsburgh, will speak on "Commercial Applications of Aluminum."

The Colorado Society of Engineers held a meeting May 2 at which W. R. Rosche spoke on "The Byproducts of Bituminous Coal and Their Production." A. L. Fellows showed samples of the concrete used in the concrete oil tankers under construction at Alameda, Calif.

The Sacramento, Calif., Chapter of the American Association of Engineers was recently formed. W. B. Carruthers is president, R. A. Bergman is vice-president, and H. A. Lathrop is secretary.

The Associated Engineering Societies of St. Louis held a joint meeting under the auspices of the St. Louis Branch of the American Society of Refrigerating Engineers, May 14. E. W. Gallenkamp, Jr., of the Pilsbry-Becker Engineering & Supply Co., presented a paper on "The Effect of Increased Condenser. Ice Can and Freezing Coil Surface on Power Consumption of Ice Plants."

The Engineers' Society of St. Paul held a meeting May 12, at which P. E. Stevens, consulting engineer who had charge of the expansion of the McDougall-Duluth Co.'s shipbuilding plant, spoke on "Building a Shipyard."

The Brooklyn Engineers' Club was addressed May 8 by Irving Blount, who read a paper on "Final Disposition of Garbage."

The Los Angeles Chapter of the American Association of Engineers was organized recently. E. G. Sheibley is president and J. C. E. McClure is secretary.

The Engineers' Club of Trenton called a meeting May 8 to discuss the proposed Assunpink Way project. Mayor Frederick W. Donnelly of Trenton introduced the subject, and a number of members participated in the discussion.

The Charlotte, N. C., Chapter of the American Association of Engineers was formed recently. J. A. Killian is president and G. T. Asbury is secretary.

The Allied Engineering Association of Charleston, S. C., will hold its next meeting May 19. The annual meeting will be held June 16. The regular meetings are held on the third Monday of each month.

The Louisiana Engineering Society held a meeting May 12 at which Prof. John Smith Kendall, of Tulane University, read a paper on "Jackson Square."

The Salt Lake City Chapter of the American Association of Engineers was organized recently. Maj. O. Simons has been elected temporary secretary.

Personal Notes

GAYLORD CUMMIN has resigned as assistant to the president, Kelsey-Brewer Co., public utility operators, of Grand Rapids, Mich., and will establish offices in New York City as a consultant in municipal and public-utility problems. Mr. Cummin's office will be located temporarily in the office of the Institute of Public Service, 51 Chambers St. Last year he resigned as city manager of Grand Rapids to enter the Kelsey-Brewer Co. He was previously city engineer of Dayton, Ohio.

LIEUT. H. J. WILLIAMS, Engineering Division, Ordnance Department, U. S. A., who recently received his discharge from the service, has been appointed engineer of the Beacon Falls Rubber Shoe Co., Beacon Falls, Conn. Before entering the service Mr. Williams was engaged in private practice in New York City as a consulting engineer, and was also a member of the faculty of the Pratt Institute, Brooklyn.

HENRY H. FOX, estimating engineer, contract department, Turner Construction Co., New York City, has been appointed a vice-president, with headquarters in New York.

MAJ. A. J. SACKETT, formerly chief engineer of the Mason & Hanger Contracting Co., New York City, and R. L. CANNIFF, formerly treasurer, Degnon Contracting Co., New York City, have incorporated the North Atlantic Construction Co., and will conduct a general contracting business under that name.

A. S. ADAMS, who during the war served as supervising engineer of construction, Camp Logan, chief engineer of construction, Ellington Field, Houston, Tex., and in other war work, has opened an office in the Union National Bank Bldg., Houston, Tex., for the private practice of engineering.

J. P. H. PERRY, manager of the contract department, Turner Construction Co., New York City, has been appointed a vice-president, with headquarters in New York.

M. L. LOEWENBERG, recently engineer, Worden-Allen Co., Chicago, and I. S. LOEWENBERG, formerly architect, Swift & Co., Chicago, have become associated under the firm name of LOEWENBERG & LOEWENBERG, engineers and architects, with offices at 29 S. La-Salle St., Chicago.

W. W. TURNER, president of the Turner Concrete Steel Co., has become a general manager of the Turner Construction Co., New York City, in charge of work in the vicinity of Philadelphia, with headquarters in that city. The Turner Concrete Steel Co. has been consolidated with the Turner Construction Company.

CAPT. JOHN F. DRUAR, Engineers, U. S. A., recently discharged from the service, and ROSCOE L. SMITH, recently engaged with the National Board of Fire Underwriters on water-supply and fire-protection work in Army camps, have become associated in partnership to engage in general engineering work, with headquarters in the Globe Bldg., St. Paul, Minn.

EDMUND F. SAXTON, formerly assistant director of the Department of Wharves, Docks and Ferries, Philadelphia, has become treasurer and a director of the John S. Boyd Co., Williamstown, Mass., succeeding Richard A. Strong, resigned. He will be in charge of the engineering work of the company.

MAX TOLTZ, head of the Toltz Engineering Co., W. E. KING, for several years treasurer and manager of

the Toltz Co., and BEAVER WADE DAY, recently engaged in the United States Housing Corporation project at Manitowoc, Wis., have become associated in partnership under the firm name of TOLTZ, KING & DAY, Inc., successors to the Toltz Engineering Co., at 1410 Pioneer Bldg., St. Paul. The new firm will carry on a general consulting and architectural engineering business, specializing in industrial structures.

A. C. SHUIT, who has concluded his work as cost engineer for the United States Housing Corporation on the project at Aberdeen, Md., has been appointed construction engineer, Washington Suburban Sanitary Commission.

THOMAS R. SPENCER, after thirty years' service with the Oregonia Bridge Co., Inc., Lebanon, Ohio, has resigned as general manager of the company, and is succeeded by Capt. A. H. ROBERTSON, JR., U. S. A., who recently received his discharge from the service and who was formerly chief engineer of the Dover Boiler Works, Dover, N. J.

T. V. STEVENS, formerly city manager of Cadillac, Mich., has resigned as senior engineer of the housing division, Emergency Fleet Corporation, to become associated with ALBRIGHT & MEBUS, consulting engineers, Philadelphia.

EDGAR I. WILLIAMS and WALTER R. MAHNKEN have become associated under the firm name of WILLIAMS & MAHNKEN, architects, 30 E. 42nd St., New York City.

A. C. TOZZER, general superintendent of the Turner Construction Co., New York City, has been appointed a vice-president and general manager of the New England territory, with headquarters in Boston.

C. W. L. FILKINS, of Scranton, Penn., has opened an office at Stockbridge, Mass., and will engage in civil engineering and construction work, in connection with his office in the Commercial Trust Bldg., Philadelphia.

C. T. JORDAN, district engineer, State Highway Department of Washington, has been placed in charge of the new office of the department in the County-City Bldg., Seattle.

CHARLES R. MCLAUGHLIN, Philadelphia, has been appointed engineer in charge of construction at the new Pennsylvania State Sanitarium at Mount Alto.

LOUVA G. LENERT, assistant state sanitary engineer, Bureau of Sanitary Engineering, Texas State Board of Health, has resigned to engage in private practice, with offices at Cisco and Breckinridge, Tex.

MORRIS R. SHERRERD, chief engineer of the Department of Streets and Public Improvements, Newark, N. J., has been appointed chief engineer of the North Jersey District Water Supply Commission, and will assume office July 1. It is understood that Mr. Sherrerd will continue his work for the city in the capacity of consulting engineer. Mr. Sherrerd first entered the employ of the City of Newark in 1895. He became engineer and superintendent of the Department of Water and in 1905 was appointed chief engineer of the Department of Streets and Public Improvements.

T. A. SMITH, general superintendent, Turner Construction Co., New York City, has been appointed a vice-president, with headquarters in New York.

H. D. JUDSON, of St. Joseph, Mo., M. S. MURRAY, of Sikeston, M. J. HANICK, of St. Louis, and H. D. GRIFFITH, of Hillsboro, have been appointed deputy highway engineers, Missouri State Highway Commission.

W. B. STEVENSON, acting city engineer of Fargo, N. D., has purchased the business and equipment of the Hopeman Engineering Co., Moorhead, Minn.

JOHN P. HARPER, first assistant state highway engineer of Arkansas, has resigned, and announces his intention of opening an office at Little Rock for the private practice of egineering.

W. E. LYLE, a general superintendent, Turner Construction Co., New York City, has been appointed a general manager in charge of work in western New York, western Pennsylvania, and eastern Ohio, with headquarters in Buffalo.

LYNN B. MILAM, of the firm of Thomas, Milam & Touchstone, attorneys at law, Dallas, Tex., has been appointed supervisor of public utilities of that city, succeeding M. N. Baker.

DONALD D. SNYDER, assistant engineer, Bureau of Engineering, Albany, N. Y., has resigned to become commissioner of public works and city engineer of Rutland, Vt.

A. W. STEPHENS, engineer, Turner Construction Co., has been appointed chief engineer, with headquarters in New York.

J. R. and R. L. BARRY have become associated under the firm name of BARRY & BARRY, civil engineers, Lawton, Okla.

HENRY WOOD, private secretary to Governor Robertson of Oklahoma, has been appointed state highway commissioner, succeeding George B. Noble.

R. C. WILSON, engineer, Turner Construction Co., New York City, has been appointed a general manager, with headquarters in New York.

EDWARD R. SCHOFIELD, draftsman, Bureau of Surveys, Philadelphia, has been appointed assistant engineer.

MAJ. JOHN R. FORDYCE, Engineers, U. S. A., who was constructing quartermaster at Camp Pike, and who recently received his discharge from the service, has announced that he will open an office for the private practice of engineering at Little Rock, Ark.

DR. OBADIAH C. BOGARDUS, Keyport, N. J., has been appointed a member of the North Jersey District Water Supply Commission.

M. D. GLESSNER, of Yuma, Ariz., has been appointed assistant to F. L. SELLEW in irrigation and dam construction in eastern Arizona near St. Johns

OBITUARY

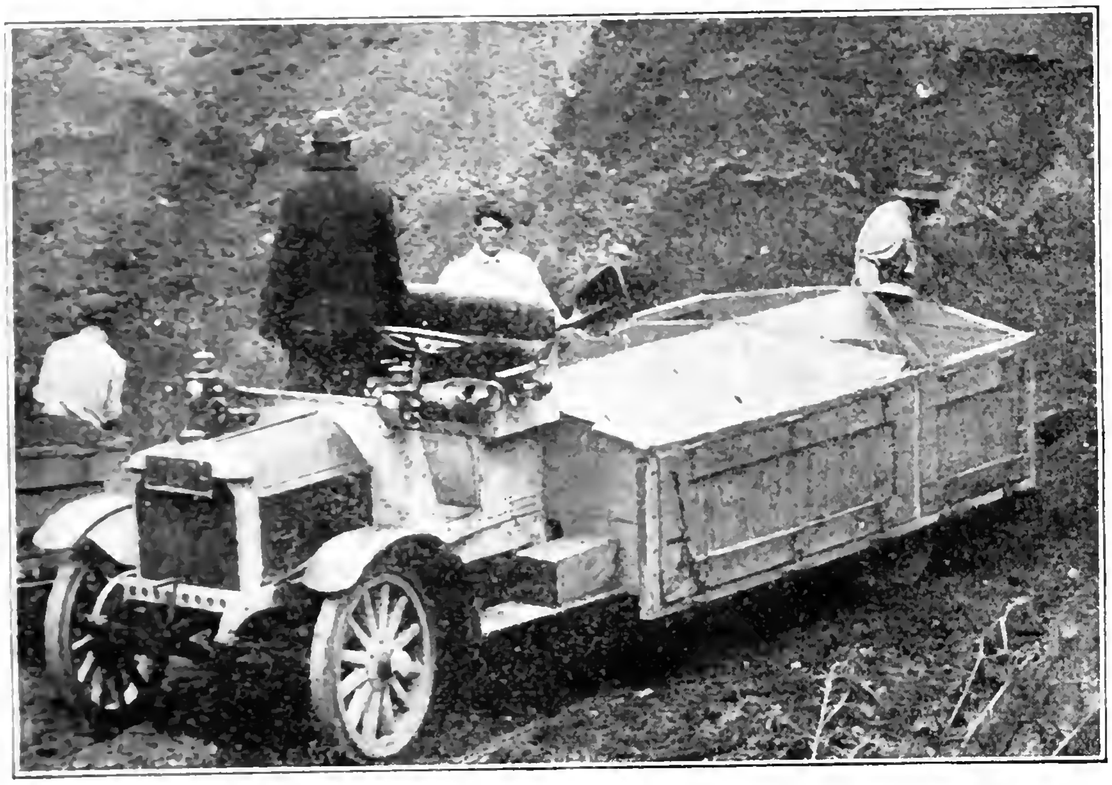
HOMER P. RITTER, hydrographic and geodetic engineer, United States Coast and Geodetic Survey, and member of the Mississippi River Commission, died in Washington, D. C., Apr. 21. He was born in 1850 and studied at the School of Mines, Columbia College, New York City. In 1880 he become United States assistant engineer, Mississippi River Commission on hydrographic and topographic surveys, remaining in Government service to the time of his death. He also served on international boundary surveys as official representative of the Government. In 1904 he commanded the steamer "McArthur," making a survey of Kiska harbor, Aleutian Islands, in the Bering Sea. In 1907 he was appointed a member of the board to investigate and report on the feasibility of a 14-ft. channel in the Mississippi River. In more recent years he was engaged in the revision of charts of New York harbor, Long Island Sound, and other waters.

ADNA DOBSON, city engineer of Lincoln, Neb., who had served in that capacity for 18 years, died May 4. He was born in 1857, and received his technical education in an engineering office. In 1878 he became deputy county surveyor, and afterwards assistant city engineer of Lincoln. After a brief period of private practice he was elected city engineer of Lincoln in 1891, and served four years, afterwards becoming under-secretary of the State Board of Irrigation of Nebraska. After engaging again in private practice for two years he was again elected city engineer of Lincoln in 1900 and again in 1909.

CARL UHLIG, engineer, California Board of State Harbor Commissioners, died in San Francisco May 5, at the age of 72. He had been connected with the engineering department of the Harbor Commission for over 42 years. In 1870 he became an assistant in the United States Coast and Geodetic Survey, four years later being appointed assistant engineer, water-supply office, San Francisco. In 1876 he became assistant engineer and chief draftsman, California Board of State Harbor Commissioners, and remained in the service of the board to the time of his death.

Sectional Truck Body for Hauling Road-Repairing Materials

A sectional, side-dumping motor-truck body for hauling gravel and other materials on road construction and maintenance is shown in the accompanying illustration. It is arranged with four pockets having two different capacities, so that a large or a small amount can be dumped as desired. The low box makes it easy to load the truck by hand shoveling.



LOW SECTIONAL TRUCK BODY IS EASY TO LOAD AND DUMP

In operation, the trucks are loaded at the gravel pit, having the trap doors in the sides held shut by straps on the lever road, which fit into iron slots on the floor of the truck. When the truck is loaded it proceeds to the road, and the compartments are alternately dumped at places and in quantities as desired by pulling the lever forward or back, as required. Free discharge of material is provided for by a peeked floor extending along the middle line of the truck box.

The illustration shows a two-ton Federal motor truck with one of these boxes, which was designed by J. A. Gould, road commissioner at Windsor, Vt. He has found this type of body particularly adapted to his purposes.

National Offices Opened by Trailer Manufacturers

National headquarters for the recently organized Trailer Manufacturers' Association of America, the organization of which was noted in *Engineering News-Record* of Mar. 6, 1919, p. 499, have just been established in New York City, in the World Tower Building, 110 W. 40th St. Matters of interest and importance to the industry will be considered and action will be taken regarding them—for example, ill-advised legislation affecting motor trucks and trailers in several states will be investigated.

It is felt that the opening of the New York headquarters marks a new era in trailer industry. From the new office will originate activities to familiarize the business world with the many applications of trailers to haulage problems and the economies to be effected thereby, with plans for the promotion of the best interests of highway transportation. Fourteen of the leading trailer manufacturers have already joined the organization, of which H. W. Perry, formerly with the National Automobile Chamber of Commerce, is general manager.

Business Notes

The Manufacturers' Sales Co., with offices at 914 American Bank Building, Seattle, Wash., has been organized by H. P. Hammond, of Seattle, to handle concrete products, Terrazzo flooring and building material specialties.

The Sterling Wheelbarrow Co., of Milwaukee, is erecting an addition to its plant, 385 x 165 ft. The new structure will accommodate a two-story office section, including a large display room.

The Bell Locomotive Works, Inc., 11 Pine St., New York City, announces that their former sales manager, J. Stanley McCormack, will return to his old position in the near future upon discharge from the Naval Aviation Corps.

The Joseph Dixon Crucible Co., of Jersey City, N. J., manufacturer of lead pencils and other graphite products, has removed its Philadelphia sales office from 1020 Arch St. to Rooms 801-802 of the Finance Bldg., South Penn Square. The manager of the sales office is W. G. Springer. The Crucible company and the American Graphite Co., a subsidiary, held their annual meetings Apr. 21. The following officers were elected for both companies: George T. Smith, president; George E. Long, vice-president. For the former company J. H. Schermerhorn was elected vice-president and William Koester treasurer; for the latter J. H. Schermerhorn was elected treasurer.

The Booth-Hall Co., designer and builder of electric furnaces, announces the removal of its executive and sales offices from 565 W. Washington Boulevard to Rooms 1007-1008, Hearst Building, 326 W. Madison Street, Chicago.

The American Steam Conveyor Corporation, of Chicago, announces the appointment of N. B. Stewart as district representative in charge of the St. Louis territory. Offices have been opened at 708 Merchants-Laclede Bldg., St. Louis.

The Union Bridge and Iron Co., Seattle and Portland, has been incorporated by Charles G. Huber, specialist in the design and construction of Luten design bridges, and George A. Sears, formerly of the Coast Bridge Co., Portland, Ore.

Trade Publications

The following companies have issued trade publications:

The Silent Hoist Co., 302-304 McDougal St., Brooklyn, N. Y.; leaflet, 4 x 9¼ in., eight pages, illustrated; describes its Model A, 20-hp. gasoline unit.

The American Steam Conveyor Corporation, 326 W. Madson St., Chicago, Ill.; pamphlet, 8½ x 11 in., 12 pages, illustrated. "Reducing Ash-Disposal Costs" is the subject treated.

The Deming Co., Salem, Ohio; catalog, 6¾ x 9¼ in., 37 pages, illustrated; covers vertical single-acting Triplex power pumps.

The John J. Macklem Scaffolding Co., Goshen, Ind.; catalog, 6 x 9½ in., 16 pages, illustrated; shows details of, and describes method of using, sectional scaffolding.

The General Fireproofing Co., Youngstown, Ohio; catalog, 8 x 11 in., 16 pages, illustrated; contains data on the use of "Self-Sentering Trussit and Steel Tile," for roofs, floors, ceilings and partitions.

The Ball Engine Co., Erie, Penn., leaflet, 8½ x 11 in., four pages, illustrated. The subject is the cost of operating Erie steam shovels on road and street gradings.

Volume 82 | NEW YORK, THURSDAY, MAY 22, 1919 | Number 21

Engineering Impossibilities

NO DOUBT there is much truth back of the optimistic saying that to the engineer nothing is impossible. For those who take the saying literally a near-metropolitan daily offers an excellent problem. Speaking of the proposed vehicle tunnel under the Hudson River, the paper says: "Shall the proposed vehicular tunnel be a twin tunnel, or shall it be a single tube with two floors? The single-tube plan is the plan of General Goethals and is favored by many of the New Jersey members of the commission. The twin-tube idea is the proposition of Vipond Davies, and this is favored by some of the New York members. The hope of some is that there may be a happy merger of the two ideas." The happy merger, we must assume, would be two tubes that beat as one. We wait breathlessly the details of the "merger" of these ideas.

A Good Government Salary

SALARIES in the Railroad Administration are good. Monthly wages counted by the thousands are common, and some few fortunates approach the thousand-a-week basis. It is the one branch of Government service where there is an approach to that ideal condition where a man's pay is commensurate with the private reward for the same work. And yet even those of us who have consistently advocated a better Government wage scale are somewhat stunned by the $25,000 a year paid to the Director of Inland Waterways. High cost of living notwithstanding, that is a lot of money for what has been done; it is altogether too much money for a subordinate who can only supervise minor operations under the direction of a none-too-sympathetic administration. Only an independent waterways bureau, which could initiate and carry out a real waterways program, would justify such a salary.

Gambling on Price Reductions

THERE appears in some quarters a tendency among highway contractors to speculate on a drop in material and labor prices. While material prices are in a state of some uncertainty, with chances of small changes in either direction, there is no apparent basis for bidding on the expectation of reduced prices, such as occurred in a recent state highway letting at Albany, N. Y. In some materials, such as cement, assurance has been given that there will be no advance during the calendar year, but the safe interpretation of that assurance is that there will be no decline. In the labor market conditions do not favor lower wages. The labor which has built our roads heretofore is returning to Europe in large number, and an oversupply is not to be looked for. The testimony of many contractors who bid on the New York State work referred to above is that the engineers' estimates for the work were none too high at present prices. And yet these were cut by the low bidders anywhere from 4 to 25%. Surely in the circumstances a word of caution seems in order. It is a big gamble to contract to do work at prices fixed in the hope that the market will decline.

Airplane Mapping

MARKING another of the scientific or technical advances recorded as the result of the great war, airplane photography for producing topographic maps promises many advantages for the future, provided the difficult problems introduced when accuracy is desired can be met. The two articles in this issue are unusually valuable in showing in complete detail just what the present status of this new field is, and presenting clearly the nature of the problems yet to be solved. With our American genius for invention, it is safe to predict that these problems will be solved, and that the production of airplane maps of relatively great accuracy is to be reckoned as a foregone conclusion. Whether the cost will be prohibitive, or so great as to offset entirely the advantages in time saving which are claimed for the methods used, will be a matter for future development. But that there are great possibilities in these methods must be conceded. Their application introduces into a somewhat tedious operation the spirit of adventure.

Half-Section Roads

PERIODICALLY some one suggests the advisability of paving only half the roadway on country highways, leaving the other half soft for the benefit of horse-drawn traffic. In other cases, as proposed in a bill now before the Pennsylvania legislature, soft roads on each side are advocated. Such suggestions generally emanate from those who are interested in livestock, for there can be no doubt that roads of this character are much easier on horses' feet. However, there are constructional disadvantages in these types, and, in the half-section road, there is one feature which tends to make the road dangerous for motor-driven traffic. In this construction it is necessary, on account of drainage, to slope the road away from the center line. Therefore, on curves where the improved strip is on the outside, there is actually a case of reverse banking. Some roads in the East built in this way, notably the Buffalo-Niagara Falls boulevard, are positively dangerous, and have been blamed for many accidents. At the same time reverse banked curves are very uncomfortable for motorists at even moderate speed. Furthermore, the earth side roads are very expensive to maintain, if there is much traffic. The maintenance on the earth section of the Buffalo-Niagara Falls Boulevard, mentioned above, is reported at about $1000 per mile per year.

Where insufficient funds exist to build an entire surface, a combination design may be used as an expedient, with the intention of future widening, but its advisability is doubtful as a permanent improvement.

Wages Reduced In One Industry

FREQUENTLY we hear it stated that it will be impossible henceforth to lower the wage level. Obviously, those who speak in this way do not take the facts into consideration. Wage levels rise and fall with price levels and, in general, it is true that wage levels cannot be materially reduced while the price levels that carried them upward remain at the high mark. Nevertheless, there is a shining example in one of our American industries which shows that wages can be cut in defiance of the high price level. The industry in question is that of copper mining. The signing of the armistice found us overstocked with copper. The condition was one that encouraged the wholesale closing down of mines with the consequent danger of widespread unemployment in the copper-producing districts. Instead of that, the operators elected to keep the mines going at reduced capacity and to retain the forces in as large numbers as possible. With copper, however, selling down to about half its war price, it was obvious that the industry was not in a position to maintain the war wage-scale, and it promptly placed these conditions before the miners. Moreover, when the time came for action the operators did not ruthlessly issue an edict as to the wage reduction, but announced some time in advance the necessity for the change and gave ample time for the miners to digest the situation, to enter their arguments and to offer suggestions. The result was that the miners, appreciating fully the position of the operators, accepted without strikes or any other disturbance the reduced scales, confident that no other course was open to the industry. Many another industry, when the time for wage reductions comes, might take a leaf from the book of the copper producers.

Concealed or Physical Deficit

IN REPORTING to the stockholders of the Delaware & Hudson Co. last week, the president, L. F. Loree, discussed what may be termed the "concealed or physical deficit" as distinguished from the apparent or financial deficit under Federal operation. The financial deficit the Government will make good to the stockholders, for the contracts call, as every reader knows, for a return based on pre-war operation. What of the deficit due to inadequacy of maintenance? Will this be appraised fairly when the Government returns the roads, or will long-drawn-out arguments and legal contests be necessary before this concealed or physical deficit is made good? The Government in taking over the roads gave assurance that the properties would "be maintained during the period of Federal control in as good repair and as complete equipment as when taken over by the Government."

On the Delaware & Hudson system, however, Mr. Loree pointed out, the tie renewals in 1918 were 241,504, as against an average annual tie renewal, during the test period, of 339,575 ties. The deficiency, therefore, was 29%. At the average price per tie in 1918 of $1.12 the deficit in money would be about $110,000. Moreover, the quality of the ties used in 1918 was much below that of the ties used during the test period. At the present time there is in stock not more than 21% of the ties accumulated at corresponding dates in the test period. Somewhat the same condition obtains with reference to rail renewals. They show a deficiency of 28% in tonnage compared with the renewals during the test period, and a deficiency in money of about $102,000. Again, the Railroad Administration has dismantled 131 freight cars and none of them has been replaced, nor does the railroad know the condition of the 90% of its cars used on foreign lines.

Mr. Loree recognized that during the stress of war there were conditions that rendered it difficult to keep the property up to the standards obtaining before Government control, but that does not change the fact that the property is not maintained as the Government agreed to maintain it. Moreover, other properties have been suffering in the same manner.

Obviously, the Government must catch up with this maintenance deficit before the roads are returned to their owners, or must be prepared then to make good the deficit. Any other procedure would be a grave injustice.

Old, Overworked Filter Plants a Serious Health Menace

OBSOLESCENT condition of a water-works and water-purification plant, as in a Middle West town, a condition which is described by a correspondent in the following paragraph, does not occur frequently. Such plants do exist in certain cases, however, and occasionally it takes a typhoid epidemic to jar public opinion sufficiently to force general overhauling. Like a faithful truck horse, the plants need considerate treatment. Quoting the letter:

"The intakes were insufficient as used and one had a serious break about 150 ft. from shore into which drainage from the plant sewer, carrying wash water and mud from the basins, entered. There was only one screen in the raw well to protect the pumps. The low-duty turbine could not draw water through the channel intake—for which purpose it was designed and installed. There was no means whatever of agitating the alum solution made in the tanks, nor means of measuring the raw water to know how much was being treated. No means of measuring or even definitely regulating the flow of the alum solution existed; therefore, it could not be proportioned to the raw water treated. A very short retention period was provided in the settling basins—nominally three hours, but actually some water passed through in less than one hour. Wash water was carried away by troughs badly out of level and leaking to such an extent as to waste much sand. Because of the 3- to 6-in. difference in elevation in the filter bottoms the air wash was almost useless, and dependence had to be placed on wash water which had a vertical rise of only 9½ in., and the very excessive lateral travel of 5 ft. 2 in.

"Is it strange that mud bars a foot wide extended along each filter, and that the bed contained fouled sand like garden soil? The supporting gravel was of all sizes—one filter had only 5 in., none of which was more than ⅜ in. in size, while another had pieces of sandstone up to 5-in. size. The controllers were out of order, as were also the loss-of-head gages.

"The chlorine machine was more than ready for the

scrap heap. There was not only no means of measuring the chlorine applied, but also there was no means of knowing how much water was being filtered, so that the treatment was of the most hazardous kind. The amount of chlorine that the machine could deliver was very limited, and we were often seriously gassed trying to speed it up.

"The filtered water reserve was absolutely inadequate, the domestic demands alone often exceeding the plant capacity plus the storage. If there had been a serious fire at such a time and the bypass could not furnish enough, the pumping-station engineer would have opened a valve allowing the high-duty pumps to take their suction directly from the raw well, and not a bit of chlorine could have been used on this water. The high-duty pumps were in need of many repairs. A booster booklet spoke of this plant as being able to deliver 21,000,000 gal. daily, but how could the filter plant produce even its rated 5,000,000 gallons?"

Many of the construction features in this filter plant were standard practice much less than 20 years ago. Modern sterilization methods have added years of life to these old filters, but it is unfair to expect a plant with crude and wornout apparatus to carry a normal burden. Stream pollution all over the country is steadily on the increase, so that the intervals between infections grow less and less. Plants which were good enough, even excellent, 10 years ago may be dangerous today, for the germs of disease are many times more prevalent in the raw supply. Standards must be higher, laboratory control more rigid, expert advice sought—and followed—more frequently. With the war over, it behooves city officials who have any doubt at all of the integrity of their supply to look into it most seriously before the blood of typhoid victims is upon their heads.

Riveted-Truss Span of Record Length

ALTHOUGH the primary reason for the adoption of riveted joints in the new 644-ft. span of the Pennsylvania Railroad's Ohio River birdge at Louisville, Ky., described on another page of this issue, was the necessity for unity throughout the structure, yet the use of a stiff riveted type is consistent with the practice of Pennsylvania Lines West of Pittsburgh during the past twenty years. This preference is based not alone upon the desire for greater rigidity, but also upon the feeling that the eye-bar type has certain disadvantages, especially in the fact that all bars in a given member do not obtain equal stress, and that unavoidable wear takes place at the pins.

The new 644-ft. span, the length of which resulted from the Government requirement of a 600-ft. clear channel and the desire to utilize the masonry piers of the old bridge, is not only the longest and heaviest simple riveted-truss span in existence, but it is third among the world's simple-truss spans, being exceeded only by the 721-ft. Metropolis span and the 668-ft. St. Louis municipal bridge span, both pin-connected. It is about 4 ft. longer than the 640-ft. suspended span of the Quebec bridge. The next in span length of the simple-truss type is the 620-ft. bridge of the Kentucky & Indiana Terminal R.R., also located at Louisville. All of these American bridges exceed in length the longest simple-truss span in Europe—610½-ft. Homberg span of the Prussian State Ry. over the Rhine at Homberg.

The new span is built of high-carbon steel rather than alloy steel because of the designer's objection to the use of high unit stresses on the score of excessive deflection and a resulting tendency to rack the floor system. Double floor-beams at each panel point, making the stringers discontinuous, not only facilitate erection in panel units, but also reduce the danger of loose rivets in the floor system. Although a high-carbon steel was specified, the unit stress was not increased, the margin being considered necessary to allow for secondary stresses, which were not computed.

One cause of the exceptional weight of the new span lies in heavy details. For example, all compression chord splices, although milled to bear, were fully spliced by providing splice plates and sufficient rivets to take the full stress. Transverse diaphragms for all members, spaced at relatively frequent intervals, and longitudinal diaphragms at the ends of diagonal members to insure stiffness and exact dimensions, also increased the weight, but at the same time were found to facilitate field assembly and aided greatly in keeping the long members in true shape and out of wind. Heavy gusset plates, required by the exceptionally large number of field rivets, taxed the capacity of the rolling mills. For example the 130 x 1½-in. plates at the hip joints are the maximum attainable.

An exceptional feature in the design of this bridge was the adoption of a live load consisting of a uniform train load combined with a single concentration. The reason for the preference of this loading lies in the designer's claim that Cooper's standards do not really represent actual engine loadings, especially for heavier locomotives, which do not have axle concentrations of equal value, nor is the actual wheel spacing the same as that given by Cooper's standards. Experiments which have been made by weighing the main drivers of such locomotives indicate that the actual loads on the main driver axles vary quite widely.

Certain features of the design are noteworthy. For example, the lower chords are built up with a constant base section, composed of vertical webs, eight angles and four narrow horizontal longitudinal plates placed at about the third points vertically and laced together. Outside and inside vertical web plates provide the additional areas required for the heavier chords near the center. The top-chord section is composed of eight angles instead of the usual four angles for lighter trusses. This made necessary the splicing of gusset plates at the joints, these gussets being inserted in the plane of the main web plates—a detail similar to that used in the 525-ft. Ohio connecting bridge at Pittsburgh, on the same road.

The replacement of this historic structure, with its long series of Fink-truss spans, by new double-track trusses of exceptional weight, is another example of the changes forced by the constant increase in locomotive loading. The old trusses, with reinforcement, long and faithfully served their time, but finally had to be abandoned. The difficult problems of erection under traffic, which will be described in a later issue, were successfully solved, and the new steel superstructure, one mile long, now stands as the latest example of heavy riveted-truss design—with its channel span of record length, its series of heavy deck trusses, a through span 370 ft. long and a 260-ft. lift span with the latest improvements.

Present Status of Photographic Mapping From the Air

Airplane Mapping Possible and Practicable, but Two Great Problems, Horizontalization of Camera and Effects of Surface Relief, Must Be Solved

By J. B. Mertie, Jr.
Associate Geologist, United States Geological Survey, Washington, D. C.

New developments in the application of photography to the making of topographic maps have resulted directly from the experiences of the war. Mr. Mertie's appraisal of the present situation in aëro-photography and his clear-cut analysis of the difficult problems which remain to be solved are the result of first-hand contact with the airplane mapping investigations carried on by the Survey in coöperation with the United States Engineer Corps. This article is followed by a detailed description of the successful Bagley camera and of the transforming camera developed by F. H. Moffit and the author. Additional information on photo-topographic methods and on the use of air-photographs in the war will be found in the article on "Stereophotographic Surveying" by Otto Lemberger in "Engineering News" of Mar. 27, 1913, p. 602, and in the description by R. K. Tomlin, Jr., in "Engineering News-Record" of May 23, 1918, p. 984, of the work of the Army topographical division in coördinating the work of the mapmakers in the air and on the ground.

Mr. Mertie's paper is published with the permission of the Director of the United States Geological Survey—Editor.

A STEADY demand exists at the present time for information regarding the possibilities and methods of photo-aërial mapping. The Geological Survey is continually receiving requests from individuals, commercial organizations, and even from foreign surveying corps, for information concerning what has been accomplished to date and what developments may reasonably be expected in the near future. The writer, having been associated in the airplane mapping investigations carried on by the Geological Survey in coöperation with the United States Engineer Corps, is reasonably conversant with the present status of airplane mapping, and undertakes herewith to set forth a short summary of results so far achieved, with the twofold intention of furnishing information to those who may be interested, and of correcting a number of erroneous impressions which appear to have been disseminated by ill-conceived and misleading publications on the subject.

Airplane mapping by means of photography is possible and practicable, but has by no means yet been developed to the point where it may be described as a smoothly working process. Problems of the first magnitude remain to be solved before the airplane camera can take the place of the plane table and alidade, and in the author's opinion it is much better to face honestly the difficulties than to gloss them over and optimistically set forth the airplane mapping method as a surveying panacea.

A number of articles have appeared recently which either from ignorance, unbalanced optimism, or from utter disregard of the facts, have described the process of airplane photographic mapping as a finished product, capable of being taken up by an organization and utilized as a complete substitute for the older methods of mapping. Such publications, in their unwarranted advertising of a method as yet imperfect, are most apt to do harm, in the same way that worthy mining enterprises have suffered from the promotion of stock-selling mining swindles. It is certainly to be hoped that a process so full of promise as the one under discussion may be spared the fate of passing through a miasma of temporary failure, with the consequent doubt and controversy, due to premature and unwise schemes of promotion.

Principles of Photographic Surveying—Two Problems

Photographic surveying on the ground has been known and practiced for many years in many countries, including the United States and Canada. A tremendous amount of work has been accomplished in this subject, and the underlying principles are thoroughly worked out and understood. With the advent of the dirigible balloon, however, and later the airplane, a new application of the method was seen and the possibilities of the aërial survey came to be recognized. It is not the purpose of the writer in this article to describe in detail the technique of the subject, but it may not be out of place to state that a photograph of a plane and horizontal surface taken from the air upon a photographic emulsion held parallel to the plane of the horizon is a true map. The lens has acted merely as a point of projection connecting one plane with another, and of course the scale is dependent both on the distance of the lens from the ground and on the distance of the photographic plate or film from the lens.

Any relief upon the surface of the object photographed, however, or any inclination between the plane of the ground and the plane of the plate or film, vitiates at once the results and necessitates the making of compensating corrections. As a matter of fact, the surface of the earth shows everywhere more or less relief, and also in actual practice it has not yet been possible to hold an airplane camera in a truly vertical position. Hence both causes of error are present, and both must be recognized and corrected. To emphasize these facts and to point out a line of progress for the correction of these causes of error is the writer's purpose.

Before passing to the more fundamental problems, a few words concerning cameras may not be amiss. A large variety of aërial cameras has been designed and manufactured, both in this country and abroad, and it is safe to say that none is truly universal in scope. Nor should the cameras be. They have been made to fulfill a variety of purposes, including scout photography along the battle line, more accurate and adequate photography from larger battleplanes, surveying cameras for peace times, cameras for pictorial aërial photography, and others. There have been automatic and nonautomatic types, equipped with various lenses and various types of shutters, and made to take plates or films or both. Also multi-lens cameras have been built, of which the first was probably the eight-lens camera built by Scheimpflug, the Austrian Army officer, and developed by himself and others. A modification

of this type is the three-lens camera, designed by J. W. Bagley of the Geological Survey, now Major Bagley of the Army Engineers.

Mere Mosaics Are Not True Maps

Coming to the subject of aërial mapmaking itself, one is confronted with much confusion of ideas. It has been the practice of some workers to take a series of pictures from the air, fit them together into a photographic mosaic, ignoring the two sources of error previously mentioned, and to call the resulting product a map, or a mosaic map. In truth, it is neither, but only a series of pictures showing distortion, differences of scale within the individual picture as well as between them, and lack of geodetic control, which are fitted and fudged together to present a pleasing appearance. This certainly is far from being a map. Others have gone somewhat further, and by means of a plain enlarging camera have corrected as far as possible the differences in scale, and also by means of a swing-back attachment on the enlarging camera have attempted, though unsuccessfully, to eliminate distortion. Such pictures, when taken over an area which has been covered previously by an accurate ground survey, may be laid out over a network of close control, and fitted together to look moderately well. But this also falls far short of aërial mapmaking, for the results are inaccurate at best, as may be proved by superimposing a transparent tissue showing the true map; nor would such mosaics be convincing even if the two images are made to coincide, for the same results could not be accomplished over an unsurveyed and uncontrolled area. It is quite safe to state that a true aërial map has not yet been made or published in the United States, using the term "map" with the connotation of accuracy usually understood by experienced cartographers. This statement is made advisedly and with full understanding of what has been accomplished up to the present time.

It does not follow, however, that such mosaics are useless, for, on the contrary, there are many ways : which they can be profitably used. Thus, in revising and bringing up to date old maps, or for securing timber culture or other visible data in previously surveyed areas, there is a distinct and useful field for them. Likewise, in the production of route charts for flying, where the need is for a small-scale guide rather than an accurate map, they can be used to advantage. Also, they may be used as an accessory to traversing, in an area where ground control is close enough that the ever-present errors may be recognized and distributed. These are all peace-times uses and take no cognizance of such additional uses that mosaics may have on the battlefield. The point that is made and emphasized, however, is that a mosaic composed of distorted photographs is not a map, and should not be represented as such.

Let us now turn to the map such as would be desired by any surveying corps, or by any commercial or real estate firm, or by any other organization that would ordinarily secure the desired results by instrumental ground surveys. Maps are of different kinds and are made in various scales and with different degrees of accuracy. Thus, there are recognized exploratory, reconnaissance, detail and ultradetail maps, ranging from scales of 1: 1,000,000 or smaller up to an extremely large scale, and on, still farther, to natural-scale maps, or even maps that are magnifications of the objects shown. Also, there are plan maps and relief maps, the former showing natural and cultural features and the latter indicating, by means of hachures, contour lines or other means, the regional relief. Likewise, there are timber maps, geologic maps, soil maps, and other special kinds. The most generally useful map is the modern topographic map, as now produced by the Geological Survey, which shows all natural and cultural features, including also timber areas, and indicates also by means of contour lines the relief of the terrain. The production of such maps, at scales of from 1: 250,000 up to 1: 62,500 is the present aim of most workers from the air.

Modern Topographic Maps—Stabilizing Camera

The modern topographic map presupposes an accurate plan map upon which the contour lines may be drawn. It is possible to derive both the plan and the contour lines from aërial pictures, provided the necessary data are given, but it is impossible to make either of them from uncontrolled pictures fitted together in mosaic form. Let us consider first the plan map, since that is all that has been attempted in the United States to date.

As before stated, no method has as yet been found to hold in a vertical position a camera in a moving airplane. Various methods have been tried, and none has been found to give the desired degree of accuracy, though of course some schemes reduce very materially the deviation from the vertical. One method has been to mount the camera in gimbal rings, and by the use of dash-pots to give the camera the movement of a damped pendulum. The centrifugal force caused by movements of the plane, however, is sufficiently great to cause a pronounced deviation from the vertical; and, in general, it may be stated that any device dependent wholly on the action of gravity is vulnerable in this respect. The writer, in association with Lieutenant Hyde, of the United States Air Service, and F. H. Moffit, of the Geological Survey, has recently tried out such an arrangement controlled by a gyroscope; in effect, a camera mounted as a gyro-pendulum. The result of this work has been decidedly encouraging, and shows that the gyroscope is a most useful accessory. The deviation, however, is still much too great to permit the production of uniformly good register between adjoining negatives. The results of measurements on such prints, so far as the work has been carried at the present time, shows deviations from the vertical ranging up to 2°. It should be mentioned, however, that these results were secured in flying with a J N-4-type Curtiss airplane, and it is likely that the same apparatus if tried out with a more stable type of machine would show smaller deviations.

In this connection it is also worth while to note that it is the maximum and not the mean deviation which concerns the mapmaker, for if one or two pictures are distorted beyond any assigned limit, the control is vitiated. The old proverb that a chain cannot be made stronger than its weakest link is well illustrated in the case of aërial pictures which are intended for map construction. Therefore, if stabilization of the camera itself is the goal in view, it remains to construct a more refined instrument that the one above noted, for a maximum deviation of 2° is much too great. A maximum deviation of $\frac{1}{4}$° from the vertical position is probably closer to the desired result. Yet it must not be overlooked that a gyro-pendulous camera, even at the pres-

ent stage of development, can be used to good advantage as an instrument for traversing, where control points are not too far apart. The errors resulting from tilt may then be distributed and the resulting traverse will be far more detailed and probably more accurate than the usual result gained by ground traversing. Also, mosaics built from such pictures will of course have a greater value than those made from negatives taken without the gyroscope attachment.

An Alternative—Stabilized Reference Point

Another alternative, however, exists than that of complete stabilization of the airplane camera. If each picture can be referred to a stabilized point, so that the tilt of the negative and the direction of the tilt may be ascertained, such data will be sufficient, with the aid of the necessary instruments and procedure, to rectify the negative to the plane of the horizon. This method of attack involves the construction of some piece of apparatus which will maintain a stabilized reference-point during the flight of the airplane; and accessory lenses, mirrors or prisms, together with a synchronizing device which will record the position of this point relative to the film or plate at the moment when each exposure is made. The gyroscope naturally occurs as the means of attaining such a stationary reference-point, and it is believed that this method is perhaps as promising as any. A gyroscope used in this manner will differ from one used in a stabilized camera in that it will have less work to do and can therefore be made lighter and more compact, and the accessory apparatus can also be constructed at a relatively low cost. Taking into account the present state of development of gyroscopic apparatus, and the limitations of the gyroscope itself, it would appear that this method gives promise of a degree of accuracy surpassing that of a stabilized camera.

The sun, being a fixed point in the heavens at any given time on any given day, also suggests itself as a solution of the difficulty. Any apparatus utilizing the sun's shadow, however, has three serious limitations: First, flying could only be done on cloudless days; second, a difficulty will arise in so placing the recording apparatus that it will never be in a shadow cast by any part of the airplane. This involves placing the device at some distance from the camera, whose natural place is in the bottom of the fuselage, and such a separation is likely to cause errors, due partly to lack of close adjustment originally between two separated pieces of apparatus and partly to differential movements due to lack of rigidity of the plane in motion. The third objection is the most serious. A little experimentation by anyone interested in the matter will show that although the sun's shadow will record the degree of tilt of the camera, it will not indicate the direction of such tilt, and it is just as necessary to know the latter as the former. A compass would have to be used to obviate this difficulty, and air compasses are notoriously inaccurate, when by accuracy one refers to the registry of fractions of a degree. Application of the gyroscope, therefore, to this problem appears to hold forth the greater promise of success.

Let us suppose that the amount and direction of tilt are known for each picture. How are these inclined negatives to be transformed to the plane of the horizon; or, in other words, how can orthographic projections be made from them? Reference has already been made to the successful attempts by some workers to attain this result by means of an enlarging camera, equipped with a swing-back. A simple geometrical demonstration is sufficient to prove that rectification to the plane of the horizon by such a method is not possible. The only practicable way in which this result can be achieved by photographic precedure is in a specially designed transforming camera; and the condition that must be met, in order that such transformation should be geometrically possible, is that the plane of the negative, the plane of the transforming lens and the plane of the transformed image meet in a common line in space. A further adjustment is necessary in order that the lens may be properly placed with reference to the line of intersection of the negative and image planes. Transforming cameras built with the necessary movements and adjustments, and constructed as instruments of precision, have been designed by F. H. Moffit, of the Geological Survey, and have been built and successfully used by the Geological Survey and the United States Engineer Corps. This problem of the transformation of inclined negatives to orthographic projections, or of the transformation of negatives from any one plane to any other, may be therefore considered as solved. A paper by F. H. Moffit, presented before the Association of American Geographers, describes the theory, construction, and use of the transforming camera. [This paper is reproduced immediately following this article.—Editor.]

Using Three-point Method

An interesting development which has been recognized in the use of the transforming camera is the possibility of horizontalizing, by a method of trial and error, a negative whose tilt and direction of tilt are unknown, provided the true positions of any three points on the negative are already known. This presupposes, of course, that an accurate and detailed horizontal control has already been established, and that three points in favorable positions can be recognized on each negative. Under such conditions an accurate map can be made, but, as before stated, this is only of academic interest, for the same result could not be duplicated over an unsurveyed area.

Merely to show the geometrical possibility of this procedure, however, F. H. Moffit, assisted by the writer and T. P. Pendleton, of the Geological Survey, constructed during the summer of 1918 a map of a portion of the City of Washington, by this method, using negatives made with the Bagley camera. [See the article which follows.] No corrections, however, were made for relief, and the result is therefore not a true map in the strict sense of that term, but it is believed to be a very close approximation to one. The writer sees one important application of this method. If, for any reason, the control is lacking in some one picture in a set of air negatives, three points may be selected which will show in the overlap with the adjoining horizontalized negative, and the uncontrolled negative may thereby be rectified with less difficulty than would be involved in a mathematical determination of the unknown tilt.

A brief reference to the matter of scale is also in order. It is very hard, even with the best type of instrument for recording altitude, for the pilot to hold a plane at any given elevation. Anyone who has done any flying where the air is "bumpy" will realize the difficulty. If one is flying or trying to fly at an elevation of 5000

ft. a rise or fall of 100 ft. means at once a change of 2% in the scale, perhaps in two adjoining pictures. In making mosaics, when the distortion due to tilt has not been eliminated, this is a very vexing condition, for the tilt itself, in addition to causing distortion, produces also differences in scale throughout any one picture; that is, the scale along a line at one side of a picture will be different from that along a line at the opposite side, and of an unknown magnitude. To attempt to correct by enlargement or reduction, under these conditions, is to undertake the impossible. But when the negative is horizontalized differential changes of scale are automatically eliminated. Hence, for horizontalized negatives, change of scale is met by simple enlargement or reduction in a plain enlarging camera. It is worth while, of course, to study the matter of flying as nearly as possible at a given elevation in order to reduce the labor of enlargement or reduction; but, relative to the other problems involved, the question of scale is a rather minor one, when dealing with horizontalized pictures.

Corrections for Relief

And now, how close are we to a topographic or even a plan map, after complete horizontalization is achieved and after all the pictures are reduced to the same scale? In regions of very low relief, such as our coastal plain areas, the result is a very close approximation to an accurate plan map. But if the pictures were taken in a region of moderate or greater relief the result is not a true plan map, because of distortion caused by the relief itself. This fact is too apparent to need any elaboration, but it is by no means an insuperable difficulty. Methods must be perfected, however, for the application of the necessary corrections, before the true map can be realized. To make this correction involves the determination, either mathematically or graphically, of station points of the camera in the air at the moment of successive exposures, and this can be accomplished by a study of the common points of two horizontalized pictures taken from two different stations. The same comparisons and computations are also necessary in working out contour lines in the making of a topographic map from air pictures. Hence it follows that the making of a true plan map in an area of any considerable relief is intimately bound up with the problem of the construction of topographic contours, and the solution of one of these questions brings also the solution of the other.

One promising method for the achievement of the desired result appears to be in the application of stereo-photogrammetry, particularly by the use of the stereo-comparator. This instrument affords an accurate and elegant solution of the problem, although, of course, the same results may also be obtained by other methods.

Finally, with regard to photo-topographic surveying in general, certain facts should be more generally recognized. In the first place, the making of topographic maps is a specialized science, and is a subject which is not mastered except by prolonged practice. Photo-topography is only a phase of the general science of cartography, and the cumulative results of long experience are just as valuable in photo-topographic mapping as in any other method. The laying out of projections, the subject of triangulation and control, with the consequent computations, the theory and practice of adjustments, and other matters familiar to the topographic engineer, are equally applicable and necessary in photographic surveying. In other words, the making of maps by photography or by any other method should be the work of experienced engineers.

Photographic Practice Subordinate

Correlative with this idea is the other that photographic practice is rather of subordinate importance. By this, the writer does not mean that the photo-topographer should neglect the photographic side of his work, for good pictures are most desirable, though the quality of the map is not necessarily dependent on the securing of perfect negatives. The idea to be emphasized, however, is that the finest pictures may be entirely useless unless accompanied by the necessary engineering data; while, on the other hand, poor pictures if properly controlled may make a perfect map. The experienced photo-topographer attempts to get the best pictures possible, but judges his work by the quality of the finished map and not by the pictorial quality of the pictures from which the map is made.

Summarizing, it may be said that photographic surveying from the air is both possible and practicable. No new principles are involved, but methods and apparatus other than those used in photographic surveying on the ground are needed and are gradually being studied out and developed. It has been shown that the production of an accurate plan map in an area of any considerable relief is intimately connected with the production of the much desired contour map, and that the latter will be produced with little more labor than the former. In areas of low relief, of course, the plan map can be produced as soon as perfect horizontalization becomes an accomplished fact.

The crux of the whole problem lies in horizontalization, and the most pressing need of the present moment is either a completely stabilized airplane camera or a successful attachment which will record the direction and amount that the camera deviates from the true vertical. Also, it should be clearly understood that map-making is an engineer's job, and that pretty pictures do not necessarily make the perfect map. Finally, although maps made by air surveys remain a development of the future, yet we may confidently look forward to an early solution of the various problems involved.

New Road Work Records Made in April

During April, 1919, the Secretary of Agriculture approved project statements for 120 Federal-aid projects, involving the improvement of 923.53 miles of road, at a total estimated cost of $16,261,326.51. On these roads Federal aid amounting to $7,528,550.68 was requested. This represents the largest number of project statements approved, the largest total estimated cost, and the greatest amount of Federal aid requested, during any month since the passage of the Federal-aid road act. The Secretary and the several state highway departments executed 55 project agreements, involving the improvement of 521.51 miles of road, at a total estimated cost of $4,626,415.48, and on which $2,039,614.99 Federal aid was requested and set aside in the United States Treasury. In addition, agreements to cover 72 other projects were placed in process of execution during the month.

Methods Used in Aëro-Photographic Mapping

Outgrowth of Experience in Use of Panoramic Camera in Alaska—Application to Problems of Airplane Photography—Theory of Transforming Camera

This article, published with the permission of the Director of the United States Geological Survey, is a reproduction, practically in full, of a paper by F. H. Moffit, in the "Geographical Review." Mr. Moffit describes in detail the Bagley camera, referred to by Mr. Mertie in the preceding article, and the theory underlying the transforming camera.—EDITOR.

THIS is not intended to be the description of a finished piece of work, but rather a report of progress in the development of a method of mapping which is only in a formative stage. It will not do, therefore, to expect that details will be given with the greatest accuracy and that all the problems connected with the work have been solved, although the general principles on which the method is based are fully established. The direction for progress has been pointed out, but many steps remain to be taken.

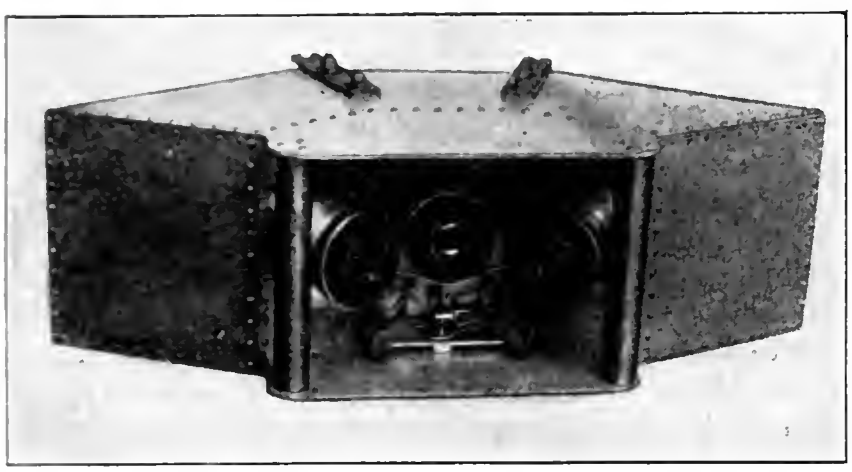

FIG. 1. BOTTOM OF AIRPLANE CAMERA SHOWING THE LENSES AND THE SYNCHRONIZING DEVICE

The work to be described is the outgrowth of experience in using the panoramic camera for topographic mapping in Alaska during the past eight years. The panoramic camera was first used in the Alaskan work of the Geological Survey by C. W. Wright in 1904, but it was not until after he had left the Survey and his work was taken over by J. W. Bagley, now Major Bagley, that the panoramic camera became one of the instruments regularly used for topographic mapping in Alaska. The opportunity to take up and carry on this method was due primarily to Mr. Brooks, now Lieutenant Colonel Brooks, chief of the Alaska division.

With the outbreak of the great war in Europe and the rapid development of the airplane for military purposes, the camera immediately took an important place as a means for gathering military information, including the making of maps. Major Bagley turned his attention to this broader field for the camera and asked the writer, who had had some small part in the previous work, to assist him, but as progress was made it was found that more assistance was needed, particularly in photography, but also in many other ways, and J. B. Mertie was invited to contribute the benefit of his experience.

These investigations, which at first were carried on under the direction of the Council of National Defense and Mr. Brooks of the Alaskan division of the Geological Survey, were later taken over by the Corps of Engineers of the Army and Lieutenant Colonel Marshall of the topographic branch of the Survey, where they have remained to the present time. Money for the first experiments was furnished by the Council of National Defense, but the large sum needed for the construction of airplane cameras and transforming cameras was allotted by the Engineer Corps. I take this opportunity to express to Colonel Marshall, under whose immediate direction I have worked during the past year, my appreciation of his enthusiasm and the generous encouragement he has given Major Bagley and myself.

The fundamental principle on which our investigations is based was first expressed, so far as my knowledge goes, by Capt. Theodore Scheimpflug, an Austrian Army engineer, who gave many years of his life to the study of the problem. He, however, lived before the days of the airplane, and his methods did not meet with the full success they deserved, so that he died without seeing any extensive application of them.

If a camera is carried above a horizontal plane and an exposure is made with the sensitive plate parallel to the plane, the resulting picture is a map whose scale is dependent on the focal length of the lens and the height of the camera above the plane. We apparently have at hand, then, a simpler way for making maps of many regions than the way ordinarily employed, for the airplane makes it possible to pass back and forth over a chosen area at will. Yet two difficulties are met when airplane photographs are employed in making maps. First, it is impracticable if not impossible with any means yet devised to keep the camera in a horizontal position; second, the angle of view of the fast lenses which must be employed in taking photographs from airplanes is small, as that the area covered at each exposure is also small and a great number of pictures must be taken in constructing the map. These, then, are the first problems that must be taken up if an accurate map is to be made at less expense than by the usual surveying methods.

The investigation to be described falls naturally into two divisions, of which the first deals with the airplane camera—that is, with photographing the terrain. To this Major Bagley gave his attention. The second has to do with correcting the inclined airplane pictures, and for the study of the principles involved and the design of the transforming camera the writer is responsible. The questions relating to photographic methods and the construction of charts and computing devices

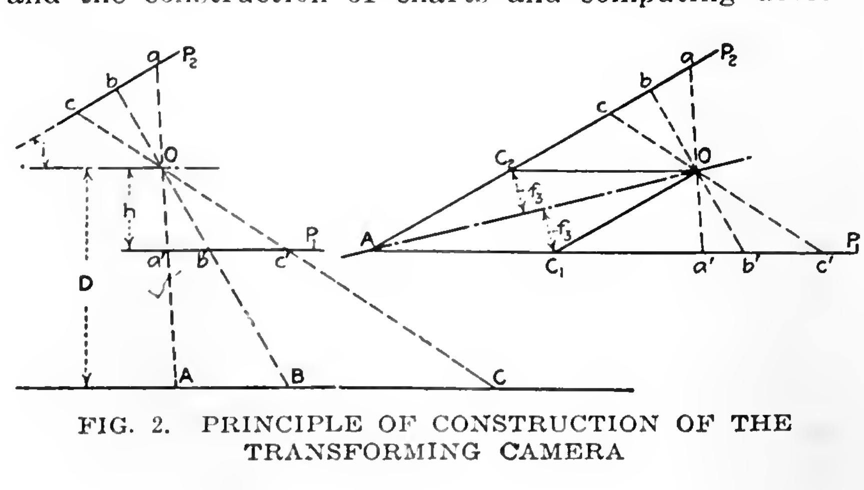

FIG. 2. PRINCIPLE OF CONSTRUCTION OF THE TRANSFORMING CAMERA

for use with the transforming camera fell to Mr. Mertie.

The Airplane Camera—The difficulty of obtaining a lens which shall have speed and at the same time a wide angle of view is met by constructing a multiple camera with its three lenses and focal planes so arranged that the central plane shall be in a horizontal position and the other two shall be inclined at a fixed angle to it.

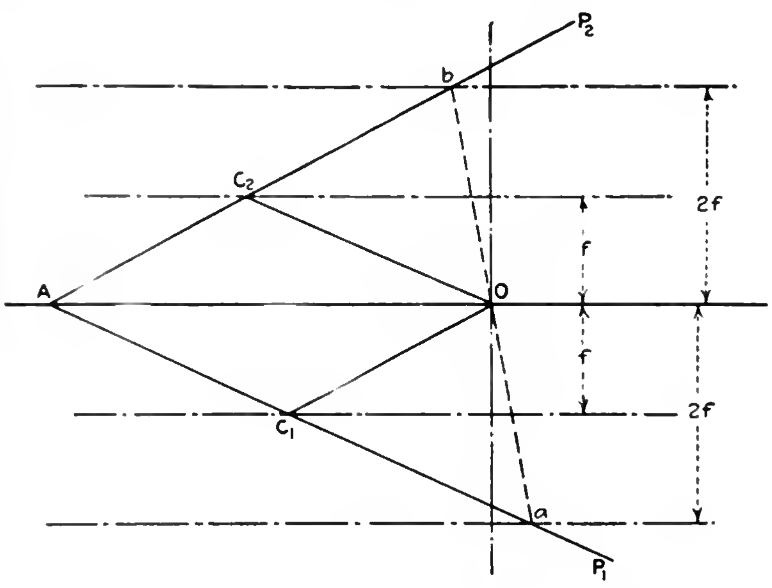

FIG. 3. THE CONDITION FOR FOCUS IN THE TRANSFORMING CAMERA

The side pictures, because of their inclination, include areas outside the field of the central picture, but overlap it slightly so as to give the means of joining them. A photograph of such a camera is shown in Fig. 1.

The camera is about 25 in. high, 22 in. wide, and 7 in. thick from front to back. It consists of two parts, which may be separated from each other. The upper part is the magazine which carries the roll film. The lower part is really three distinct camera boxes, each fitted with its own lens and shutter, joined together.

The two side-focal planes of the camera are inclined to the central plane at an angle of 35°, and as a consequence the angle between the axes of the two side lenses and the central lens is the same. Lenses of about 7-in. focal length are used on the two side boxes and one of about 6 in. on the central box. The automatic shutters, Fig. 1, are released by a special cable release which acts on the triggers of the shutters through a synchronizing device shown in the photograph. This release is so adjusted that the shutters open and close at exactly the same instant. It is necessary that the time of exposure shall be as short as possible, in order that a sharp image may be obtained. This necessity is the result of several causes, chief of which are the vibration of the engine and the angular movement or roll of the plane.

When a film is to be inserted in the camera the magazine is lifted off the boxes, the unexposed spool is placed in position in its supports near the center of the magazine, and the free end is attached to the winding spool in the top of the magazine. After being replaced the magazine is made fast to the lower part of thumb-screws which bring the two sides close together and prevent the entrance of light. The film is 5 in. wide and has a maximum length of about 400 ft. The individual negatives are 5 in. wide and 6 in. long. It was found that pictures taken on the Eastman Company's ordinary "noncurling" film are not marred by static, which so frequently injures airplane photographs, although pictures taken in this camera on other kinds of film, made specially for airplane work, have shown this defect.

Mounting the Camera—To mount the camera in the airplane a hole is cut in the bottom of the fuselage in front of the observer's seat, and a cradle, closed below by a sliding door for the protection of the lenses, is fastened securely to the floor. This cradle is padded with felt or sponge rubber, and the camera is strapped securely in it. Some airplane cameras are mounted on gimbal rings whose movement is damped by a dash-pot arrangement. Such a mounting has been constructed for this camera, but has not yet been tried out. It is not expected that this mounting will keep the camera in its proper position, for seemingly no device dependent on gravity alone for its effect has been able to do this fully. Probably it can do no more than reduce the errors of deviation.

The frequency with which exposures are made at a given altitude in getting pictures with proper overlap depends on the rate of movement of the plane over the ground, which in turn is dependent first on the airplane itself and second on the movement of the surrounding air, for the speed of the plane referred to the ground may be greatly increased or retarded as the plane flies with or against the wind. The time interval between exposures varies roughly from ¼ min. to 1 min. The observer making the exposures, however, does not rely on a time interval for getting properly spaced pictures, but is chiefly dependent on a large negative lens about 6 in. square which is set in the bottom of the fuselage and enables him, as he views objects below him, to judge both the direction and the rate of movement over the terrain.

This camera still lacks one essential feature necessary to make it fill its purpose fully. It should have incorporated in it a device for recording on the film at the time of exposure the amount and the direction of the tilt of the central plate, for, as has been stated, it is not yet possible to keep the camera in a horizontal position. Correction of this fault appears to be only a matter of adapting to the camera some such principle as that of the gyroscope on which others have been at work and which seems now to be brought to condition for practical application.

Principles of Transforming Camera—Pictures taken with the airplane camera just described are subject to

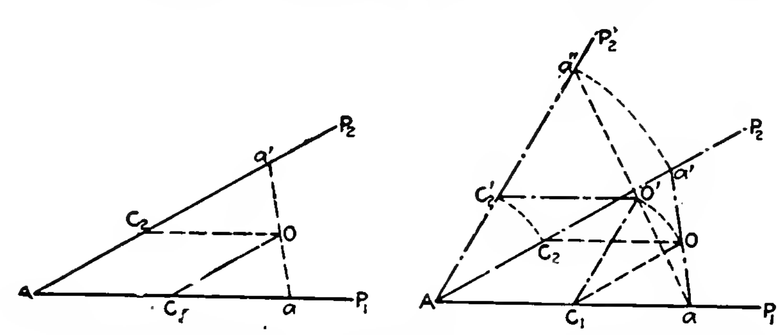

FIG. 4. PRINCIPLE IN APPLICATION OF THE TRANSFORMING CAMERA TO THE RECTIFICATION OF INCLINED PHOTOGRAPHS

errors arising from the construction of the camera itself and from the tilt of the airplane, for only when the plate is taken in a horizontal position is the resulting picture a map. These errors may be corrected graphically by projecting chosen points one by one on a plane representing the plane of the horizon, but the process is long and tedious. It was for the purpose of making these projections photographically that the transforming

camera was designed. Before the working of the transforming camera is described it will be desirable to state two principles on which the construction of the instrument is based. Let A P_1 and A P_2, Fig. 2, be two planes intersecting in the line A, and through any point O pass planes C O and C O parallel to planes A P_1 and A P_2,

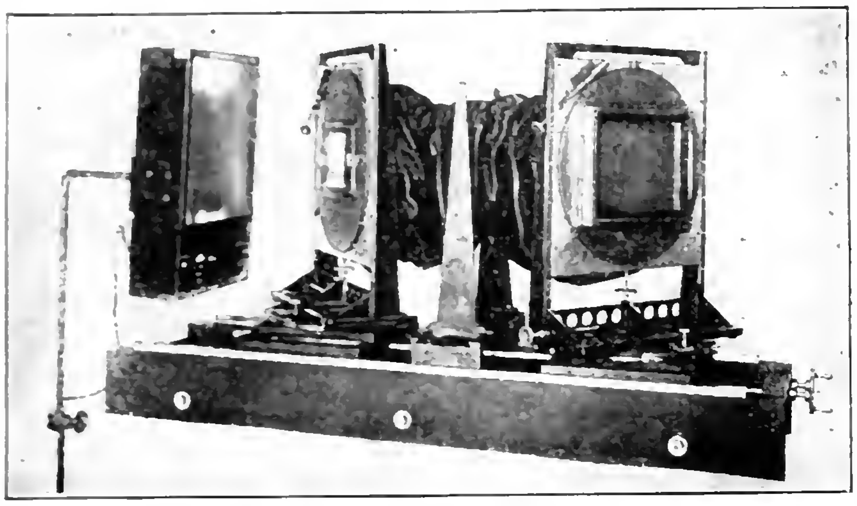

FIG. 5. TRANSFORMING CAMERA, WITH REVOLVING DISKS CARRYING NEGATIVE AND PLATEHOLDER

respectively. Project point a, through point O onto the plane A P_2 in a′.

Now, if we revolve the plane A P_2 about line A, the point a′ is revolved to a″, the point C_2 to C'_2, and O to O′, and it may be demonstrated that the points a, O′, and a″ lie on the same straight line; that is, O′ remains the center of projection for point a and its projection a″ on the revolved plane A P'_2. This principle has an important use in the construction of the transforming camera.

The second principle deals with lenses. Let O, Fig. 3, be a lens of focal length f, whose axis is perpendicular to the plane passing through the optical center of the lens and the intersection of two planes A P_1 and A P_2; and further let O be so situated that it lies on the line which joins a, the intersection of A P_1 with a plane parallel to the focal planes, whose distance from O is twice the focal length, to b, the intersection of A P_2 with a plane whose distance from O is also equal to twice the focal distance. These conditions may be expressed in a slightly different way, thus: Let the plane of the lens, O, pass through the intersection of the planes A P_1 and A P_2 and let O lie in the intersection of two planes, C_1 O and C_2 O, which are parallel respectively to A P_2 and A P_1 and pass through the intersections of planes A P_1 and A P_2 with the focal planes of the camera. If these two conditions are satisfied it may be proved that all points on either plane A P_1 or A P_2 are sharply in focus on the other plane. This fact is the second principle which we need to use. Let us now see how these principles are applied to the correction of pictures taken in an inclined position.

Let P_2, Fig. 4, be a negative on which are photographed the points A, B and C. Let f_1 be the focal length of the lens, i the angle of inclination of the plate, and D the height of the camera above the ground. Points a, b and c are images of the points A, B and C. Now, the size of the image a, b, c (with any given inclination, i,) depends on the focal length of the lens and the height of the camera above the ground. This inclined photograph does not show a, b and c in their true relative positions but it can be made to do so by projecting the image onto some plane parallel to A B, such as P_1 and the scale of the resulting image depends on h, the distance of the plane P_1 from O.

In order to show how this projection may be made photographically, produce the planes P_1 and P_2 till they intersect in A, Fig. 4, and draw C_2 O and C_1 O through O parallel to A P_1 and A P_2. Also replace the lens of the taking camera by another lens whose focal length is f_3, the length of the perpendicular let fall from either C_1 or C_2 to A O. It should be noted that A O is the plane of the new lens. We have now fulfilled the conditions that must be fulfilled if we are to obtain sharp images of the points a, b and c on the plane P_1, but we have limited ourselves to the use of one lens in making any given projection and will require a different lens for every different angle of inclination. If, however, we revolve plane P_2 about the axis A we may vary the distance f_3 and thus, within certain limits, adapt our figure to whatever lens we find is convenient to use in the transforming camera. In the description so far the separation of the principal points of the lens has been disregarded. This was done to simplify the description and is entirely proper, for the same conclusions would have been

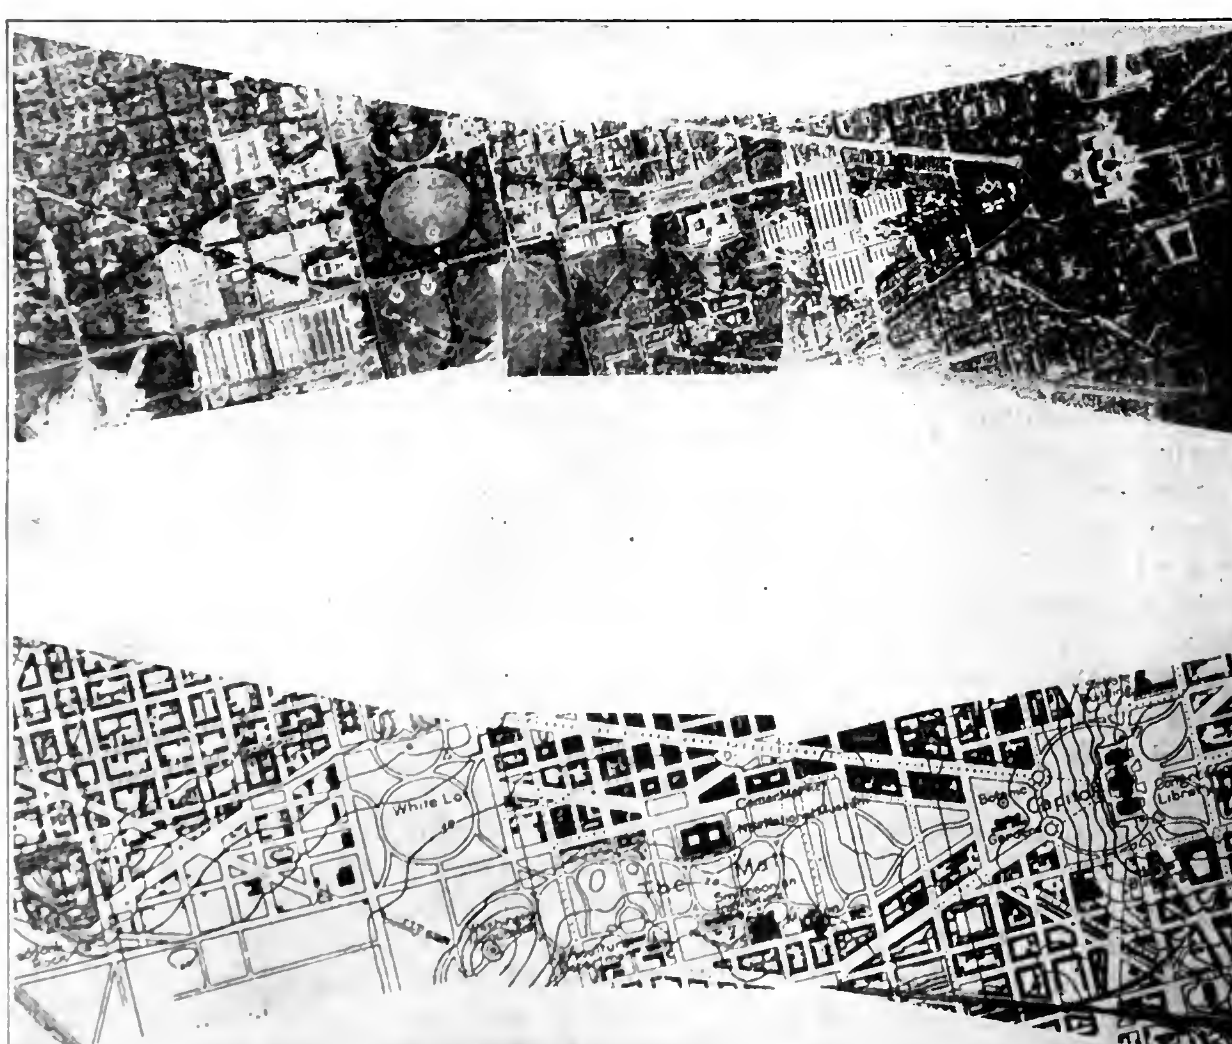

FIG. 6. SET OF THREE PICTURES COMPARED WITH PART OF MAP OF WASHINGTON
The Mall connecting the Capitol, on the right, with the Washington Monument, near the center of the picture, and other prominent landmarks, are easily distinguished.

reached had this been taken into consideration.

The Transforming Camera—The simplest form of transforming a camera capable of transforming photographs taken at different angles of inclination is one in which the two sides are hinged together and have their line of intersections in the plane of the lens. Such a camera is impracticable if the angle of inclination is small or has a wide range of values. The form of camera we have been using is shown in Fig. 5. The two sides, instead of being hinged together, are made to revolve about vertical axes and, together with the lens, are capable of movements that permit all the conditions indicated in the previous diagram to be satisfied. The vertical axes may be moved to and from the lens, and in addition one axis and the lens may be moved transversely. The two axes are so connected with the frame supporting the lens that they and the lens are always in line. The large disks supporting the negative and the sensitive plate may be revolved or they may be moved horizontally in their own planes.

FIG. 7. SERIES OF PHOTOGRAPHS TAKEN WITH THE AIRPLANE CAMERA AFTER BEING REDUCED TO HORIZONTAL PLANE AND JOINED

The transforming camera is an instrument for doing accurate work. It is necessary that the films or plates be put exactly in their proper positions and that the settings of the scales be correct.

In setting up the transforming camera it is assumed that the focal length of all lenses employed, both in the airplane camera and in the transforming camera, are known, and that the inclination of the pictures to the horizon plane is known or can be found. With these data the setting of the instrument can be made after certain simple trigonometric calculations are completed, or the setting may be taken from charts constructed for the purpose. The charts are graphical representations of the trigonometric formulas, and simplify greatly the work of making transformations. The camera is provided with scales and verniers so that the settings may be made with the required accuracy. It is best, nearly always, to have solutions represented graphically.

The inclined airplane photograph shows distant objects on a smaller scale than the near objects, so that the problem of the transformer is to restore a uniform scale to the picture by enlarging or reducing some part of it. Ordinarily, one part of the photograph is enlarged, another is reduced, and the two parts are separated by a line where no change has taken place.

The procedure followed so far in working up the airplane photographs is, first, to transform the side pictures to the plane of the central picture, Fig. 6, and when necessary all three to the horizontal plane, and then by an independent operation to bring all the pictures to the required scale, which as a rule is much smaller than the approximately 1:10,000 scale on which the original pictures were taken. After being brought to the chosen scale the pictures are cut to fit and joined together, Fig. 7. A certain amount of independent horizontal control is needed in this method of mapping as in all others, particularly if an extensive area is to be mapped, but our experience is not yet wide enough to show just how much of such control will be required. It will, of course, depend in part on the scale of the map.

Chief Difficulties—The chief sources of difficulty that arise in making maps from airplane photographs lie first in the lack of suitable means for obtaining the data for transforming the inclined pictures into a truly horizontal position, and, second, in the errors introduced into the pictures by relief of the terrain. The first of these has already been spoken of in describing the airplane camera, and will be solved by installing in the camera the means for recording on the film at the time of exposure the direction and amount of inclination of the central negative. It may be solved in another way if sufficient horizontal control is available, for three or more points on the photograph may be brought into coincidence with corresponding known points plotted on the ground glass of the transforming camera, or, rather, on a tracing paper which can be compared directly with the image on the ground glass, and this of itself brings the picture into the horizontal position.

The second source of difficulty—that arising from relief of the terrain—becomes of greater and greater importance as the relief increases. If the scale of the map is large the error must be taken into consideration even when the relief is small. Apparently, the errors of relief cannot be corrected directly by photographic means, and for the proper location of individual points it becomes necessary to determine the station point or the point on the ground directly below the camera at the moment of exposure, and to find the position of the desired points by intersections from two photographs. This adds an extra operation to the work which it is desirable to avoid where it is possible. Another line of attack on the errors brought in by relief is through the properties

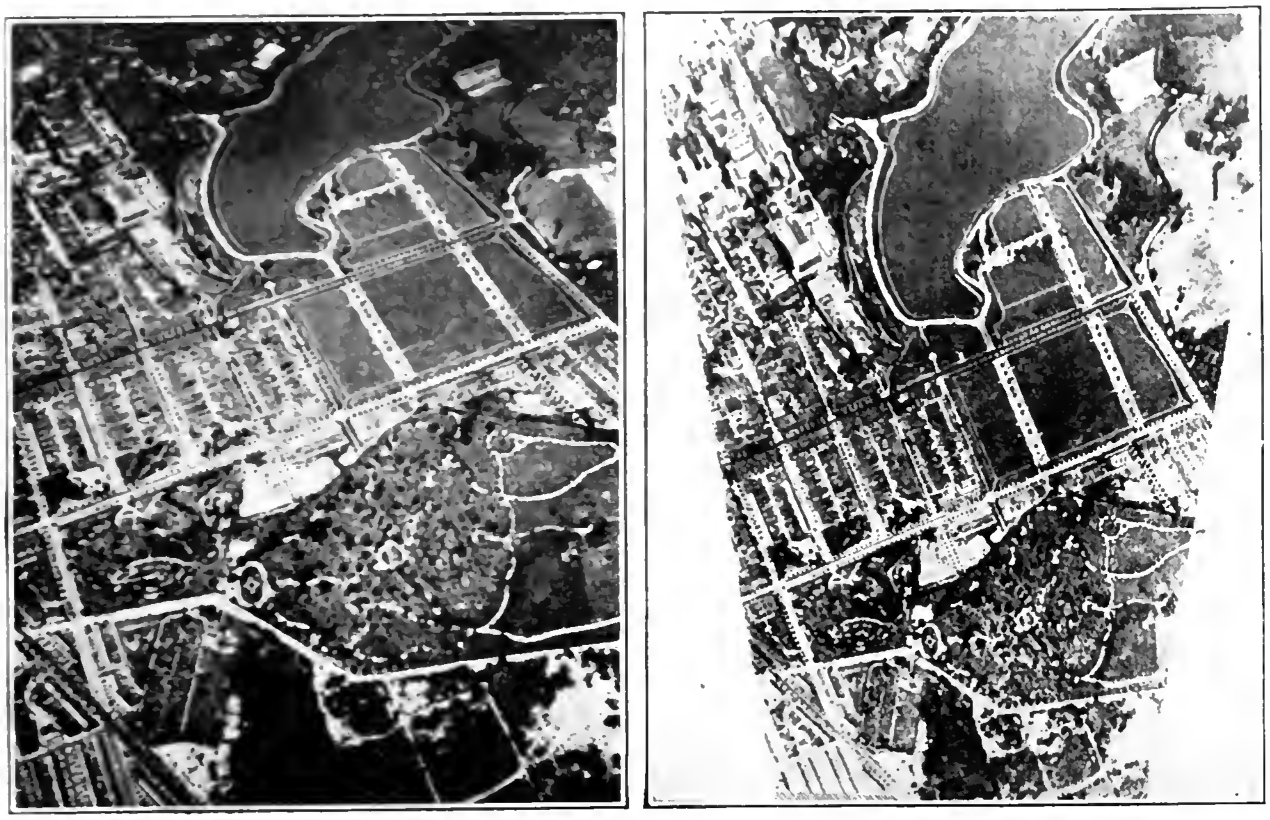

FIG. 8. ON LEFT, ONE OF THE SIDE PICTURES TAKEN WITH AIRPLANE CAMERA; ON RIGHT, SAME PICTURE TRANSFORMED TO THE PLANE OF THE HORIZON

of stereoscopic vision. This involves the use of overlapping pictures and some instrument such as the stereocomparator, constructed for accurately measuring parallax, which may be employed in correcting errors of relief, and if the necessary data are obtained affords an elegant method of drawing the contours to express the relief. This important part of the work is a feature on which we have hardly touched as yet. Fortunately, a certain amount of error due to relief comes within the limits of error for the scale of the maps usually made in this country. "Mosaic" is a term commonly employed to designate most of the maps made from airplane photographs. It will be of interest to make a comparison between such maps and maps made by the method just described.

The design of airplane cameras and the focal lengths of the lenses used vary widely, but the capacity of the lens is practically the same in all. The lens is a "fast" lens of moderate angle whose field of view is further reduced in many instances owing to the size of plate used.

The advantages of the method under consideration may be divided into two classes, those arising from the use of the multiple camera and those due to the use of the transforming camera. It will be well to state again that there would be little advantage in the use of a multiple camera if it were possible to get well corrected fast lenses of wide angle and good illumination. The chief advantage of the multiple camera over the single-lens camera is the increased field of view which makes it possible to cover a given area with fewer flights and therefore in shorter time and at less expense. The area covered by the three pictures of the three-lens camera at a given elevation is about four times the area covered by the central picture alone, and this is roughly the ratio that holds between the three-lens camera and most of the single-lens cameras. Furthermore, the three-lens camera reduces the probability of leaving parts of the terrain unphotographed and make easier the final assembly of the pictures. A uniform overlap in the series of pictures made during successive parallel flights is difficult to maintain, so that frequently it is found either that the overlap is too great or that a part of the terrain is unphotographed. A wide field of view in the airplane camera helps to minimize this difficulty. The advantage due to the use of the transforming camera is chiefly that it makes possible the use of pictures that without it would be unusable or greatly in error because the subject photographed was not parallel to the plate and therefore the pictures do not have a uniform scale, but no advantages arising from it are such that they may not be enjoyed in either method. It would be much more nearly correct to say that until the means is devised for keeping the camera plate in a horizontal position the transforming camera is essential to either method if accurate work is to be done. So far as my knowledge goes, no airplane camera has yet been constructed whose pictures are not subject in some degree to errors arising from the tilt of the plane. In practically all, the error may be, and often is, much greater than any allowable error.

Advantages of Airplane Photographs—The advantages that will arise from the use of photographs taken from the airplane or dirigible airship for the making of maps can hardly be overestimated. These advantages are of many kinds and include among others greatly increased speed, greater accuracy in details, reduction in cost, and, for special purposes such as the use of aircraft pilots, the possibility of representing on the map the actual appearance of the terrain as it is seen from above. Furthermore, it will make possible the mapping of areas which, because they lack roads and other means of transportation, or for other reasons, are now practically inaccessible. When a strip of country from three to five or more miles wide can be photographed at the rate of 75 or 100 miles per hour, depending upon the speed of the airplane, it is not difficult to see that the length of time per square mile devoted to actual field work in the older, established methods now in use must be even hundreds of times greater than in the new.

The errors that arise from the relief of the terrain have been referred to and are fully appreciated, and for that reason it is believed that the first application of the method should be in areas of low relief. Many thousands of square miles of such land are still unmapped in the United States, including most of the Atlantic and Gulf coastal plains as well as great areas in the West. The coastal plain in particular is well adapted to test the merits of the photographic method of mapping, for it is a region of low relief, largely unmapped, and in many parts extremely difficult of access.

Another field of application in which it is believed that the photographic method will be most useful is in the revision of existing maps, as in the addition of features like new roads built since the map was made, or of timbered areas not mapped originally. Only those who have had experience in the study of airplane photographs can realize fully the wealth of material they contain for the mapmaker.

Chicago Chapter, A. A. E., Adopts Schedule of Salaries

From Chief Engineers to Draftsmen, Rodmen and Inspectors on State, County, Municipal, Corporate and Private Work

A COMPREHENSIVE list of salaries for a wide range of engineering positions in varied lines of work has been adopted by the Chicago Chapter of the American Association of Engineers. This has been referred to the association with the suggestion that it be utilized in a nation-wide study of the subject, for the formulation of a general schedule of salaries. The present schedule covers architectural, highway, municipal, state and electric-railway work (steam-railway work has been covered by the parent association); county and rural positions, large engineering organizations, public-utility boards and corporations, telephone work and expert service.

It is explained that the salaries recommended are for positions which provide continuous employment and offer advancement in rank and pay as a reward for efficient service. For seasonal employment, where the work continues from year to year, but is interrupted by idle seasons, it is suggested that the pay should be such as to amount to about half pay during the period of enforced idleness. Thus, for an eight-month season, where the schedule rate is $2400 per year, the pay should be $250 per month. For temporary positions, where there is no developing future, the pay should be 50% above the schedule, in order to provide greater incentive for good work and repay the employee for changing location.

A few revisions were made at a meeting at which the schedule was discussed, and these are included in the lists given below. The work was done by a committee composed of A. M. Van Auken, chairman; W. H. Dean, G. S. Eaton, W. A. Ireland, Langdon Pearse and J. H. Prior.

Proposed Schedule of Salaries Adopted by the Chicago Chapter

Architectural Engineers—The committee states that to those who are not architects the rates seem to be low, but the schedule is thought to be reasonably fair to employer and employee. There appear to be no uniform rules as to education or training required for the positions.

Architect in charge of office	$5000–$8000
Designing draftsman	4000– 5000
Construction design draftsman	4000– 5000
Outside superintendent	4000– 5000
Senior draftsman	2400– 3000
Junior draftsman	1500– 2100
Student draftsman	900– 1200

Road Engineers—This schedule is for a state having 60,000 to 100,000 miles of roads and in which the highway department spends not less than $5,000,000 annually

Chief highway engineer	$8,000–$10,000
Road engineer	5,000– 7,000
Maintenance engineer	4,500– 6,000
Bridge engineer	4,500– 6,000
Engineer of tests	3,000– 4,000
Division engineer (7,000 to 10,000 miles)	3,600– 5,000
Assistant engineer	2,700– 3,600
Resident engineer	2,700– 3,600
Chief designing engineer	3,000– 4,000
Designing engineer	2,700– 3,300
Junior engineer, class A	2,100– 2,700
Junior engineer, class B	1,500– 1,800
Inspector*	1,320– 1,800

*Technical training desirable but not essential, but must have had experience in highway construction if lacking such training.

Municipal Engineers—The proposed schedules for municipal engineers are as follows:

City engineer: annual work, $5,000,000	$12,000–$15,000
City engineer: annual work, $2,500,000	8,000– 10,000
City engineer: annual work, $1,000,000	6,000– 7,500
City engineer: annual work, $500,000	4,000– 5,000
Department engineer	5,000– 7,500
Division engineer	4,000– 7,500
Assistant engineer	3,000– 3,600
Instrumentman (preferably technical graduate)	2,000– 2,400
Rodman (high-school, 2nd grade)	1,080– 1,500
Inspector	1,380– 1,800
Architect	3,000– 5,000
Designing engineer (technical graduate, 10 years' experience)	4,000– 6,000
Designer (technical graduate, 5 years' experience)	3,300– 4,400
Detailer (technical graduate preferably)	2,000– 3,000
Tracer (technical high school)	1,200– 1,800
Draftsman, architectural	1,800– 3,000
Draftsman, map or topographic	1,800– 2,400
Draftsman, structural	1,800– 2,400

Electric Railway Engineers—For the case of railways with 60 miles of track:

Chief engineer (track, structures and transmission lines)	$3,600– $4,800
Assistant engineer (field)	2,400– 3,000
Roadmaster (preferably technical education)	2,400– 3,000
Mechanical-electrical engineer	4,200– 5,400
Office engineer (mechanical-electrical)	2,400– 3,000

For railways with 200 miles of track:

Chief engineer	$4,000– $5,400
Assistant engineer	2,400– 3,000
Roadmaster	2,400– 3,600
Electrical-mechanical engineer	4,500– 6,000
Assistant engineer (electrical-mechanical)	2,400– 3,000

County Surveyor—As a rule this is not a salaried position, but it is of such importance that a sound policy would provide an office and pay for keeping open a stated number of days per week, depending upon the wealth and population of the county. The pay per day for land surveying should be adjusted to correspond with the value of the land, as follows, since the surveyor is responsible and may be sued for damages due to erroneous work:

	Surveyor	Assistant
Land up to $25 per acre	$12.50	$3.75
Land at $25 to $200 per acre	18.00	5.00
Land over $200 per acre	20.00	5.00

A similar rate should be paid for work of the intermittent class or for drainage, levee or road work, with pay for a specific number of days per month to cover consultation and correspondence.

Deputy county surveyor	$3000–$4200
Employees on drafting and instrument work	2100– 2700

County Engineer—Good roads organization in counties spending at least $500,000 annually on highway work:

County highway engineer	$4200
Assistant engineer	3000
Junior engineer, class A	2400
Junior engineer, class B	1800
Inspector (for qualifications see under "Road Engineers")	1500

A similar organization is desirable for levee and drainage work, but must adapt itself to wider variation than the road work. Such adaptations can be made according to the particular work in hand.

State Public Utility Board—For the engineering department of a board in a state having a population of 5,000,000:

Chief engineer	$12,000–$15,000
Assistant chief engineer	9,000– 10,000
Chief of railroad division	8,000– 9,000
Chief of gas division	6,000– 7,500
Chief of telephone division	6,000– 7,500
Chief of waterworks division	6,000– 7,500
Chief of service division	6,000– 7,500
Assistant engineer, grade 1	3,600– 4,800
Assistant engineer, grade 2	3,000– 3,300
Assistant engineer, grade 3	2,400– 2,700
Assistant engineer, grade 4	1,800– 2,100

State Public Improvement Project—For such a project as the Illinois River improvement:

Chief engineer	$15,000
Assistant chief engineer	9,000
Principal assistant engineer	8,000
Bridge engineer	7,500
Office engineer	6,000
Field engineer	6,000
Office and field assistants	Same as in municipal schedule

Large Structural Engineering Organization—Proposed schedules in this field are as follows:

Chief engineer	$12,000
Assistant chief engineer	9,000
Construction engineer	$3,600– 6,000
Inspecting engineer (10 years' experience)	3,000– 4,200
Inspecting engineer, junior grade	1,800– 2,700
Office engineer	4,800– 6,000
Engineer of design	4,200– 5,000
Assistant engineer of design	2,400– 3,000
Engineer of estimates	3,300– 4,000
Squad engineer	3,300– 4,000
Assistant engineer, class 1	3,000– 3,600
Assistant engineer, class 2	2,400– 2,700
Junior engineer (technical education, with or without experience)	1,500– 2,100
Student engineer	1,000– 1,400

Expert Service—An engineer having a standing equal to the chief engineer of a railway or city engineer of a city spending $2,000,000 annually, $100 per day. An engineer who can qualify in court to give expert testimony, $25 per day. Intermediate figures for engineers of intermediate rank. All incidental expenses should be in addition to the rate named and should be paid for. Court testimony simply identifying a map or plan is not considered expert testimony.

Mortar Test Does Not Insure Good Concrete Aggregate

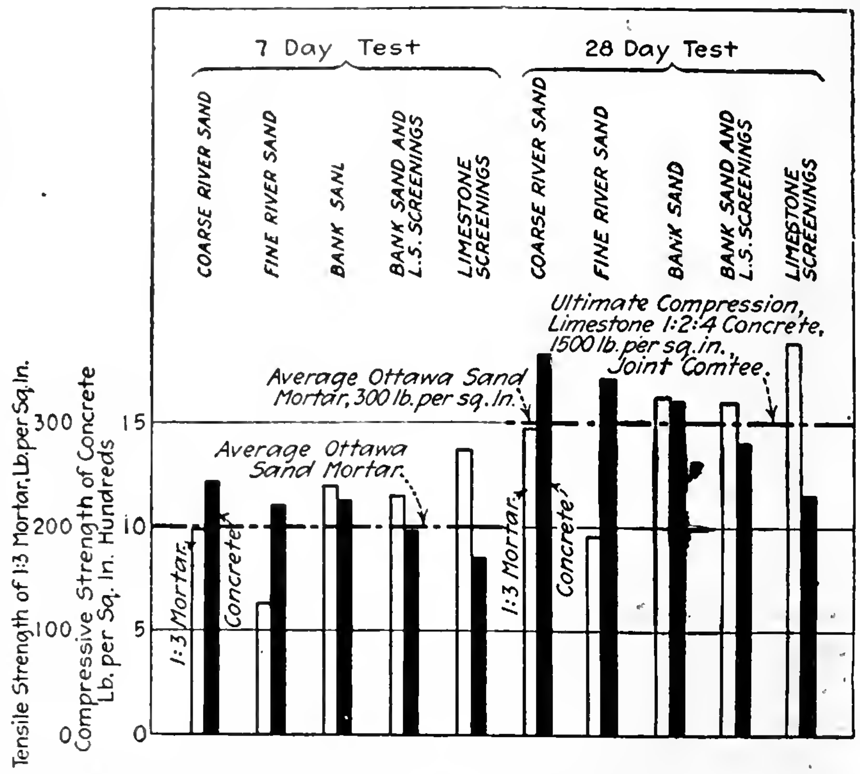
Experiments Show That Commonly Assumed Relation To Standard Ottawa Sand Test Has No Effect on Compressive Strength

By Clement C. Williams
Professor of Civil Engineering, University of Kansas
Lawrence, Kan.

CONCRETE specifications frequently contain the clause "the tensile strength of a mortar made of one part cement to three parts of the aggregate shall be at least 75% of ['equal to,' in the Joint Committee report] the strength of a mortar of one part cement to three parts Ottawa standard sand." Some tests recently made by the writer show that this precaution does not insure an aggregate giving a concrete strong in compression.

The tests included five different materials: A coarse river sand, a fine river sand, a coarse bank sand containing some clay, a mixture of the bank sand and limestone screenings, and limestone screenings crusher run. The screenings contained from 5 to 15% of dust passing an 80-mesh screen. The results of the tests are tabulated herewith and also shown graphically. Each result represents an average of approximately 20 individual tests. The coarse aggregate was somewhat variable, but was chiefly crushed limestone fairly well graded. The concrete was nominally a 1:2:4 mixture.

From these data it is obvious that the fine aggregate which gives a mortar of high tensile strength does not necessarily yield a concrete having a high compressive strength. Moreover, since Ottawa standard sand 1:3 mortar has an average tensile strength at seven days of about 200 lb. per square inch and at 28 days of 300 lb. per square inch, it is also apparent that a fine aggregate which yields a mortar having 75% of this strength or even equal to it may not produce a strong concrete.



COMPARISON OF MORTAR AND CONCRETE TESTS WITH OTTAWA SAND MORTAR TESTS

Not only in these special tests with limestone screenings did this fact become manifest, but similar results were observed with screenings from a local sandstone quarry. In this case the screenings gave a 1:3 mortar that exceeded the standard sand mortar in strength, but they proved to be entirely unfit for making concrete.

A 1:3 mortar is a comparatively lean mortar, especially with Ottawa standard sand, which is nearly uniform in size and contains a large amount of voids (about 40%). It is a matter of common observation in the laboratory that a well graded sand, even if inferior in other respects, will produce a stronger 1:3 mortar than Ottawa standard sand. In the case of a fine aggregate containing a considerable amount of silt, such as crusher-run screenings, the fine particles help fill the voids and bring about a better distribution of the available cement in the lean mortar and hence produce a denser and stronger mortar.

COMPARISON OF MORTAR AND CONCRETE TESTS

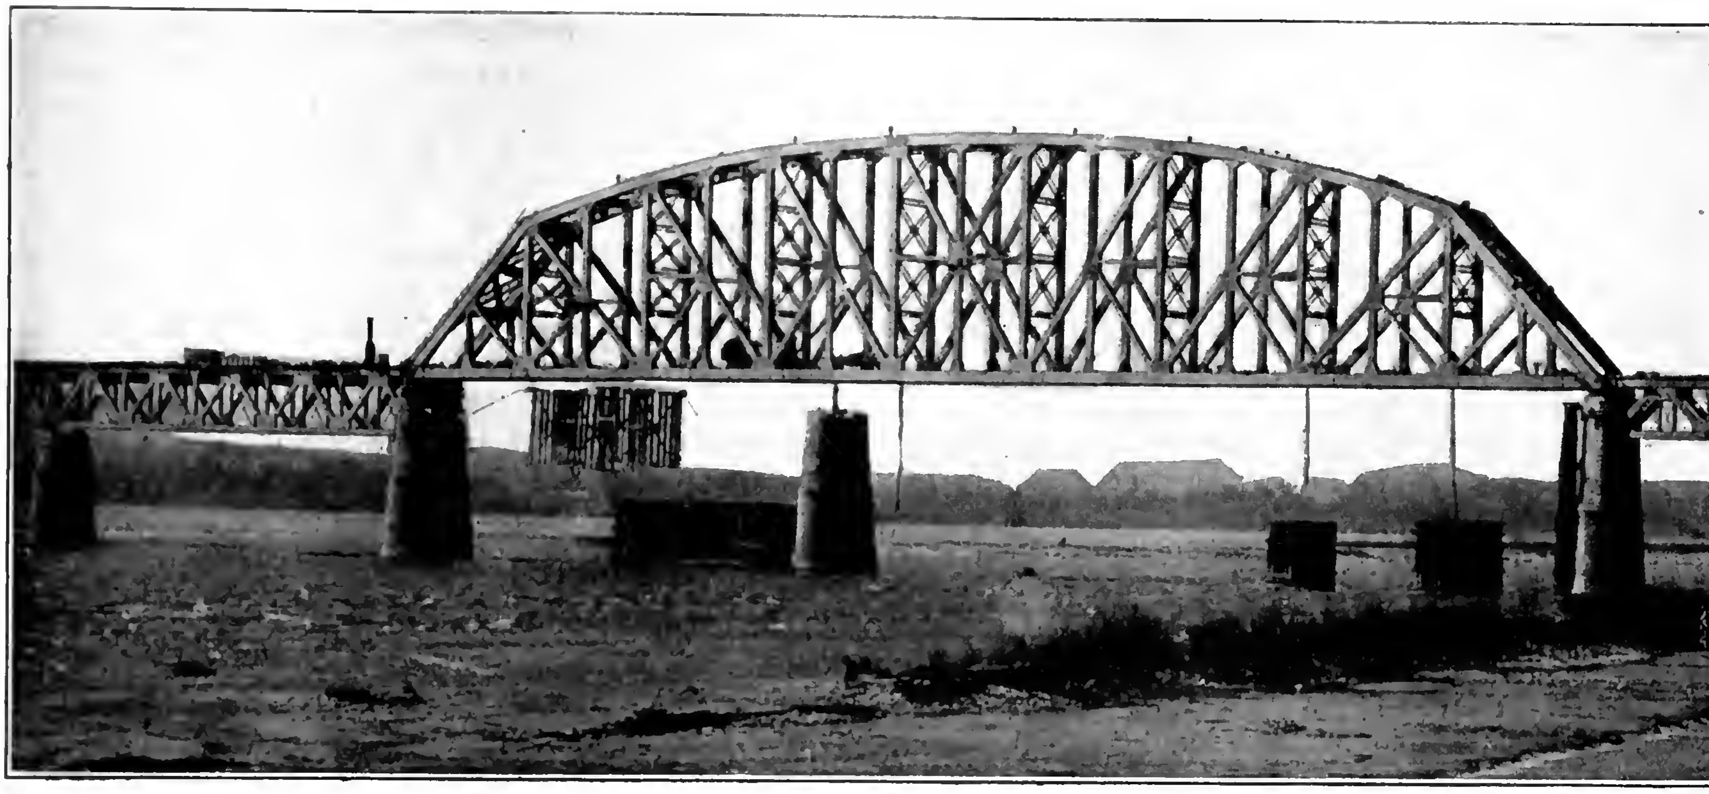
Aggregate	Average Tensile Strength of Mortar Lb. per Sq.In. 7 Days	28 Days	Average Compressive Strength of Concrete Lb. per Sq.In. 7 Days	28 Days
Coarse river sand	201	294	1210	1810
Fine river sand	123	180	1120	1690
Bank sand	239	323	1130	1590
Bank sand and screenings	229	318	1010	1380
Limestone screenings	273	364	847	1160

Incidentally, attention may be called to the fact that while stone screenings prepared in the laboratory free from an excess of dust may produce a strong mortar and give good results as a fine aggregate for concrete, commercial screenings on the market, being crusher run and containing a large proportion of clay and stone dust from the quarry, generally do not yield a strong concrete.

If the mortar test is to be used at all as a criterion for judging fine aggregates, lean mortars should be used to try materials for lean concrete and richer mortars for richer concrete mixtures. The only reliable criterion is a test of the concrete itself made up with the coarse aggregate to be used on the work. However, the old specification that the fine aggregate shall be clean and coarse and shall consist of hard, durable grains well graded in size from finest to coarsest particles, if strictly observed, will give satisfactory results.

Design of New Superstructure of Louisville Bridge With 644-Foot Riveted Span

Historic Bridge One Mile Long Replaced by Double-Track Spans on Same Masonry Piers—Details of Design and of Deck Trusses and Lift Span



RIVETED SPAN 644 FEET LONG REPLACES THE 400-FOOT CHANNEL SPAN OF OLD BRIDGE—OLD INTERMEDIATE PIER BEING REMOVED

REPLACEMENT of the Pennsylvania's historic Fink-truss bridge over the Ohio River at Louisville, Ky., involved the design and erection under exceptional conditions of the longest and heaviest simple-truss riveted span in existence, 643 ft. 10½ in. in length between the 24-in. end pins. The adoption of riveted instead of pin-connected trusses resulted mainly from the fact that when the Government ordered the Louisville Bridge Co., a subsidiary of the Pennsylvania Railroad Co., to provide a 600-ft. clear channel instead of the 400-ft. Indiana channel of the old bridge, the other through span had been designed and fabricated with riveted trusses. To preserve unity in the structure, therefore, the same type was adopted. The 644-ft. truss contains top and bottom chords of special section, 1½-in. gusset plates spliced into the main webs of the chords, and in the web members transverse diaphragms and longitudinal end stiffening diaphragms.

This article describes the principal features of the design of the long span, typical details of the deck trusses and special details of the 260-ft. lift span over the Louisville Canal. The erection of the new trusses around the old structure while traffic was maintained, the remodeling of the masonry piers to carry the new superstructure, and the erection equipment will discussed in a separate article.

The original superstructure of this bridge, built in 1870, was composed of 26 deck truss spans and two through-truss channel spans, the total length center to center of the end masonry supports being 5294 ft. The deck spans were of the Fink-truss type, except the swing span over the Portland Canal at the Kentucky end, which was of the Warren type. This deck swing span was replaced about 17 years ago by a through-truss span. The two original through spans, one 370 ft. and one 400 ft. long, were of the Warren type. The original bridge was described in *Engineering News* of Feb. 8, 1917, p. 217.

When it was decided to replace the old bridge with a new one, it was found that the existing masonry would, with the use of pier girders, be long enough to take the superstructure for a double-track bridge, and it was concluded to make the renewal with a double-track superstructure on the old masonry. To this end, request was made of the War Department for a permit to use such falsework as would be necessary to carry out the erection; at the same time the offer was made to replace the existing swing span by a vertical lift span giving 200 ft. clear opening.

The response from the department was an order not only to provide a lift span for the canal opening, but also to increase the span over the Indiana channel from 400 ft. to a length that would provide a 600-ft. clear opening for the channel.

Required 644-Foot Span.—This order brought about a long battle in the courts regarding the increase in length of the 400-ft. channel span, and a decision was not handed down by the Supreme Court until January, 1917. In the meantime the replacement of the bridge, which was begun in June, 1916, had been proceeding rapidly, and the 370-ft. through-channel span, which was the only other fixed through-truss span in the bridge, was completely designed and fabricated. As the 370-ft. span was designed as a riveted-truss span, in order to preserve unity of design it was decided to build a 644-ft. span of the same type, and the subpanel outline of the long span, as indicated in the diagram herewith, was adopted.

A K-truss outline was also investigated, but for the above reason was not used, although the greater simplic-

ity in detailing of joint connections was recognized as a real advantage.

As the order of the War Department called for a 600-ft. clear opening under the long span, it was necessary, to meet this requirement, to remove the pier between the old 400-ft. span and one of the 245-ft. deck spans just south of it. This brought the south end of the long span (643 ft. 10½ in. between centers of end bearings) over the pier built for supporting the old 245-ft. deck spans, and as this pier was much too small to accommodate the bearings of the long through span, it was extended on both axes by incasing it with a ring of stone masonry securely doweled and clamped to the old pier.

Old Masonry Piers Used

The new double-track deck spans are of the Warren truss type, and the old piers were sufficiently long to accommodate the new spans after being cut down to the required lower level for deck trusses, and capped by steel grillages incased and filled with concrete. All the new spans are therefore of practically the same length as the old spans, except the Indiana channel span and the lift span over the canal.

A striking illustration of the difference in weight of the new and the old structures is seen in the fact that the new 370-ft. span weighs 12,272 lb. per foot as compared with 3050 lb. per foot for the old structure. The new 644-ft. span weighs 19,650 lb. per foot. These great weights resulted largely from high assumed live loads and the unit stresses adopted.

Live Loads and Impact—The live loading specified for this span consisted of a uniform load of 5000 lb. per foot of track and a concentrated single load of 60,000 lb., except for the floor system and web members of trusses, which are designed to support a uniform load of 5500 lb. and a concentration of 66,000 pounds.

In addition to this live load, a shock stress was introduced in the computation of all web members. This stress for verticals was equal to 50% of the concentrated live load, which was increased for diagonals by multiplying by the secant of the angle of inclination.

The wind load was assumed at 900 lb. per foot, moving on the top chord, and 1200 lb. per foot moving on the bottom chord.

Special Steel Adopted—A special high-carbon steel was required for all the main members of this truss. The ultimate strength was specified as 66,000 to 76,000 lb. per square inch, and the yield point, determined by drop of beam, at 38,000 lb. per square inch minimum. For this steel the elongation in 8 in. was required to be 1,400,000 divided by the tensile strength as a minimum, with a reduction of area of 35% minimum allowable, except that for thicknesses 1 in. or over the percentage of elongation might be reduced by 1 for each increase in thickness of ¼ in. or fraction, but not to be less than 16%. Similarly, for steel thicker than 1 in. the percentage of reduction might be reduced by 1 for each ¼ in. or fraction over 1 in., but not below 30%. Rigid requirements for cold bending tests were specified.

In case the ultimate strength fell outside the specified limits by less than 1000 lb., or in case the elastic limit fell below the specified minimum by less than the same amount, all other requirements being fulfilled, then two more tests might be taken, and if both retests filled all the requirements, the material would be accepted. It was required that when a melt of steel was rolled into several shapes, each shape must be separately tested. It was further specified that in case a melt was rolled into plates 1 in. thick or over and the two tensile tests showed any wide variation in physical results, a test should be made on each plate and each plate accepted or rejected according as it met the requirements of the specifications.

Unit Stresses and Make-up of Sections—The unit stresses allowed in tension members were $9000\ (1 + \phi)$, in which ϕ is the ratio of minimum to maximum stress in the member. For compression members, the unit stress $(9000 - 33R)(1 + \phi)$ was allowed, R denoting the ratio of the length to the least radius of gyration. These stresses for the main chords averaged 14,890 for the tension members and about 13,760 for the compression upper chords. For members having reversed stress, the allowable unit was $9000(1 - \phi/2)$. For hangers the unit stress was made $8000(1 + \phi)$.

The main top chord sections are of an exceptionally heavy type using eight angles 8 x 8 in. and 8 x 6 in., with 60-in. webs and 60-in. cover plate. Increase in section for center chords is obtained by adding plates to the outside of the vertical webs.

Special Section for Lower Chord

The lower chord is of special section, as shown by the drawings, in which the constant area consists of eight angles, four horizontal plates, laced, and six 60-in. vertical web plates. The additional areas required for higher stress in the center chords are obtained by adding plates both inside and outside of the vertical webs.

The thickness of main material in top and bottom chords does not exceed ¾ in., the web plates being spliced to the big ¾- or 1½-in. connection plates, which were inserted in the chords with $\frac{1}{32}$- or $\frac{1}{16}$-in. clearance.

In the detailing of all the main members, the plates and lacing bars or angles are placed inside the corner angles. This gives a much more finished effect, with square outlines to improve the general appearance.

Floor and Lateral Systems—The old floor system had to be removed and replaced, under traffic, by the new one, and in the designing of the new floor it was decided to use double floor-beams at each panel point so that each panel of the floor would be independent, and could be erected as a unit. This simplified the erection of the floor system considerably. The use of these double floor-beams also prevents the racking of the floor system, due to deflection of trusses under loads, which takes place in long spans where a continuous floor system is used.

Another special feature is seen in the arrangement of the top lateral system, the diagonals being connected to the top chords at mid-panel, with points of intersection opposite the panel points to which connection is made of struts. Curved gussets were used throughout the sway bracing, the radius being 4 ft. Intermediate sway bracing was introduced only at the main vertical posts, two panels apart.

Design of Chords, Web Members and Chord Splices—In the design of the cords, maximum stress was computed for an assumption of full loading on both tracks simultaneously. In designing the web system, the maximum and minimum stresses were found by the following assumptions: (1) For maximum stresses—trains on each track headed same way, directly opposite each other and passing simultaneously across the bridge; (2) for minimum stresses—trains on each track, headed same way but opposite to the direction causing maximum,

GENERAL ELEVATION, TYPICAL JOINT DETAILS AND CHORD SPLICES OF 644-FOOT RIVETED TRUSS OF THE PENNSYLVANIA RAILROAD'S BRIDGE OVER THE OHIO RIVER AT LOUISVILLE, KY.

the trains directly opposite and passing simultaneously across the bridge.

While the above method was used in obtaining the maximum and minimum stresses for the web members subject to reversal of live-load stresses, the value of ϕ used in connection with the above stresses was based on *immediately successive* values of a maximum and a minimum. It is obvious that the minimum stress described above cannot immediately succeed a maximum stress, or vice versa, until both trains causing the maximum have passed off the bridge and two more trains come on the bridge advancing in the opposite direction, which cannot be considered as producing immediately successive stresses.

It was, therefore, assumed that in order that a maximum and a minimum stress could be immediately successive, the maximum stress was produced by one train on the near track, and the minimum stress by one train on the far track, but facing in the opposite direction. Since the tracks are 13 ft. apart center to center and the trusses are 34 ft. center to center, 69% of the maximum live-load stress was considered

* Dead load stress computed for 9,823 lb. per foot of truss. All total stresses given in thousand pound units.
† Minimum stress to determine Φ.

in connection with 31 per cent. of the minimum live-load stress.

The location of the splices in the lower chord was fixed by erection requirements, which explains why a field splice occurs at L_7, the point of maximum stress. This splice is exceptionally heavy, and, although symmetrical about the center line, considerable care was required in computation to insure sufficient net section, and at the same time provide enough rivets to develop the value of the plate. The top-chord shop splice at U_9 is also especially heavy, because all compression members were required to be fully spliced, even though the main sections were milled to bear

The maximum grip of the $1\frac{1}{8}$-in. rivets in these heavy splices was $8\frac{1}{16}$ in. It will be noted that countersunk shop rivets are used to hold the plates together for the purpose of preventing separation under the process of reaming. These stitch rivets proved to be very effective in facilitating the work of assembling in the shop and reaming in place, as was required for all main trusses, and also in field riveting.

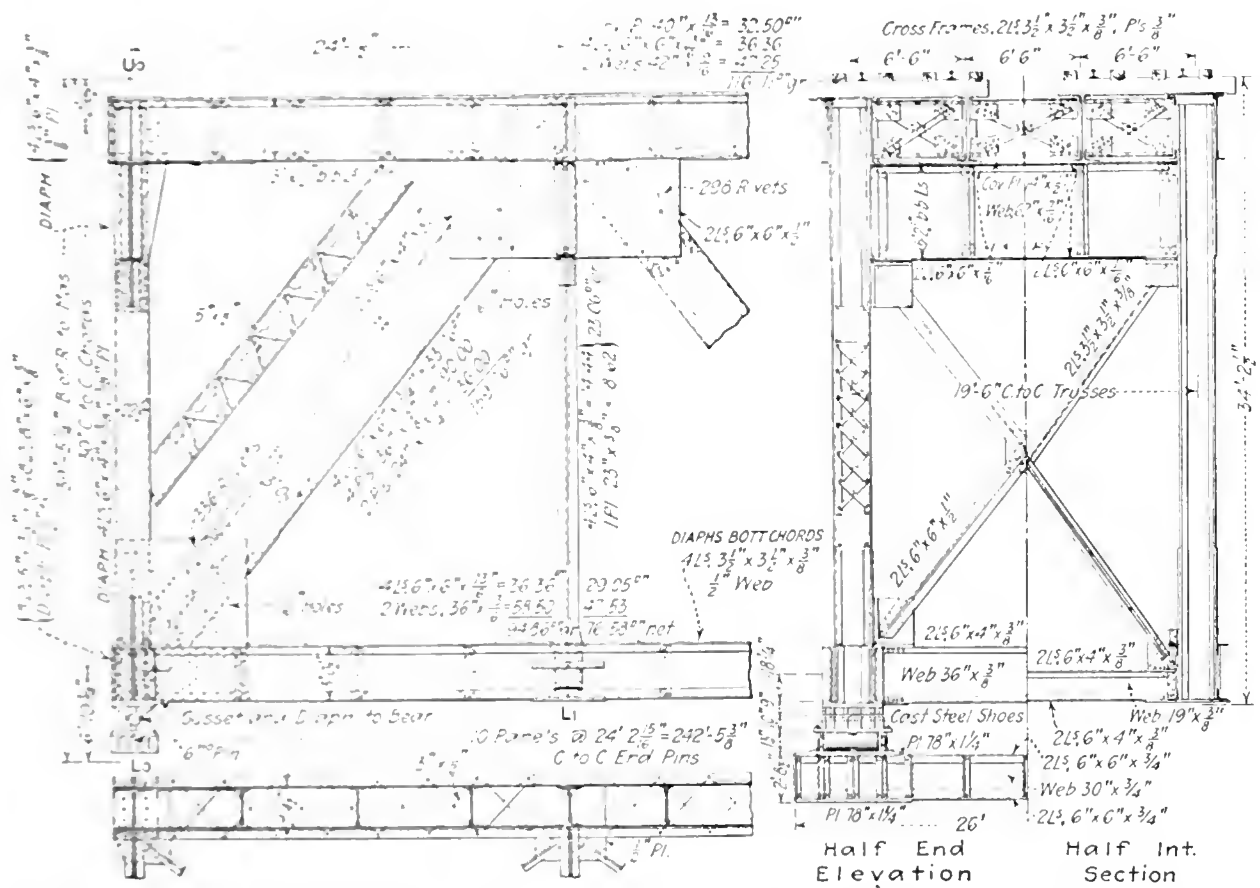
The length of the main plates in these heavy 5-ft. chords was of course limited by the available mill sizes for sheared plates, about 35 ft. This required shop splicing, as is indicated by some of the drawings. Typical joint details are also shown, the heavy hitch angles and the free use of diaphragms being noteworthy. The size of the gusset connection plates was limited by the maximum possible mill sizes, the largest gusset being 130 x $1\frac{1}{2}$ in. at the hip joint U_7.

The hitch angles were made as long as the gusset plates would permit. Longitudinal diaphragms were designed to keep the ends of the main members to exact dimension and facilitate erection, to distribute the stress, and for added stiffness. The intermediate diaphragms in all main members were especially valuable in keeping such large sections out of wind. Drain holes in the plates of these diaphragms were provided to permit the water to run off and prevent rusting.

As seen in the detail drawing, the end shoe is of unusually heavy design and is bored for 24-in. pin; at the expansion end the span is supported upon segmental rockers of $2\frac{1}{2}$ ft. diameter. The main bearing plate is supported by exceptionally heavy grillage girders, as illustrated in the drawing. These substantial pier caps simplified the placement of the end shoes, as any relatively small inaccuracy would not be of such importance as if they were set directly on the masonry.

Typical Details of Deck Spans—The Warren or triangular type was selected for the deck trusses because of its advantages in economy and simplicity of details. The cross-section and the typical details of the 242-ft. deck spans are reproduced, particularly to show the floor construction with track ties supported directly on the top chords of the trusses, the sway bracing, and the details at the main panel points. Hitch angles, countersunk stitch rivets, longitudinal and transverse plate and angle diaphragms were used for the main end diagonals in a manner similar to the corresponding details in the 644-ft. span. The lower struts of the sway bracing were made particularly stiff, and required special hitch connections, as indicated.

The lift span to replace the drawbridge had been promised by the railroad company with the object of providing a clear channel for the full width of the canal. The greater proportion of all the water traffic is passed through this canal and not through the main channel of the river.



TYPICAL DETAILS OF 242-FOOT DECK TRUSSES CARRYING FLOOR ON TOP CHORDS

LIFT SPAN CAN BE RAISED 32.5 FEET IN 45 SECONDS

Lift Span Features—This span, 260 ft. long between centers of end bearings, is also of the riveted-truss type with triangular web system, and with curved upper chords. It can be lifted 32.5 ft. in 45 sec. The design of the lifting mechanism has certain modifications found from experience with the lift span of the Pennsylvania R.R. in Chicago to be advantageous, as follows: Chains with cast-iron links, as seen in one of the photographs, are swung from the towers to the bottom of the counterweight for counterbalancing the steel cables and maintaining balance for all positions of the span. An effective pneumatic cushioning device, which acted in connection with a centering device, was developed. In order to keep the lifting cables at fixed angles and prevent movement and consequent wear on the equalizer pins, cast-steel rope clamps were designed, held in position by high-strength steel links, providing for sixteen 2¼-in. cables to carry a total load of 660,000 lb., one quarter of the span weight.

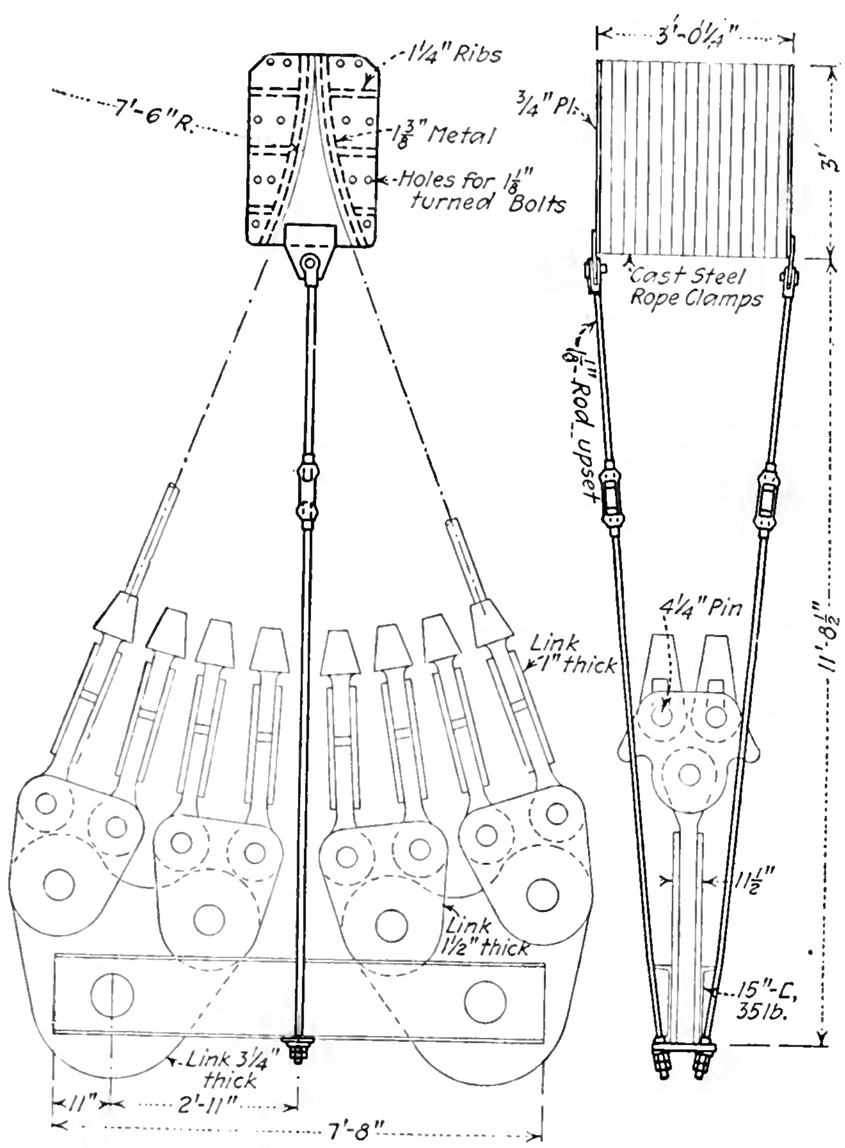
The counterweight sheaves, the heaviest yet constructed, are built up of steel plates, angles and castings. Each rim segment is fastened to the side plates by sufficient rivets to take the entire load coming upon it from the ropes. Between the segments ½-in. spaces were left, to avoid trouble if the lengths of the segments should overrun. Originally, it was intended to fill these spaces with hemp, but the cutting tools gave trouble when the machining of the grooves was begun, and it was necessary to fill them with babbitt. Trouble from bad fit of the side plates on the hub casting was eliminated by making the side plates bear directly on the shaft, instead of on the hub casting. The hole for the shaft was bored out after the sheave had been completely assembled and riveted. The hub is keyed to the shaft by three 1½ x 1-in. keys, secured from longitudinal movement by setscrews. The bearings are lined with phosphor-bronze bushings.

On account of the relatively large amount of play in the vertical guides, they do not center the span closely enough for the rail locks, which have very little play. Therefore a transverse centering casting, having small play, is placed at the middle of each end floor-beam. This is an improvement over the previous practice of using centering castings at each L_0 point, in which case considerable play had to be left in order to provide for expansion and contraction, and they did not center the span accurately enough for the locks.

To eliminate the jar when the span comes to a bearing, air buffers near each end of each of the end floor-beams were provided. Adjustable needle valves on the exhaust ports of these buffers permitted the variation of the resistance at will. Bridge locks were not used, but the counterweights were made about six tons lighter than the span, the excess weight of the latter overcoming any tendency for it to rise.

The towers are 105 ft. high from the top of the masonry to the center line of the 15-ft. main cable sheaves; the span when lifted 32 ft. gives a clear headroom of 79 ft. above the pool level of the canal. Provision was made in the detailing of the connections between floor-beams and vertical posts of the lift span to permit the former to be raised vertically if necessary, to provide for a change in grade of this approach over the canal. This was done because of the possibility of later grade-separation development in the City of Louisville.

J. C. Bland, engineer of bridges, Pennsylvania Lines



ASSEMBLY OF EQUALIZERS AND ROPE CLAMPS—LIFT SPAN, LOUISVILLE BRIDGE

West of Pittsburgh, personally designed the through-truss spans, and all details were developed under his supervision, using the standard specifications of the Pennsylvania Lines West. The contractor for the manufacture and erection of the entire bridge was the Pennsylvania Steel Co., which before the termination of the work was absorbed by the Bethlehem Steel Bridge Corporation. The erection was done under the supervision of W. W. Priest, assistant engineer of bridges, Pennsylvania Lines West. The mill and shop inspection, as also the field inspection, was in the hands of F. M. Masters, of Harrisburg.

The work was begun and all contracts were made by the Louisville Bridge Co., the original owners, which company was succeeded by the Louisville Bridge & Terminal Co., a subsidiary of the Pennsylvania company, the present owners of the property.

Freight Distribution by Motor Trucks

Having 900,000 sq.ft. of warehouse storage capacity, closely connected with the terminals of the New York State Barge Canal, Callan Bros. of New York City, receive and distribute merchandise in that city and throughout New England, New Jersey, Delaware, Pennsylvania, and other seaboard states, by operating forty 7½-ton trucks on schedules indicated in the following table:

	Miles	Hours per Trip
New York to Philadelphia	100	12
New York to Baltimore	188	22
New York to Dover, Del	172	21
New York to Waterbury, Conn	95	11

New York to Hartford, Conn	113	16
New York to Springfield, Mass	139	18
New York to Worcester, Mass	190	23

Operation of Fine Sewage Screens at Long Beach, California

Tests Indicate That Screens Remove 16.3 Per Cent. of Solids—Screenings Incinerated by Gas—Operating Costs

EXPERIENCE with the Riensch-Wurl screens for more than two years at Long Beach, Calif., indicates that gas is cheaper than oil as a fuel to incinerate the screenings, that the screens need renewal after two to three years' use, that the average cost per 1,000,000 gal. has been $10.92, and that the installation has served its purpose of keeping the beach clean in an inoffensive manner.

A description of this 14-ft screen with $\frac{1}{32}$-in. slotted holes, handling 2,600,000 gal. of domestic sewage of 22,000 persons appeared in the *Engineering News* of May 4, 1916, p. 836. The operation as described in a report by engineers of the state board of health is as follows:

The cans of screenings are hoisted by hand by means of a chain-and-gear-set suspended from a track on the roof, and emptied into the top of an incinerator. The incinerator is 7 x 15 ft. in plan, and 8 ft. high. It is of brick and is lined with firebrick. On the inside are three platforms, equally spaced one above the other, built of firebrick with openings about 1 in. wide between the rows of bricks in the two upper platforms so that they serve as grates. At one end of each of the upper platforms is a large opening through which heat and fumes may pass. These openings are at opposite ends of the platforms, so that the circulation is forward and back and forward again as the current travels downward and out toward the chimney. The screenings are placed on the top platform, where heat is applied in the form of burning gas blown in on top of the screenings together with a blast of air. Occasionally during the burning the screenings are raked over, which causes part of them, together with ashes, to drop through the grate openings onto the platform below.

Gas Substituted for Oil to Burn Screenings

Prior to April, 1917, oil was used as a fuel for incinerating. Natural gas was then substituted because it was easier to handle and cleaner. Also, with oil at present prices gas is more economical.

The volume of screenings is measured in the can whenever a can is emptied into the incinerator. The screenings have practically the same weight as water. An average of five hours a day is required for burning. The screenings of each 24 hours are all burned at once. About one wheelbarrowful of ashes is produced during each burning. For an estimated average flow of 2,600,000 gal. daily the screens removed about 70 cu.ft., with a moisture content of about 87%. Burning with oil required 0.8 gal. per cubic foot at a cost of 2.5c. The gas consumption was 81.4 cu.ft. per cubic foot of screenings, at a cost of 3.5 cents.

The electric power used averages about 75 kw.-hr. per day, of which about 55 kw. are used to operate the screening plant, and the remainder for pumping.

Under normal operation there is an almost complete absence of offensive odors. No indications of sewage are visible in the ocean. Around the outlet sea gulls are notably rare.

Some experiments carried on with composting screenings gave rise to slight odors in the immediate vicinity of the work. The experiment consisted of preparing a bed of sand 6 in. deep, placing over it 6 in. of screenings and then covering with 6 in. of sand. After a few days the entire volume of sand and screenings was spaded and mixed. Another experiment consisted of drying the sludge in a nearby fish canning plant used to dry fish offal. Analysis indicated a value of $35 per ton dry on the basis of $5 per ton per nitrogen unit.

After about two years' use the brass screen plates began to show wear. The brushes rub the plates in a line transverse to the slot openings, which probably facilitates rapid wear around the slots and also tends to hasten clogging. It is intended to try out a new type of plate in which the slots will be sawed along the line of travel of the brushes on their upward sweep. The brushes are renewed twice a year at a cost of $44 a set.

Tests to Determine Work of Screens

Tests made in May, 1916, on eight composite consecutive samples, each sample representing about 2½-hour periods in one-half-hourly portions taken from 10:15 a.m. to 4 p.m. the next day, gave an average removal of 43.5% with a minimum of 10% and a maximum of 62.7%, as indicated by settleable suspended matter. At the time the test was made the 50-cc. samples dried and weighed in the Gooch crucible did not give very dependable results. The amount used was so small that it appeared a large error crept into the results. Some of the screened samples tested in this manner showed a higher residue than the raw sewage, which condition is accounted for more by the inability to obtain fairly average samples of raw sewage than by inefficient screening. The test was not considered very satisfactory.

Later tests were made in 1918, under the direction of W. J. Knowlton of the Los Angeles sewer department, by J. W. Geeks, head of the substructure department. The following notes are abstracted from his report:

No odor was noticeable 200 ft. from the plant. When the fire is drawn from the incinerator the incompletely consumed ash is the greatest source of odor, but the ash is quickly disposed of.

Samples to determine the amount of solids removed were taken below the screen rather than above, because of the more uniform character of the effluent. Above the screen representative sampling was impossible because of the heavy flow of solid matter on the invert moving at a slow rate. A sample 4 x 4 in. in cross-section was taken, extending from the surface to the invert, but this, compared with samples taken at and below the screen, showed a ridiculously large amount of solid matter.

Two-gallon samples were collected every hour and placed in a 7-cu.ft. sludge can. After they had settled 20 hours the clear water was siphoned off and the resi-

OPERATING EXPENSES PER MILLION GALLONS

Fuel oil	$0.700
Fuel gas	0.909
Electric power	0.868
Electric lighting	0.128
Salaries	2.690
Supplies	0.359
Repairs	0.213
Office overhead	0.383
Interest at 5% on investment	2.097
Depreciation	2.574
	$10.921

due was collected and weighed, when the moisture was judged to be the same as that of the screenings. Proper corrections were made for variation of quantity of flow and of "density"—i.e., the relation of the flow of the sludge to the flow of sewage. Dried samples indicated that the error in the method was within 6% of being correct.

Data obtained May 7, 13 and 14, and on Jan. 3 and 4, 1918, when the average, maximum and minimum daily rates were 2.6, 3.9 and 1.5 million gallons, indicated 1810 lb. per 1,000,000 gal. removed, equivalent to 16.2 per cent.

Unit costs based on a period between Mar. 31, 1917, and Apr. 28, 1918, from records kept by Charles B. Murphy, superintendent, are given by Mr. Geek as shown by the accompanying table.

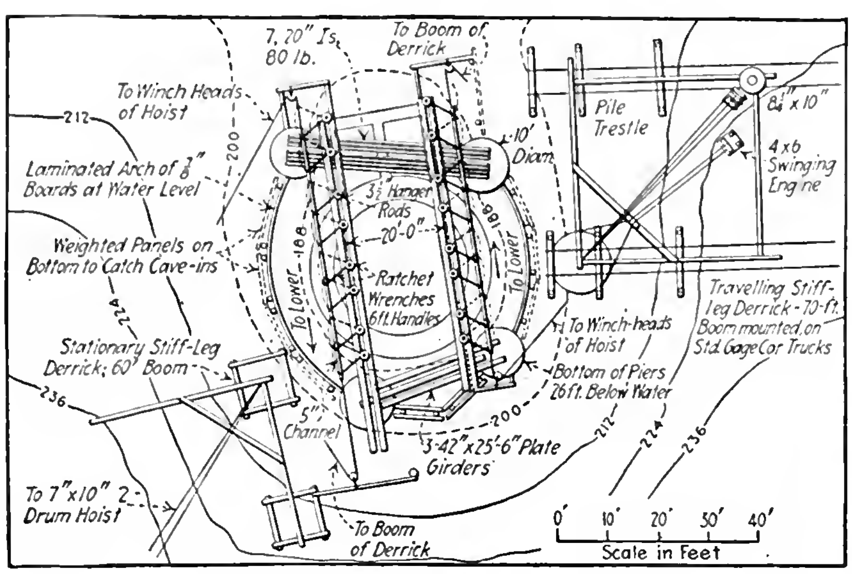
The investment per 1000 population within the sewered district is $181.80, and the yearly operating cost per each thousand of the city's population is $181.20.

Sinking a Concrete Pumping Station in a River

House Consisting of Concrete Cylinder 30 Feet in Diameter Is Lowered While Being Built From Frame Controlled by Ratchet Wrenches Tied Together for Simultaneous Movement

By Keith O. Guthrie
Engineering Contractor, Schenectady, N. Y.

Feed and condensing water for the General Electric Co.'s Schenectady, N. Y., plant is now supplied from an abandoned stretch of the Erie Canal maintained at level from a new pumping station on the nearby Mohawk River. The main house for this station, a cylindrical concrete shaft, was built in the severe winter



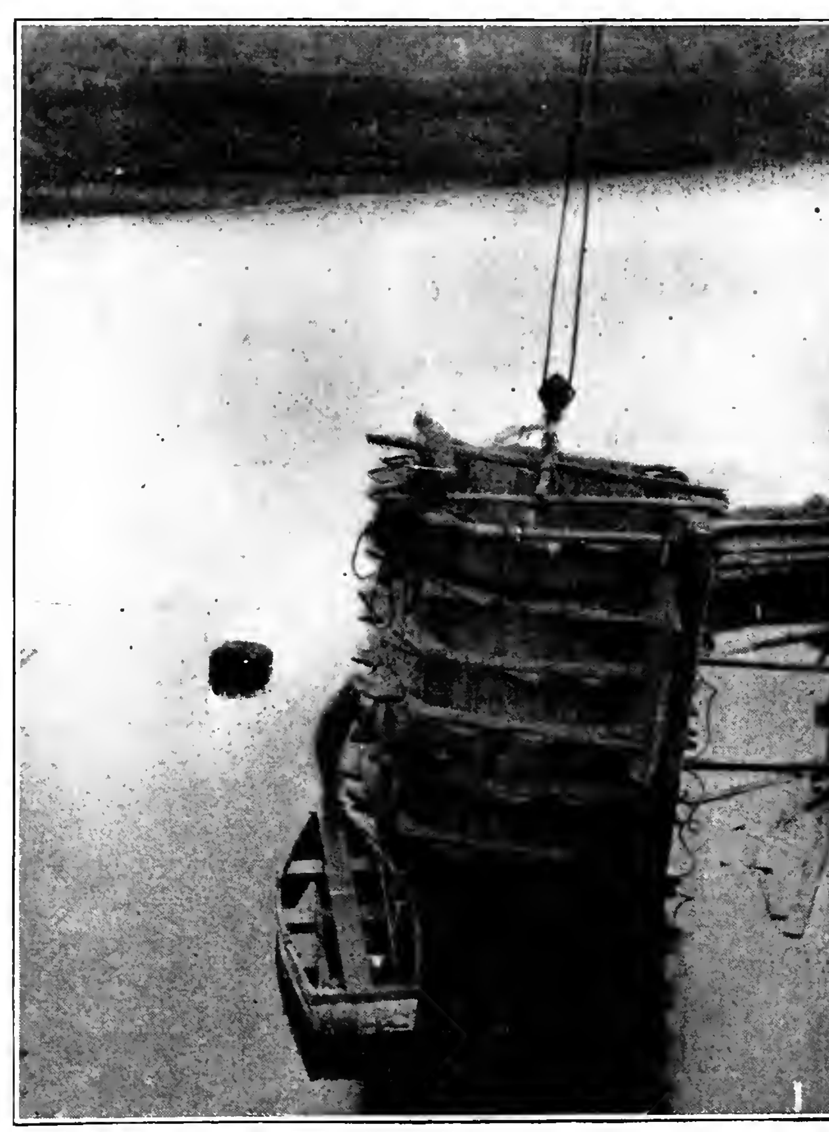
LAYOUT OF PLANT AND STRUCTURE USED IN SINKING CONCRETE CYLINDER PUMPING STRUCTURE

of 1917-18 by a novel method. Temporary piers were sunk around the site, and on them, as foundations, a platform forming the bottom of the house was hung by rods, which were controlled by wrenches tied together so as to permit simultaneous operation. The house was then built up on this platform, and was lowered as the walls progressed in height.

The station is located between the river and the canal where the river bank is only 80 ft. from the towpath and on the outside of a bend in the river, making it likely that the current would make the intake free from silt. It is in the water, the contours of the bottom running around 188 where 212 is the normal shore line. The pump-room floor is 15½ ft. below normal summer river level and about 40 ft. below record stage. The material at the site is a compact, coarse, water-bearing gravel, unsuited to any kind of cofferdam.

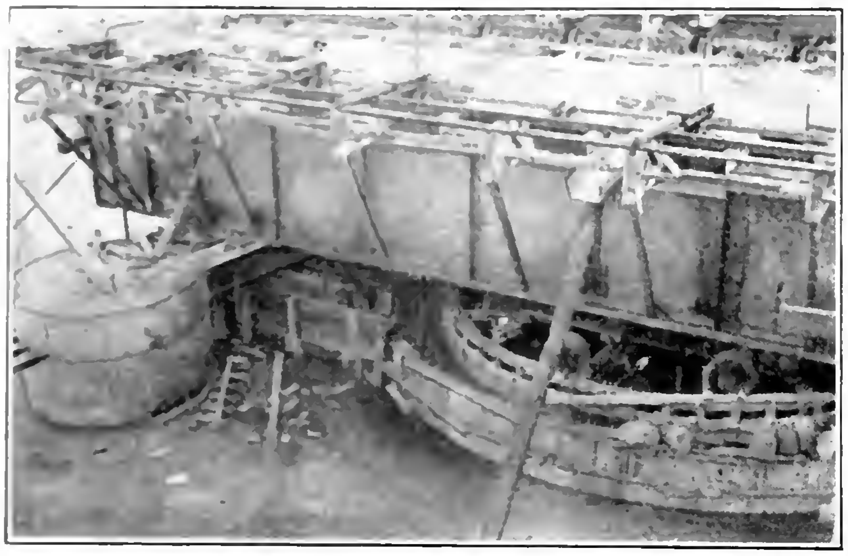
At the start of the work a 2½-yd. dipper dredge made 16 ft. of water over the site of the house and for about 20 ft. around it. The spoil was removed in scows. At the same time, stiffleg derricks were erected on either side of the cut; these operated 1¼-yd. clamshells and completed the excavation to 24 ft. below water level.

When excavation had been roughly completed, four piers were built around the location of the house, as shown in one of the drawings. The forms for these piers were round barrels, of 10-ft. inside diameter, and 30 ft. long, with outside ribs of 2 x 10-in. plank lapped and well spiked. To provide a cutting edge and also weight for sinking, a reinforced-concrete ring was attached to the bottom of each form. The complete form units weighed about eight tons, and were set in place by the derricks and guyed. It was desired to have these piers extend at least 2 ft. below the grade



LOWERING FORM FOR SUPPORTING PIER INTO MOHAWK RIVER

of the excavation for the house, so as to secure the full bearing power of the gravel. The forms were sunk quite readily by excavating inside them with the clamshell. As soon as a form reached grade, nine 45-ft.



CONCRETE BEING PLACED AT SAME TIME HOUSE IS LOWERED

piles were driven inside with a five-ton steam-hammer to practical refusal, which came at from 15- to 20-ft. penetration. Concrete was then placed by tremie, and the piers were brought to 9 ft. above water and capped with a grillage of old rails.

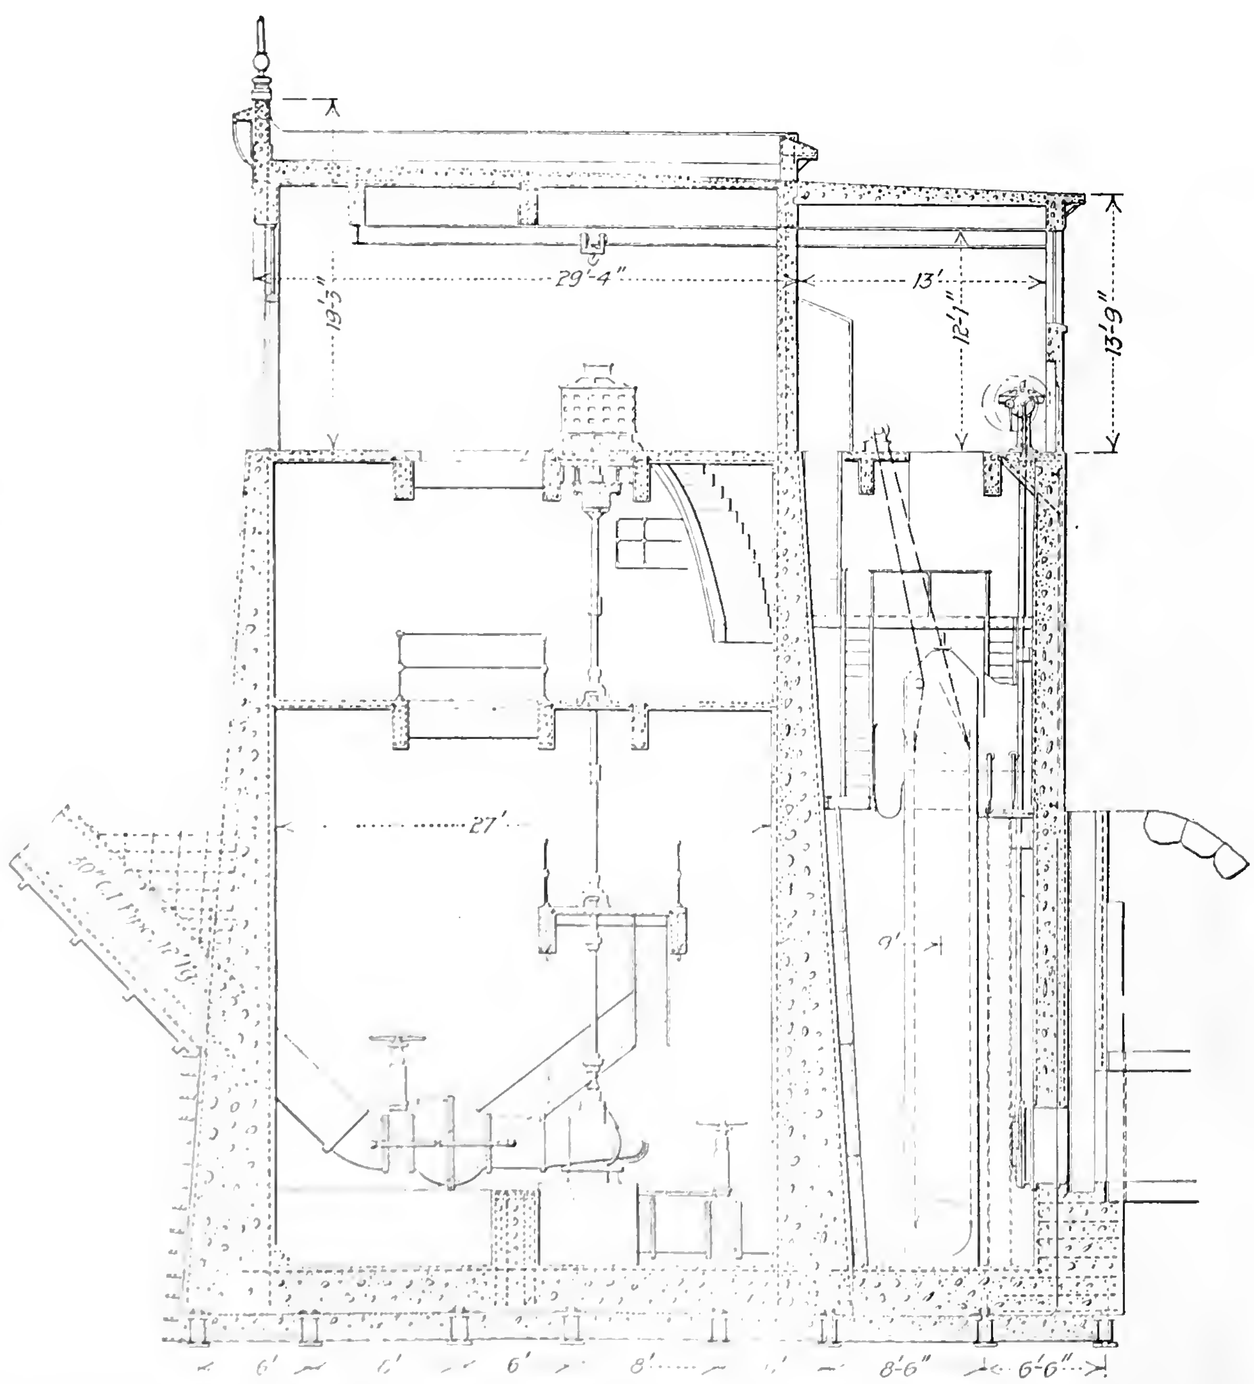
The two inshore piers were then bridged by three 42-in. plate-girders, and the two outshore piers by eight 20-in. 80-lb. I-beams. Both the girders and the I-beams were girdled with heavy clamps, and the space between the webs was filled with concrete from pier to pier, to resist lateral buckling under load. In addition, the girders and beams were securely anchored into the pier tops, to minimize the danger of any pier leaning.

Seated on the cross-beams and the cross-girders were two pairs of heavy plate-girders, from which hung the suspender rods that carried the house itself. The girders of each pair were spaced with the flanges just far enough apart to pass the connecting sleeve-nuts of the rods. The girder pairs were spaced on 20-ft. centers. Pains were taken to give the main girders evenly distributed bearing as well as an anchorage to the beams and cross-girders on which they were seated. The girders of one pair were 6 ft. deep by 58 ft. long, of the other pair 7 ft. deep by 67 ft. long. Both sets were built to Cooper's E-50 specifications and were bought from the American Bridge Co. out of a bridge built for a railway project that was abandoned.

To secure maximum supporting power from the main girders, they were cantilevered at the screen-well end for about 12 ft., giving roughly the same bending moment at the outshore piers as at the middle of the long span.

Eight $3\frac{1}{2}$-in. V-threaded rods were hung from the top flanges of each pair of girders. At each rod the girders were bridged with a pair of 10-in. 30-lb. channels on which rested the washer carrying the lowering nut. To obviate the danger of the nut cutting under a load of at least 30 tons and possibly much more, the washers were made of two $1\frac{1}{2}$-in. plates, of 16-in. diameter, with the faces in contact faced, oil-grooved in opposite directions, and packed in light grease.

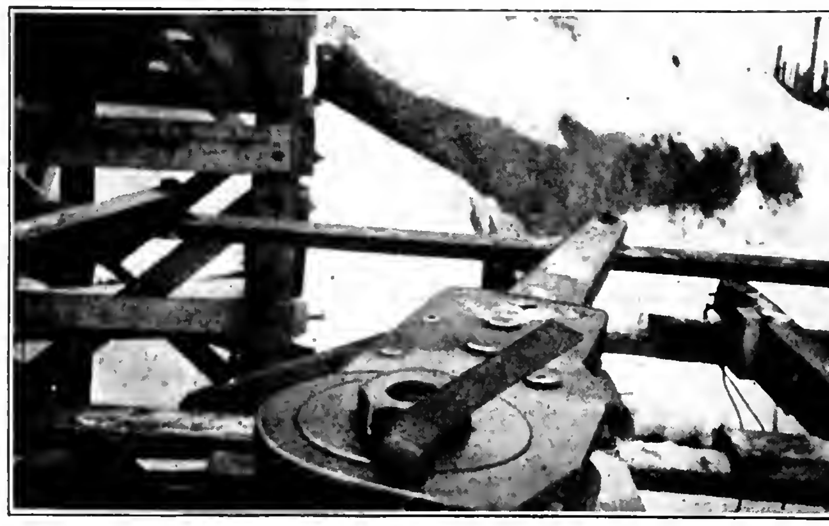
The lowering nuts were 12 in. long, of standard hexagon section, and were engaged by ratchet wrenches with 6-ft. handles, as shown in the views. The ends of the wrench handles were bolted to 5-in. channels, one on either side of the house. Lines ran from each end of the channels to derrick hoists seated on temporary trestles outside the house area. These lines operated the wrenches back and forth in unison, each movement giving the nuts one-sixth turn. Electric door-switches, engaged by the moving channels, rang bells in the engine-rooms to indicate to the hoist-runners the limits of the stroke.



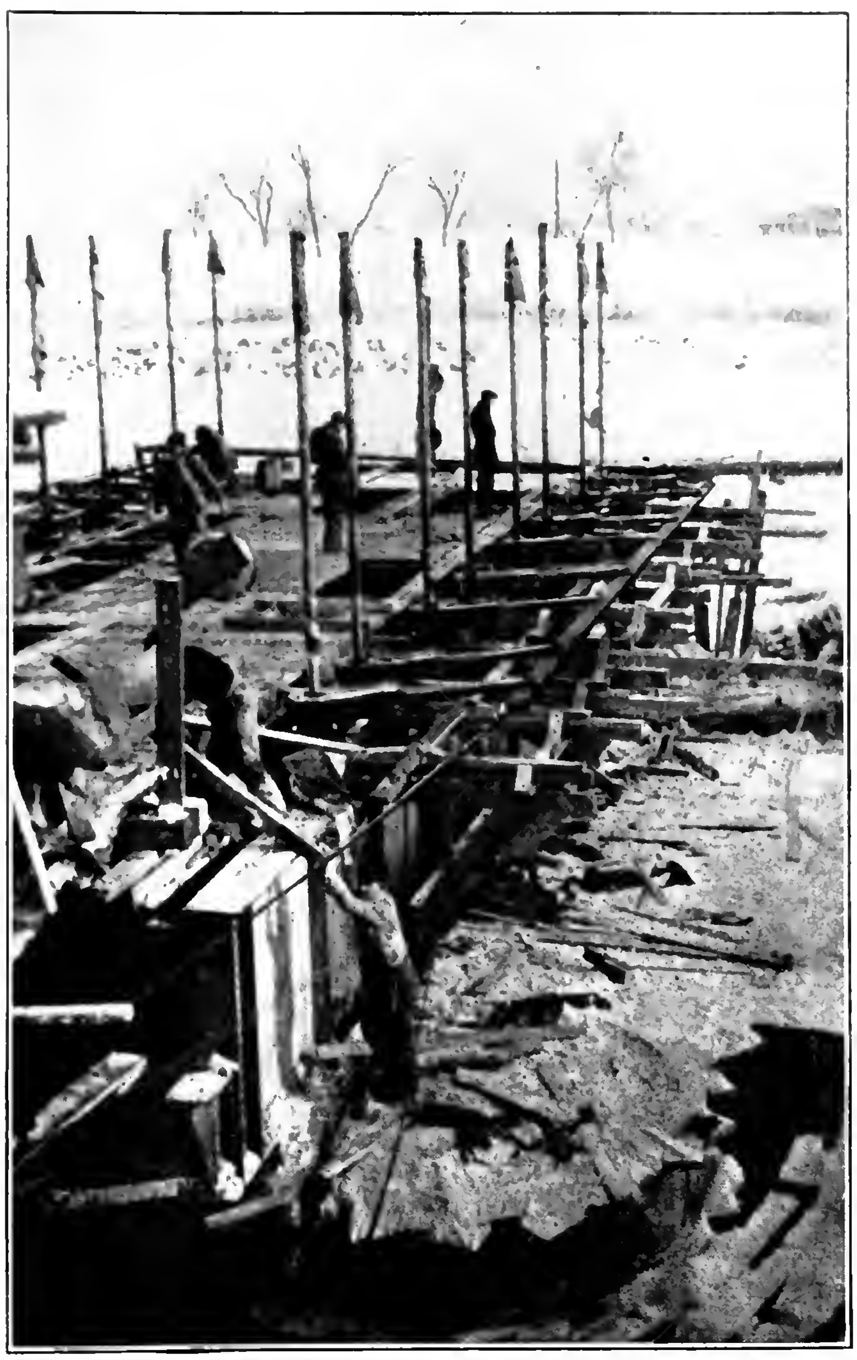
VERTICAL SECTION THROUGH PUMPING STATION SHOWING ALSO DETAILS OF SUPPORTING FLOOR

Opposite rods supported pairs of 15-in. I-beams which formed a floor under the entire house. As erected, these beams just reached the water. They were tied together with $\frac{3}{4}$-in. tie-rods, on 4-ft. spacing, and separated by a 4-in. wooden floor resting on the bottom flanges. After the first ring of the outside forms was set, resting directly on the floor-beams, a subfloor of concrete was placed, covering the top flanges 2 in. and with an 18-in. fillet at the outside form. On this subfloor and up the outside forms were laid five layers of patent roofing felt very thoroughly mopped with waterproofing pitch. This work was done by Craig & Vrooman, of Schenectady. The reinforcement, inside wall forms, and forms for the inverted floor-beams were then placed and concreted. The house was lowered at the same time, keeping the level of the concrete about 1 ft. out of the water. The best progress in lowering at any time was 15 in. in an hour.

The outside forms were built 1 ft. higher than the inside, to provide a lap for the waterproofing of the succeeding lift. No difficulty was experienced in lowering fresh concrete into the water. Frequently, concrete in the walls an hour old was under water—amply protected by the five-ply waterproofing. This waterproofing passed a remarkable test one night when a thaw up the valley caused a sudden rise in the river. Before a gang could be brought out from the city and concreting started, the water level was 20 in. above the concrete in the walls, and at one point 3 ft. There was not so much as a drop of leakage through the outside forms. While it has always been customary to place waterproofing against such a masonry wall, this was dispensed with on the work, to save time and expense. It is believed that the wooden forms—always under water—will prove a permanent protection.



CLOSE VIEW OF ONE OF THE RATCHET WRENCHES



OPERATING WRENCHES ON ONE SIDE TIED TOGETHER FOR SIMULTANEOUS OPERATION

It was felt in advance that the chief danger in this method of lowering a heavy structure lay in the possible settlement of one of the piers. It was conceivable that a material relative settlement of one pier would concentrate the entire weight on a few rods, overloading and even snapping them, with consequent disaster. To guard against this possibility, a great deal of care was taken with the piling and concreting of each pier. The rods were made heavier than required for even loading, and the subfloor, on which the house proper was built, was made flexible in one direction. The first pour of the house, including the floor and a portion of the walls, weighed about 600 tons. This was cast without being lowered into the water, with the idea that this entire load would be likely to bring about immediate and maximum settlement and, being fairly flexible up to this point, would adjust itself to any relative settlement of the piers. As it developed, however, there was no observable settlement in any pier.

A further fear was entertained that, through unequal running off of the lowering nuts, some of the rods might be overloaded. Considerable thought was given to the application of strain-gages, but it was soon found that an underloaded rod shifted on its support as the heavy wrench swung back and forth, while an overload rod groaned. A one-sixth turn of the nut—about $\frac{1}{20}$ in. on the rod—was usually sufficient to equalize the loading.

The hanging equipment went through a very severe test in the early part of February. The house had been lowered 16 ft. into the water, a set of forms made ready for a new pour, and the entire structure covered with a board house as protection against the severe cold. A fire, started presumably by a salamander, consumed forms, runways, and protection housing, to the water edge. The girder webs were badly buckled and one girder sagged 2 in., but, after the forms were made good, the lowering was resumed without any difficulty except in lubricating the lowering nuts.

The method of construction was developed by the writer, and the station design was worked out by him in consultation with A. W. Nesbit, superintendent of

power, and C. G. Hulth, superintendent of grounds and buildings, of the General Electric Co. W. R. Abbott acted as construction engineer and James J. Fahey as superintendent.

Flat Slab Substituted for Groined Roof of Reservoir

Money Saved in Dayton Water-Works Structure Due to Less Concrete and Excavation and Simpler Forms

By H. C. Wight
Superintendent, Division of Water, Dayton, Ohio

Groined arch roofs have been the practice in concrete flat-top reservoirs for a number of years. Only occasionally has another type of design been utilized. In the recently completed reservoir for the water-works of the City of Dayton a flat-slab reinforced-concrete roof was substituted for the groined roof originally designed and it is the opinion of the engineers that this revision, together with a lower amount of excavation required in the new design, resulted in a considerable saving to the city.

An additional water-supply for the city has been under way for about five years. One of the main improvements, planned in 1917 and completed last autumn, had a capacity of 10,000,000 gal. It is located in the hills to the south of the city, on a site of about four acres. It is in a flat-top reinforced-concrete structure sunk about half its depth in the original surface and covered over with 2 ft. of loam to keep the water cool and to prevent freezing.

INSIDE OF DAYTON RESERVOIR JUST AFTER FORMS WERE STRIPPED

HEAVY GRAVITY CONCRETE WALL FORMS SIDE OF FLAT-SLAB TOPPED RESERVOIR

The contract was first offered July 31, 1917, at which time bids were received on the groined-arch type of construction. These bids were rejected on account of their being excessive. Apparently, the contractors were afraid of the groined arch on account of the complicated form carpenter work required and the shortage in that war year of carpenters. Accordingly, a second design was made, and alternate bids were opened Sept. 17 of that year for the groined arch and the new flat-slab type.

These bids were rejected on account of a technicality and a third letting on the same types occurred on Oct. 5. Contractors in this letting were allowed to submit alternate designs and bids, and the award was made on the flat-slab design at an amount about $60,000 less than the lowest bid in the first letting and $10,000 less than the lowest groined-arch bid in the last letting. The unit prices on this low-groined arch bid, however, were considerably lower than the bid accepted, and it is doubtful if the margin of profit for the contractor would have been as large.

The design accepted was submitted by the contractor, the Danis-Hunt Co. of Dayton, Ohio, and was prepared by Nelson J. Bell, engineer with Schenk & Williams, architects, of Dayton, Ohio. The savings in this design are due to three things: The formwork, the excavation and the concrete.

At this time lumber was very hard to get, owing to the heavy demand. The flat-slab roof design was much simpler, so far as formwork went, and the lumber was used actually some three times with a very small amount of cutting.

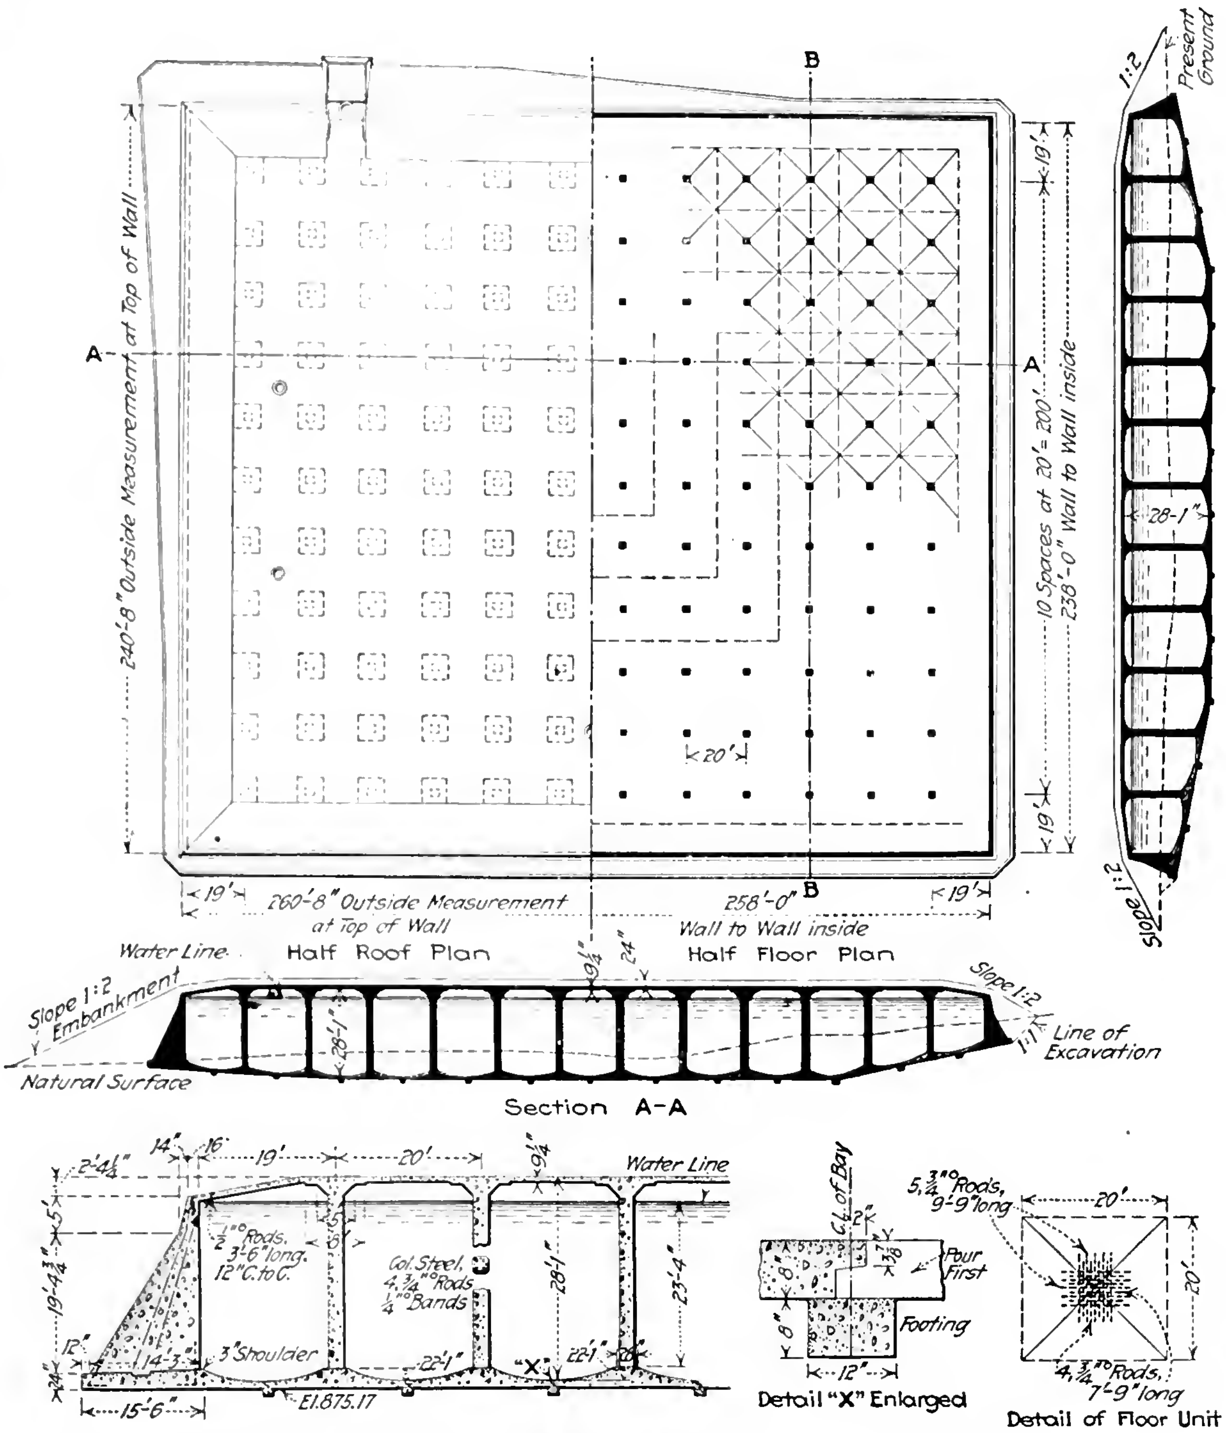
The class of saw-and-hatchet men available could handle the work with reasonable speed. In excavation, the fact that the new design utilized a bottom slope, as shown in the drawing, saved some 7000 cu.yd., about 26,000 yd. of dirt being handled as compared with the 32,700 that were estimated for the straight-bottom groined arch.

This would have been more had the reservoir been located on level ground instead of on the side of a gradual slope.

The third saving effected in the concrete is due to the fact that the groined arch required 8820 cu.yd., as compared with 7902 cu.yd. for the flat slab. However, in the actual construction the roof was increased from

8 in. to 9.25 in., so somewhat more concrete was used. The final payment was $136,760, as against the bid of $133,934, which compares with the $193,412 bid on the first groined arch.

General details of the reservoir are shown in the accompanying drawing. As will be seen, it has a groined-arch floor with gravity side walls retaining the embankment and a flat-slab roof supported on columns on 20-ft. centers, footing on the rise of the floor groins. The bottom is sloped up on all sides for reasons of economy, as stated. The retaining walls, as shown, are built separate from the floor with a dap joint there and at the vertical construction joints. The groined-arch floor is also designed to be laid in square sections with expansion joints, as shown in the details. Under each joint there is a concrete block 12 in. square by 8 in. thick. There has been no leakage through these joints to speak of. The only place waterproofing or asphaltum was used was in the roof, over the joints there. The reservoir was designed and constructed under the direction of J. E. Barlow, director, Department of Public Service, with the writer as superintendent of the Water Division. Leonard Metcalf, Boston, was consulting engineer.



RESERVOIR HAS FLAT-SLAB REINFORCED-CONCRETE ROOF

Speed and List in Side Launching of Ohio River Boat

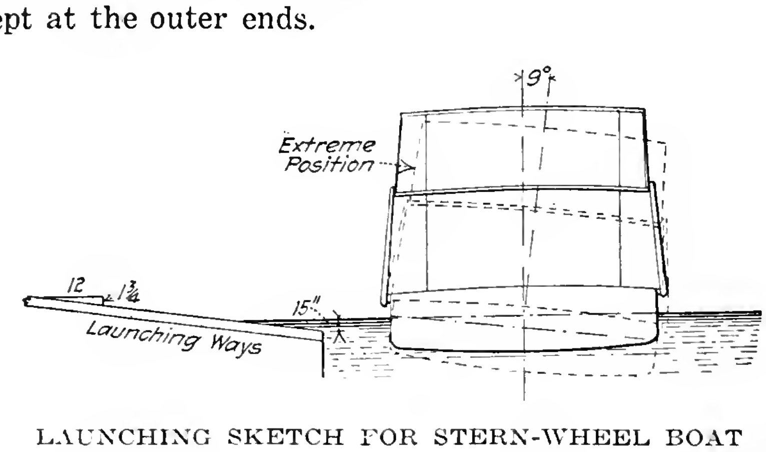
At the launching of the stern-wheel river towboat "Warren Elsey" at Neville Island, near Pittsburgh, Mar. 29, engineers for the Dravo Contracting Co. of Pittsburgh, the builder, made observations of the behavior of the vessel during the launch.

Briefly, they found that the boat was moving at a speed of 16 ft. per second when she left the ways, which were laid on a slope of 1¾ in. in 12. Upon striking the water the boat listed 9°, as determined by a glass U-tube, with legs spaced 3 ft., half filled with thin paint; an attempt to measure the list by a pendulum consisting of a 10-lb. weight on a 24-in. arm was unsatisfactory. On recovery the boat listed 5° in the opposite direction. At the time of dropping from the ways it dipped 18 in. lower at the stern than after it came to rest, presumably because of the inertia of the machinery. The boat moved square to the ways, dropping off with not over 6 in. lead of one end over the other, as determined by two observers sighting past range poles.

An unusual feature of this launching, for Ohio River practice, was that the boat was practically complete, all equipment having been installed on the ways, including engines, boilers and stern wheel. Its launching weight was 367 tons, corresponding to a draft of 2 ft. 8¾ in. forward and 4 ft. 3⅜ in. aft.

The boat itself is of steel, but the crew's quarters on the upper deck are of wood. Its length over all is 162 ft., and the length of the hull 137 ft. 5 in.; its beam is 27 ft. and its depth 6½ ft. It carries a wheel 20 ft. in diameter by 18½ ft. long. Power is furnished by tandem-compound engines 14 and 30 in. by 72 inches.

The vessel was carried on four pairs of launching cradles equally spaced. Of these the stern cradle carried the heaviest load, 111 tons, equivalent to 4.1 tons per square foot on the sliding surface. As indicated in the sketch herewith, the water ends of the ways are submerged 15 in. The ways rest on concrete piers except at the outer ends.



LAUNCHING SKETCH FOR STERN-WHEEL BOAT

Concrete Used to Patch Worn Brick Paving

Old Surfacings, Broken Up by Excessive Loads, Have Been Successfully Repaired by this Method in Cuyahoga County, Ohio

PATCHING with concrete is the method used to repair some of the older, brick-paved roads in Cuyahoga County, Ohio. The patches vary in size from small areas to those covering 400 to 500 sq.ft. Repairs of this kind were made on a road leading west from Cleveland, where the brick paving had been partly broken up, due to its light construction, by dense traffic, consisting largely of heavy loads for the American Shipbuilding Company's plant at Lorain, Ohio. The repairs are shown in the accompanying views.

The brick surface, which was placed some years ago, rests on a 2-in. sand cushion over a 6-in. base of rolled slag. While unsuited for the heavy traffic it is now called upon to carry, reconstruction was out of the question during the war, so that the best method available had to be used to keep it in serviceable condition. Experiments were first made by repairing the broken parts with crushed stone and cut-back bitumen, but this type of patch did not give satisfactory results. Concrete was then tried, and has proved successful.

CONCRETE PATCH BEING MADE ON WORN BRICK HIGHWAY IN CUYAHOGA COUNTY, OHIO

All worn and broken brick are removed, the projecting halves of alternate brick being broken off, so that a vertical base is provided. The old base is dug out, and the subgrade is tamped. A new base of 1 : 2½ : 5 concrete is then placed, using crushed slag for the coarse aggregate. On this is laid a 2-in. wearing course of 1 : 1 : 2 concrete made with crushed granite ¼ to ¾ in. in size as the coarse aggregate. The patches are from 10 to 12 in. in thickness. The concrete is struck off level with the surrounding pavement and is finished with a concrete pavement roller, where practicable. Care is taken to make sure that the patch does not project above the adjacent brick surface. It is protected from traffic for at least two weeks, a precaution which is considered of the greatest importance.

COMPLETED CONCRETE PATCHES IN BRICK ROAD

The work is done by a maintenance gang, using materials which have been distributed along the road in the required quantities. The concrete is mixed by hand for the smaller patches and a small mixer is used for the more extensive repairs. Where patches extend more than half across the pavement the surface is reconstructed in sections so that traffic will be hindered as little as possible.

The work is carried out under the direction of J. F. Gannon, superintendent of road repairs for Cuyahoga County.

Fire-Service Connections Menace Pure Water Supply of Cities

THE relation between domestic and fire supplies of water in small towns received careful consideration at the recent meeting of the Minnesota Section of the American Water-Works Association, at Minneapolis. That the state board of health, which must pass on all plans for small cities, has had considerable trouble in correcting some undesirable conditions was shown in a discussion of the dangers of polluting a public water-supply by means of private fire-supply connections, following papers on "Water-Works as Fire Protection," by H. F. Blomquist, of St. Paul, and "Features of Design in Small Water-Works" by F. H. Bass, of Minneapolis. A resolution was passed requesting the parent association to appoint a committee to secure standard practice and coöperative action in order to combine fire protection and sanitary conditions, with a view to placing these features under local or state control.

That legal responsibility for pure water rests on the municipal officials is indicated by the decision in the Mankato case, according to a paper by John Wilson, of Duluth. This case arose from sewage pollution of the artesian supply, due to floods in the Minnesota River in 1908.

Mr. Wilson pointed out that fire supplies planned to supplement the municipal supply are responsible for any contamination due to such supplementary supply. A resolution was passed opposing the use of cross-connections between a polluted fire supply and a pure or purified public supply. This resolution also commended the state board of health for its work along these lines.

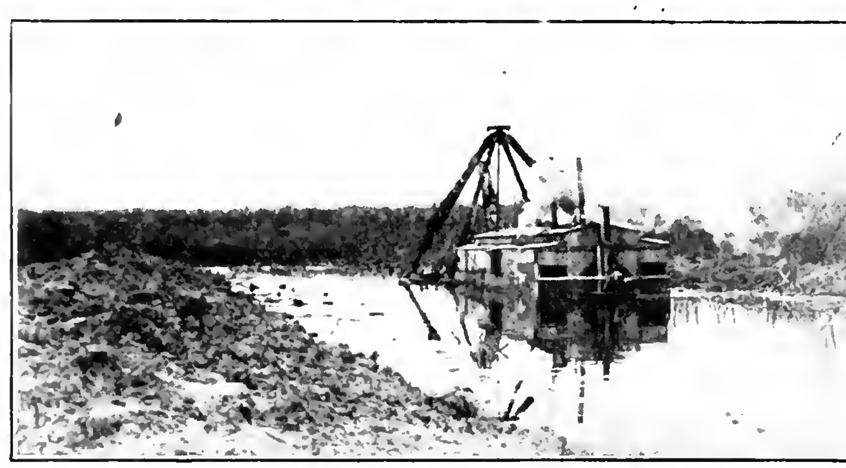
Inspection of Drainage Ditch Cross-Sections After Contract Dredging

Soundings First Made by Level Rod Gave Way to Lead and Line Following Along Tape—Boat Used by Sounding Man Was Pulled Across by Means of Tape

BY E. S. BLAINE
Engineer, Residency No. 4, Little River Drainage District, Kennett, Mo.

NEARLY 650 miles of floating dipper dredge work has been completed by the Little River Drainage District in southeastern Missouri. Previous to the legislation which made this district possible, the jurisdiction of a drainage district in this state was limited to one county. The engineering work was usually done by the county surveyor. We have been unable to hear of a case where the ditch was cross-sectioned behind the dredge. The "inspection" was usually done by rowing along the center of the ditch, or riding along it in a motorboat and sounding with a pole at more or less frequent intervals, depending upon the speed of the boat. Too often even this "formality" was dispensed with. The work was then accepted by the "engineer." As it was desired not to accept work when no more was known about its actual condition than such meager data would permit, a set of "Instructions for Resident Engineers" in this district was issued, outlining methods for inspection. The outline was added to, or revised, as improvements developed. This article tells of the methods that have been used and explains their development.

The size of the ditches varies from 4-ft. bottom and average depth of 8 ft. to 123-ft. bottom and average depth of 11 ft. All ditches have 1 to 1 slopes specified. The land within the district has a surface so nearly a plane that it was considered an unnecessary refinement to cross-section the natural surface, except in special cases where an old channel was appropriated, or where a large river crossing or some local irregularity of considerable magnitude made such cross-sections necessary. Levels were run along the center line and benchmarks set approximately one-fourth mile apart. The cut at each station, description of benchmarks and alignment notes were all placed on the profile. Tables were made for the different base widths, giving the quantities of excavation, for level sections, in a prism 100 ft. long, at 0.1-ft. intervals. For estimating the yardage, the quantities were taken from the tables for the center cuts written on the profile.



FIGS. 1 TO 4. PROGRESS VIEWS ON DITCH NO. 1, LITTLE RIVER DRAINAGE DISTRICT, MISSOURI
1. Cypress and tupelo timber along ditch line. 2. Looking up the pilot cuts. 3. Setting slope stakes; note man and boat on either side. 4. A 4½-yard dredge at work.

After the excavation, cross-sections were taken at each station on all the ditches. These cross-sections were used for computing the yardage in special instances only, as follows: River crossings and other local irregularities in the natural surface; pilot cuts where part of the prism was excavated; reaches where it was necessary to excavate below ditch grade to get material for raising spoil-bank levees to an established grade; where the work consisted of improving an existing channel. The rest of the cross-sections were taken for the purpose of insuring the removal of all the material in the specified prism. At times it was necessary to take as many as four sets of cross-sections before the ditch was brought to grade.

As the excavation was under water at all times, the cross-sections were taken by means of sounding from the water surface along a tape stretched across the ditch. It was not practicable to pick out the irregularities and limit the number of readings by the governing points, as is done where the work is visible, so soundings were taken at regular intervals. For the small ditches, the interval was 3 ft., except that a reading was taken 2 ft. from each bank to show up better the actual slope being excavated. On the large ditches the soundings were taken at intervals of 3 ft. on each slope and 5 ft. across the bottom.

The inspection of a reach of ditch would proceed in the following order: On arrival at the work, if on one of the smaller ditches, the chaining was picked up, preferably ahead of the dredge or from a reference point on one side, and the chaining was connected up with previous work. If on the larger ditches, points were located on the spoil bank from reference points which had previously been established to one side of the right-of-way far enough to insure their not being disturbed by the work. A base line was then run parallel to the center line and a known distance from it. All stakes were cut from timber along the ditch, and were marked on the side facing the ditch, to permit their being read from a boat. This saved a great deal of time and labor when looking for a bench mark or reference point, as most of the moving from point to point was done in boats. Due to openings in the spoil banks at

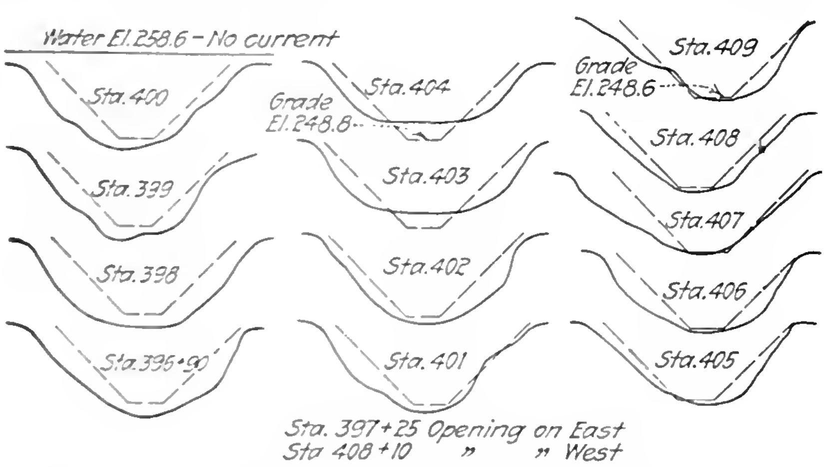


FIG. 5. SAMPLE OF DITCH CROSS-SECTION NOTES

intervals of 1000 ft., it was seldom possible to walk very far along the spoil banks without getting wet to the waist, as the openings usually had too much water in them for wading in hip boots, and we only used wading pants or "waders" when absolutely necessary and never in preference to a duck boat or dugout. After a few trials at walking along a new dump thrown up by a dipper dredge working in gumbo or clay one soon learns to use that route only when absolutely necessary to accomplish a definite object. It might be asked why the berms were not available for our work. This was due to their being under from 1 to 4 ft. of water for at least a mile behind the dredge, and they had a surface profile much resembling, on a large scale, the teeth in a cross-cut saw. This irregular surface was caused by the spud feet, or anchor feet, as all but four of the dredges used bank spuds. The spuds left depressions 2 to 4 ft. deep each time the dredge moved up. The surface of the berm was further roughened by the dipper when scraping loose stumps and roll from it.

After the ditch was chained, the elevation of the water surface was found and a gage set near the dredge, giving the cut from water surface to grade line. At least two benchmarks were used in finding this elevation. Where there was an appreciable current in the ditch, the elevation was taken at each end of the reach, and where the reach was long and had diversions into old channels intermediate elevations were necessary. A Chicago tape was then stretched across the ditch. The recorder handled the chain on one side while the chainman held the other end on the opposite bank and the rodman did the sounding from a boat which he pulled across by means of the tape. Three men were used for most of the work, but some of it was done with only two, and where the current or the wind was too strong to permit the boat being held in line by means of tension on the chain, a fourth man was necessary to row or paddle the boat. To standardize the work, the zero end of the tape was always placed on the east or south side of the ditch. The recorder also noted the visible defects, such as logs and loose stumps, on the berms or in the openings; loosened or overhanging stumps in the edges of the ditch; trees leaning toward the ditch and high stumps on the berms which had been overlooked or were inaccessible when clearing was accepted.

On the small ditches a piece of light rope was fastened to the zero end of the chain. The rodman would sound until he found the edge of the ditch and direct the shifting of the chain until the zero end was located at this point where the recorder would fasten it by means of a lining rod, set through a loop in the rope, into the slope of the spoil bank. On the larger ditches the zero end of the chain was placed on the base line and the soundings were thus accurately located with respect to the center line. When cross-sections were taken on pilot cuts where the spoil had all been placed on one side, it was usually necessary for the man holding the tape, on the side having no spoil bank, to wear waders if the weather was cold, and sometimes the cross-sections had to be located at points where a high place was available for him to stand, the move from one point to the next being made in a boat.

When work was found to be above grade or too narrow, the contractor was required to correct it, and another set of cross-sections was taken.

Method of Recording

During the early part of the work the cross-section notes were recorded in the usual manner, the soundings replacing the rod readings and the elevation of the water surface replacing the usual H. I. The reductions to sea-level datum were then made by subtracting the soundings from the elevation of the water surface, and the cross-sections were plotted and inked in. These sheets were sent to the main office, where blueprints were made, and returned to the resident engineer, who then issued orders for any necessary correction and mailed copy of the order and blueprint of the cross-sections to the contractor. As each engineer had supervision over the work of about nine dredges during the peak of the construction work, at least four of them averaging from one to two miles per month, the office work consumed time needed badly in the field, while the total time necessary to get the prints back to the contractor was still more important where the work was on small ditches. It took from one-half to one day to reach a dredge from a postoffice and it usually required a lot of difficult "hiking," wading and a long motorboat or "duck-boat" ride; so, due to the difficulty in reaching the dredge, the contractor rarely received mail more often than once a week.

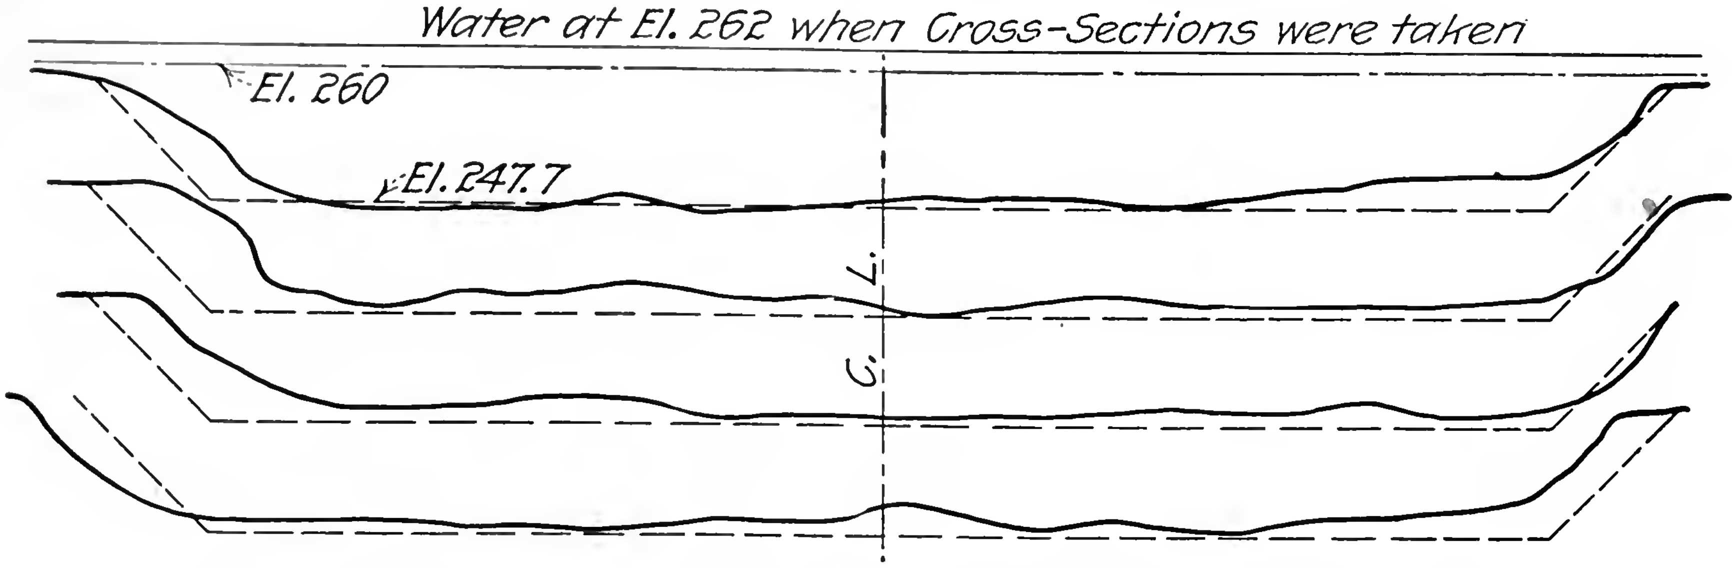

FIG. 6. CROSS-SECTIONS OF DITCH NO. 1 AS SPECIFIED AND AS FIRST LEFT BY DREDGER

The contractor supposed that the work was properly done. The example shows the need of a base line to obtain proper alignment when bringing ditch to grade. This ditch has a base width of 123 feet.

By the time the order reached him the dredge would be about a mile from the work requiring correction.

An improvement in the method of recording the notes was suggested. It received a trial and was found practicable for the small ditches where the need for a quicker method was so apparent in order to cut down delay in "kicking back." This delay was serious at times where it caused the recrossing of a river or slough which had a swift current flowing out of, or across the ditch. The method involved the use of specially made up blocks, or tablets, of cross-section paper held in a suitable stiff-backed cover. The tablets were of letter size, composed of thin paper ruled each way into ten divisions to the inch, with every third sheet blank or unruled. Instead of giving the heavy lines an even sea-level elevation, the heavy line was used as the water surface and the soundings were plotted down from them as the rodman called them off. Three copies were made by the use of carbon paper and a hard pencil in plotting. The distance from the water surface to the grade line was computed and marked on each section. Templets having the specified slope and bottom width, to a scale of 10 ft. per inch, were cut from thin celluloid. The proper templet would be laid on the section, centrally located with respect to the section as excavated, and with its base coinciding with the grade point. The theoretical prism was then drawn in and the amount of material, if any, inside the specified lines would be indicated. The order was then written and delivered to the contractor, along with the unruled copy of the cross-sections, before the work was left. The second copy was kept in the resident engineer's file, and the original was inked in and mailed to the chief engineer. The elevation of the water at the time the sections were taken was recorded on the sheet so that they could be referred to sea-level datum if desired. When the method was proposed it was feared that tablets bound so that the ruling would coincide would involve an excessive expenditure, but no difficulty was encountered in procuring tablets of this size, bound in this manner, at a reasonable cost. A "Lyflat Holder," sold by Buxton & Skinner of St. Louis, was used as a clip for the tablets in the field. Fig. 5 is a sample sheet of notes recorded in this manner.

On the larger ditches the work progressed more slowly in distance covered, and the need for quick service was not so much felt. The handling, in the field, of a book large enough to permit the plotting of sections having a top width of 150 ft. would be somewhat difficult, so no tablets were made for this class of work. The notes were recorded in a notebook, reduced to sea-level datum, and platted in the office. On these ditches the cross-sections were taken from a base line parallel to the center line. While this was not considered absolutely necessary, except when the cross-sections were used to compute the quantities, it was the means of settling several arguments due to the dredge operator on the night shift "getting lost" and departing badly from the line, and also permitted us to secure a better alignment when sections showed the excavated prism to be too narrow. Fig. 6 illustrates an extreme but actual case of this kind. With the sections referred to a base line, it was at once apparent which side should be widened, while without the base-line control it was impossible to tell this unless the water was low and the contraction of considerable magnitude.

Sounding Line Used

During the early stages of the work the sounding was done with a level rod, but the disadvantages connected with its use were so numerous that other means were tried until a satisfactory one was found.

The soundings often ran as deep as 15 ft., and in an extreme case 22 ft. A level rod was useless at these depths. Even at depths up to 8 ft. it was extremely tiresome to work with even a very light rod made for the purpose, due to its resistance to lateral movement through the water and because one hand only was available, the other being occupied in moving the boat along the tape. The figures being necessarily small, it was difficult from a standing position to read the rod at the water surface. We found it impossible for the rodman to tell, from his position in the boat, when the rod was plumb. In order to make any time at all with a rod, it had to be drawn nearly out of the water while moving laterally, and then thrown down with considerable force to overcome buoyancy and the lateral forces of the wind or the current.

There is found in the bottom of all dredge ditches in silt or clay soil ½ to 2 ft. of thin mud. It requires very little pressure on a thin rod to cause it to penetrate this slush, and the force used in throwing the rod down is usually sufficient to cause it to sink through the semi-fluid mud. While this gives the true value of the depth actually reached by the dipper, it gives a more or less false value with respect to the actual amount of material removed. The use of a spread footing or shoe to

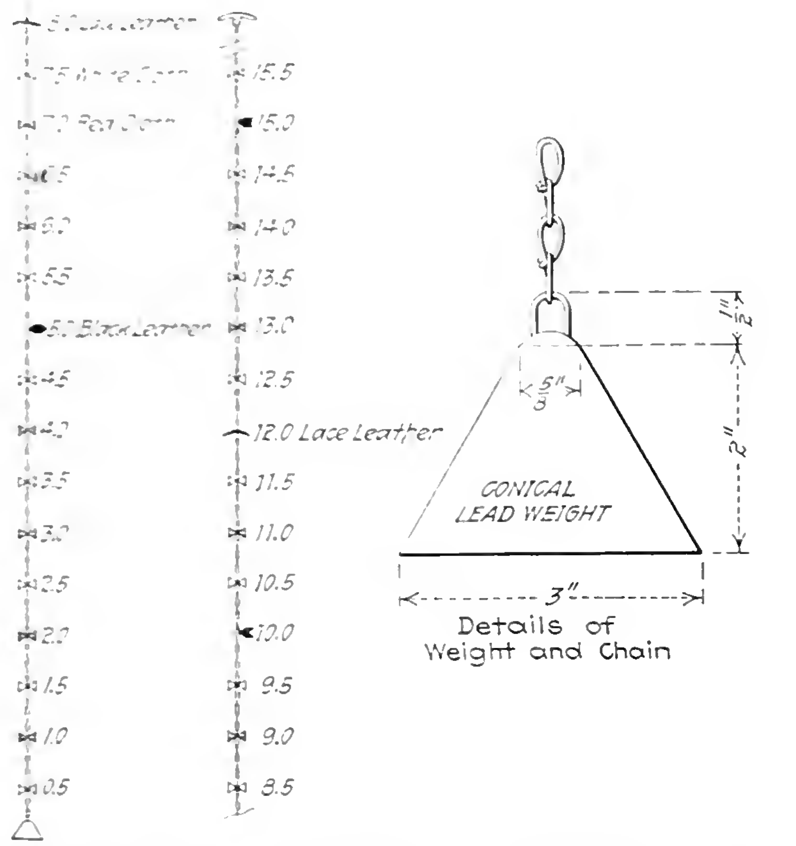

FIG. 7 SOUNDING LINE USED ON DRAINAGE DITCHES

increase the bearing area of the rod was not practical, as it in no way helped the resistance to lateral movement, made the rod harder to handle vertically, and slowed up the work. It is easy to see that the errors incident to the use of a rod are all in the contractor's favor, and a few of them made verbal complaint when its use was discontinued.

Three Kinds of Chain Tried

When looking for a means of overcoming these difficulties, a lead line, such as is used on the river boats, at once suggested itself. We required greater accuracy than that required on a river boat, and a chain promised to give better results than a rope, both as to constant length and ease of marking. Three kinds of chain were tried before one was found that gave satisfaction. First, brass sash-chain was tried, the links of which were stamped from sheet brass and looped through each other. This was far from satisfactory. When the weight caught on a root or other projection under water, and the 18-ft. chain was subjected to considerable tension, it would permanently increase in length 0.3 or 0.4 ft., and when accidentally stepped on while in the boat the links would be flattened and the chain would lose much of its flexibility. A steel chain was then tried, the links of which were made up of flat steel wire. This chain stood the accidental strains put upon it without material increase in length, but tangled and kinked to so great an extent that it had to be abandoned. Finally, a chain having locked links made of No. 18 round steel wire was tried and answered all the requirements. (See Fig. 7 for a sketch of the system of marking and details of the chain and weight.) The marking of the chain proved a simple problem, as 0.5-ft. intervals made it possible to read to within 0.1 ft., which was a greater refinement than is justified with dipper-dredge work.

A leather tab was sewed at each 5-ft. mark. The intermediate footmarks, with the exception of those at 8 and 12 ft., were indicated with small pieces of red cloth tied through the links nearest the correct distance. Pieces of lace leather were tied at the 8- and 12-ft. marks, as depths 1 ft. either side of these marks prevailed. Small strips of white cloth were used to indicate the 0.5-ft. marks.

The weight was made of lead or cheap babbitt metal cast in the form of a cone, with a wire staple projecting from the top. Two pounds proved ample to weight the line on a greater part of the work. Where more weight was found necessary an iron nut or some washers placed over the weight furnished the additional stability. With this weight and line, the measurements, or soundings, were those along a plumb line, except in swift water, and as the chain offered very little resistance to water it had only to be lifted a foot or so when moving to the next point.

With the chain taut, the weight used was not heavy enough to penetrate the slush, and therefore the results more nearly approximated the correct ones. Some of the contractors objected to this method, on the ground that on other work, which had been sounded with a pole, the slush was disregarded. In other instances, where the contractor had previously sounded the ditch with a pole and found it apparently to grade, and our measurements would show it above grade, the contractor had to be "shown" by checking the line and measurements.

Only Small Quantity of Work in Swift Water

On stretches of pilot cut connecting two reaches of finished ditch, which were short enough to act as contractions in the larger channel, the current was, at times, too swift for accurate work with the line, but this objection also applied to a rod, and as dams were placed across them except during a high water, the quantity of work that was done in really swift water was comparatively small.

The chain was checked up at least once a month, and the placing of the marks was corrected if the error was found to be sufficient to justify it.

After the stakes were set and other preliminary work was done, this method permitted us to cross-section 50 stations of the largest ditch in ten hours. These cross-sections averaged 30 soundings each, making possible a total of 1500 readings per day and representing 250,000 cu.yd. of excavation. There were only a few instances where there was enough work to require a full day of straight sounding.

While it is departing somewhat from the subject as indicated by the title, it may be of interest to some to mention another detail of the construction work, illustrating the difficulty encountered in doing work which in principle is the limit of simplicity. It was required to set slope stakes on each side of the ditch across a flag field one-half mile long. The ground was near enough a plane to permit the stakes being placed in a straight line. The obstacle consisted of 5 ft. of water and 1 ft. of soft mud. Ten-foot "stakes" were used, and the rodman worked in a boat. A fore-sight was set from a reference point by working in boats. The instrument tripod was made 10 ft. long by splicing poles on the legs with wire. The instrumentman lined the stakes in from a boat held in position behind the instrument by means of more poles. There were other cases where compass lines were run in this manner.

L. L. Hidinger is chief engineer of the Little River Drainage District.

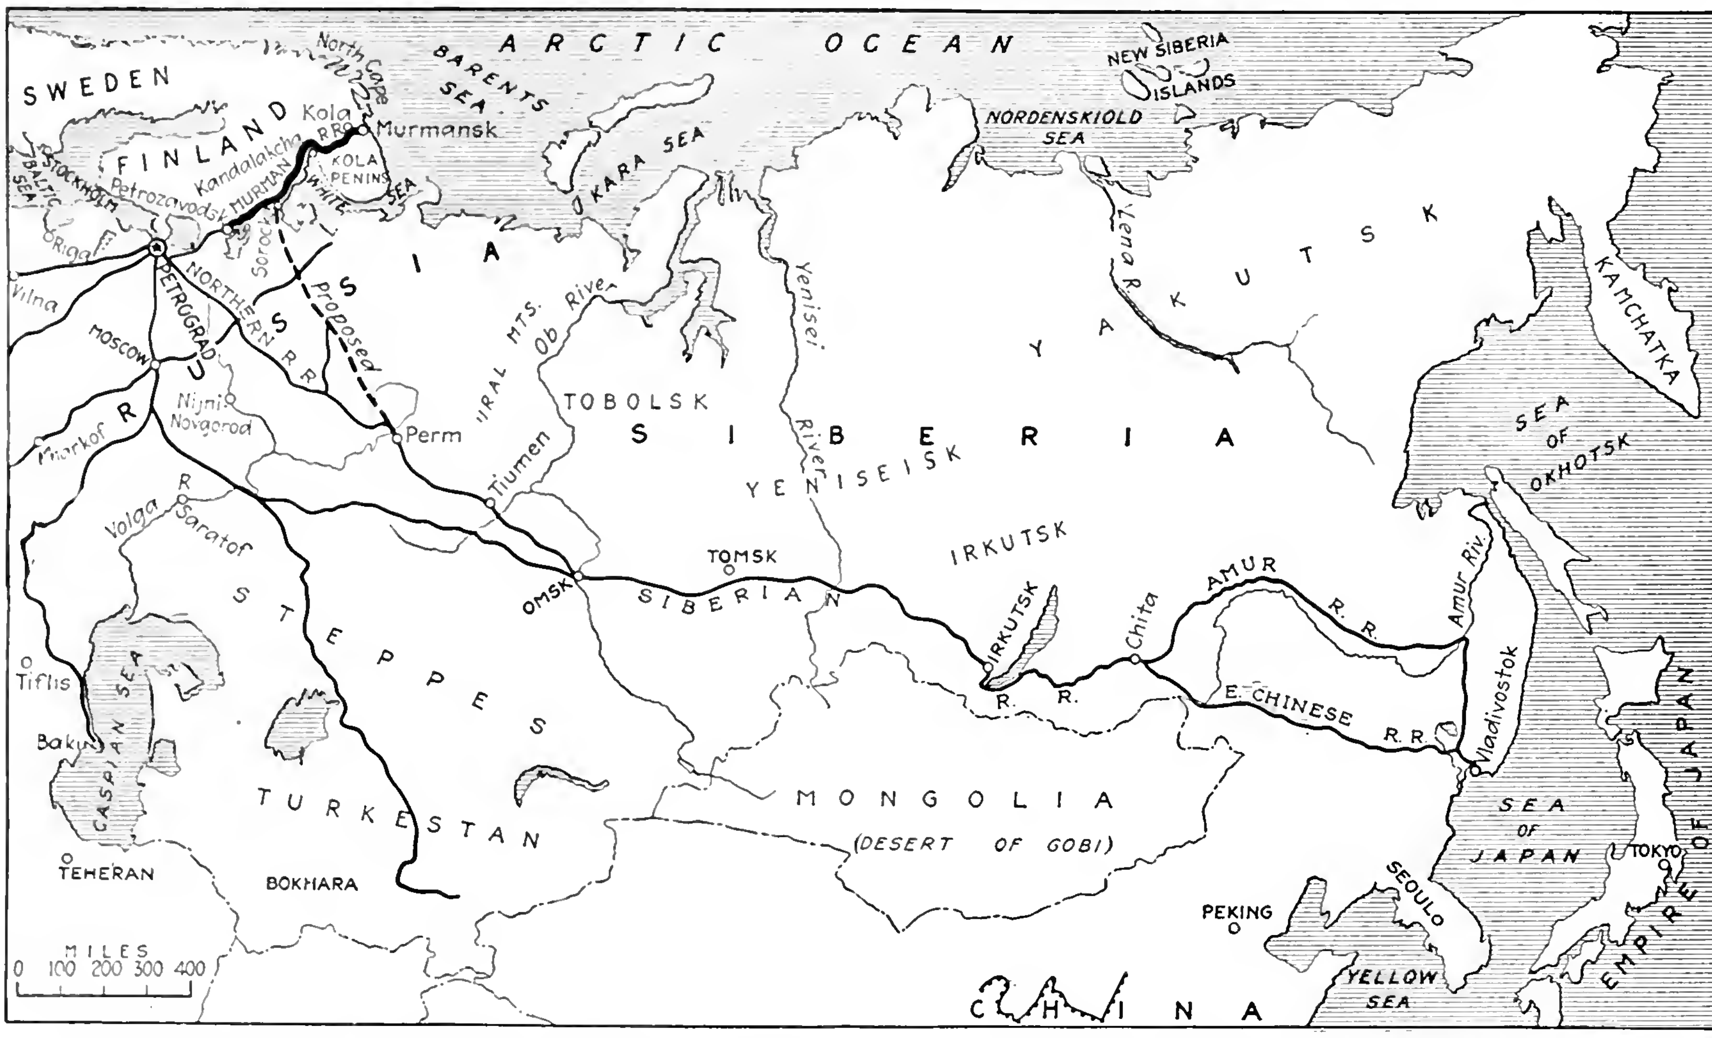
Murman Railroad: New Outlet to Sea in Russia

Ice-Free Port on the Gulf of Kola Is Reached by Connection From Northern Railroad—Freight From Siberia for Export Provided With Shorter Route

By V. Goriachkovsky
Vice President, Youroveta Home and Foreign Trade Company, Incorporated, New York City

VAST possibilities for development of Russia as soon as conditions become settled make a description of the railroad connecting the new port of Murmansk, situated on the Gulf of Kola which never freezes, although it is one of the most northerly ports in Russia, of special interest at this time. This road was built during the second year of the war as a result of the necessity for Russia to have a direct connection with the allies. All communication through the Black Sea was cut off when Turkey declared war and closed the Dardanelles. The Baltic Sea was closed by Germany. The only access left was through the north, by the White Sea and Archangel harbor, but the latter is closed every year for a period of five to seven months during the winter when drift ice clogs the White Sea outlet to the Arctic Ocean, and renders navigation impossible. This article outlines the general conditions and the details of the construction of the Murman R. R., 650 miles long, successfully completed in 18 months, beginning in the spring of 1915, with the author as chief engineer. While this article is based upon an informal address delivered at a meeting of the American Society of Civil Engineers in New York, additional descriptive matter has been introduced.

Starting from the port of Murmansk on the north, located on the Gulf of Kola, which, owing to the Gulf Stream coming from Central America around the Norwegian coast, is open to navigation all the year around and has natural facilities making it accessible to ocean-going steamers of the largest tonnage and deepest displacement, the Murman R.R. follows the Kola River valley, near Imandra Lake, up the Neva River valley, spans Kandalakcha Bay, touches the towns of Kem and Soroka, and reaches the town of Petrozavodsk. From this point to its connection with the Vologda-Petrograd R.R. at Zwanka, the railroad was formerly privately owned. The new road was projected in 1915 as a Government railroad to connect with the latter existing road, which was then bought by the Government. It was laid out by the late Czar Nicholas personally, who wanted the railroad constructed on old Russian territory and not through Finland, on the advice of his short-sighted experts and friends.



PRINCIPAL EXISTING RAILROADS IN RUSSIA AND PROPOSED CONNECTION WITH NEW MURMAN RAILROAD

The line of the Murman R.R. runs along the eastern part of the so-called Scandinavian Shield territory. This territory was profoundly affected by the glacial epoch; the powerful glaciers descending from the Scandinavian Finnish heights brought great destruction and deposited masses of glacial material in their wake. When the ice melted away, the numerous basins and hollows became filled with water, and gave origin to lakes, many of which have either entirely disappeared, or have been transformed into marshes and turf pits. The railway, therefore, was built partly through mountainous country of irregular hills of granite and partly through swamps divided by lines of mountain rocks, or along the steep slopes of rivers and lakes.

The climate, of course, was very severe, with long winters. The first snow falls on the Kola peninsula in August. The mean temperature in winter is 14° F. During the winter months the thermometer hovers around —23° F. There is no sunrise during two months, a period known as the "polar night." It is fairly warm in summer, with a mean temperature of about 51°, and the sun does not descend below the horizon at all; this is the season of the "midnight sun."

The port of Murmansk lies nearer to America than any other Russian harbor, and is nearer to Siberia than any other ice-free port in Europe. As soon as the new railroad from Soroka to Perm, noted on the map by the dotted line, is built, the freight from the Ural region and from western Siberia can be shipped to Archangel and Murmansk, as the distance by this route will be considerably shorter than that by Vologda. Thus the distance from Perm or Omsk to Archangel will be reduced by 282 miles, giving Archangel a tremendous advantage over Petrograd, as during the winter, when the port of Archangel is covered with ice, the freight for shipment abroad will be sent by Murmansk, which is 133 miles nearer Omsk than is Libau. The latter port before the war was the harbor for importing to Siberia

TYPICAL CUT THROUGH GRANITE OR DIORITE

all American goods, and for exporting a million tons of goods, mostly butter, from Siberia.

Siberia ships such products of animal husbandry as butter, cheese, meat, bacon, hogs, bristles, wool, etc. In the eastern direction American agricultural implements, dredging machinery for the mining industries, steam shovels and road-building machines, separators for milk, turbines, timber-sawing machines, chemicals, automobiles, cloths, cotton, etc., are transported.

In addition to the through freight, this proposed new connecting line would carry a tremendous quantity of local shipments. It is stated by Professor I. D. Simpson in the *London Geographical Journal* of June, 1918:

"I believe that this region will one day prove to be something infinitely more profitable to Russia than Alaska has proved to the United States."

As it was expected that the future trade through the new harbor would be large, the harbor of Alexandrovsk, which had been selected many years ago by Count S. Witte, was examined to see whether it was sufficiently adapted for the purpose. It was found that the bays were surrounded by high granite cliffs without sufficient space near the water for placing a big railroad terminal with the necessary tracks, yards, etc. For this reason Alexandrovsk had to be abandoned and another location sought. Finally, in the Kola inlet near the Semenovo Islands was discovered the location for the future harbor, which the author named Murmansk. This location was selected as the best harbor in the whole Kola Bay, which is here 1½ miles across and 32 ft. deep near the piers and 70 ft. deep in the middle.

Country, Inhabitants and Occupations

The country over which the railroad is located is unexplored. The difficulty in traveling prevented the making of geological surveys, although iron ore and silver lead ore are found in many places, and traces of gold have been found. Copper ore and zinc, also asbestos and mica, have been discovered in several locations. The population is small; before the railroad was constructed there were only 14,000 inhabitants, consisting of Russians, Lapps, Finns and Karelians, in the Kola peninsula. Here the Russians were never under the Tartar yoke, and therefore speak very pure Russian. The first Russian settlement at Kola is recorded as early as the year 1264. Agriculture and animal husbandry are undeveloped. Among the domestic animals are reindeer, for transportation of mail and passengers, but few cattle and horses. The chief occupation is fishing.

The lumber trade is of great importance, the country in northern Russia being covered by forests exceeding 325,000 square miles in extent. For the most part these forests have not been explored, except along the banks of rivers where rafting is possible. The best forests, with very thick growth, are near the southern part of the railroad in the Olonetz district, and further from the sea in the Kem district. There is very profitable hunting for wild birds and wild animals. There are no roads, the inhabitants do not know what a wagon is, and to communicate in summer they use rivers and numerous lakes, although traveling in canoes is difficult because many cataracts make portage necessary.

Surveying had to be begun in the winter of 1914-15 in order to prepare for construction in the summer, beginning in the month of May. There were very few villages along the proposed line, making it necessary to live in tents or sometimes to sleep in a sledge with the temperature far below zero. For the survey and construction of the railroad the whole line, 650 miles long, was divided into three administrative districts: First, from Petrograd to Soroka; second from Soroka to Kandalakcha, and third from Kandalakcha to Murmansk. At the head of each district was a special assistant engineer, who had had wide experience in railroad construction in rugged sections of Siberia; to these were subordinated the section superintendents, each of whom was in charge of about 50 miles of line.

There were no previous surveys available except one of the first district, which was made about 15 years before. The maps of that territory were by no means exact or detailed, having been drawn on a scale of 1 in. : 10 versts (6.63 miles); these maps were not based on measurements but were composed principally in accordance with data obtained from local forest administrations, from inhabitants or travelers. They could be used only for preliminary and approximate figuring, as they contained neither altitudes nor exact distances. In the second and third districts preliminary surveys had to be made in the winter in order to obtain necessary al-

titudes by the aid of barometers, while in laying out the first districts the previous survey could be used for data on altitudes and location of river beds.

The leader of each surveying party received detailed instructions regarding the layout of the proposed line, and also auxiliary tables to aid in the location of stations and passing sidings. It was required to survey a single-track line with a capacity of seven daily trains in each direction for the first year, but with a view to allowing 13 trains in laying out first-class sidings, and finally increasing the capacity to 23 daily trains in each direction after the second-class sidings are laid. The theoretical running time of the trains between two consecutive stations was calculated, and tables were prepared giving the speed of normal trains pulled by standard locomotives on various grades, curves and straight sections. By the aid of these tables it was easy to compute the required traveling time from one station to the following.

All the calculations of distances were based on tape measurements in the field,and all altitudes were determined by the aid of leveling instruments. When the running time of trains had been calculated according to the tables, a suitable level site was selected for the future station. From there the engineers started again in the direction of the line and continued their reconnoissance, while separate parties of engineers remained on the line already determined in order to prepare profiles of especially difficult sections and to locate the line on slopes so as to minimize the amount of earthwork. As the territory was entirely without population, the location of the stations was determined exclusively by the endeavor to apportion the distances between stations as nearly as possible in accordance with the required running time of trains.

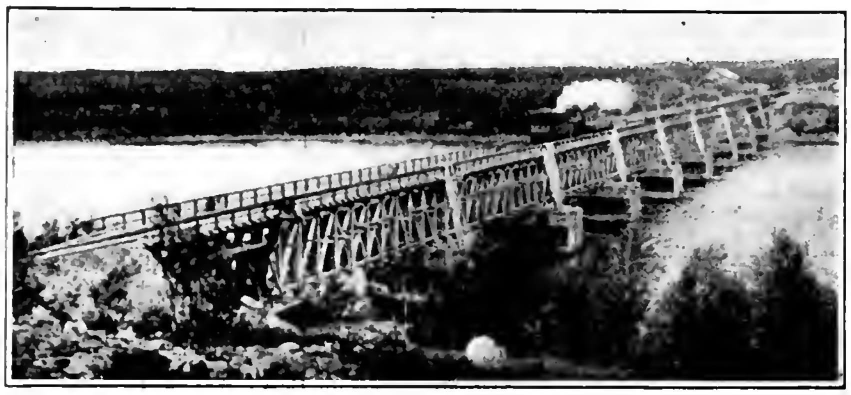
The specified conditions for the construction of the road were as follows: Minimum radius of curvature, 2100 ft., although in special cases 1050 ft. was used; 0.6% maximum grade from Soroka to Murmansk and 0.8% from Soroka to Petrozavodsk. In order to accelerate construction and reduce the amount of earthwork the road, however, was built on a 1.5% grade. The restoration of the originally planned 0.8% or 0.6% grade will require little reconstruction as the excess grades are nowhere of great length, and the track will remain in the same location.

Construction of Bridges

The bridges across all rivers and creeks are of wooden construction and designed to be easily replaced by permanent bridges later on. Therefore, at the larger rivers they were built on auxiliary lines, so that the future permanent steel bridges could be constructed on the main line alongside the wooden bridges without interrupting traffic. The small wooden bridges will be replaced later by stone culverts, and their construction was such as to permit the setting of the masonry supports without interfering with the movement of trains.

The bridges, 1112 in number, of timber construction, were designed with a view to reduce the amount of iron to a minimum and to use the simplest type. They were standardized as follows: Spans of 14 ft. or less, plain round logs; spans from 14 ft. to 35 ft., braced timbers; spans from 35 ft. to 70 ft., special trusses consisting of upper and lower chords connected by a system of diagonals and vertical web members. The trusses were as simple as possible; for example, the web members were not hewed to cylindrical shape, but butts and tops were joined alternately; all connections were made without notching or rabbetting the logs, using steel plates and screws. The bridges were tested by loading with two locomotives and a loaded train.

Foundations for the wooden bridges were usually of piles, except in stony ground where boxes, constructed of logs and filled with stones, were used. These boxes or cribs, in the case of the swifter rivers, were constructed



TEMPORARY BRIDGE ACROSS KEM RIVER—800 FEET LONG, 70-FOOT SPANS

with double walls and with a bottom for the inner compartments only. This was found quite effective in preventing washouts in the spring torrents, the stone contained between the two outer walls of the box dropping down to fill the place of material under the base, it being necessary only to fill up with stones the outside compartment of the box when the contents had settled.

Special Difficulties at Swamps

The swamps needed special examination, and had to be thoroughly explored. These swamps, covered by deep snows, never freeze. Their depths were determined by long poles, the shallow places being designated on the surface by yellow flags, while the deep places were indicated by red flags. Separate crews of workmen assigned to this work facilitated the final survey. The swamps consisted mostly of peat, which filled them to the bottom. These swamps covered more than 200 miles, or about 30% of the line. The laying of the line on this swampy ground required special and different methods of construction. Very often a temporary line, consisting of a number of longitudinal and traverse beams, had to be laid first, partly with the object of allowing the first train to go through and make it possible to fill in the swamps with sand and gravel.

Laying the track followed immediately after the construction of bridges, embankments and cuts, and had to be carried on through the autumn and winter. As the work was very urgent, track-laying continued throughout the 24 hours of the day. For making embankments and excavations 100,000 workmen and 15,000 horses were needed, 30 big steam shovels, 120 miles of light, narrow-gage railroad, 20 locomotives and about 2000 cars. The final work was completed during the summer of 1917, when embankments were raised and cuts were deepened, so that the grades became easier, sharp curves were reduced, and the greater part of the road-bed sufficiently ballasted. Sidings were laid out, and at the stations double, independent water-supplies were constructed, and preliminary wooden roundhouses and locomotive shops for small repairs, with offices and warehouses, etc., were completed. All the buildings were of

WAGON ROAD THROUGH SWAMP OVER WHICH THOUSANDS OF TONS OF MATERIALS WERE TRANSPORTED

wood, even the water towers, which were completely equipped with pumps and vertical boilers. Movable electric stations were placed in box cars, with all equipment necessary to furnish electric lights. In Murmansk a big electric station was constructed for the purpose of lighting up the harbor, terminal station, roundhouses, houses and barracks.

The last spike was driven Nov. 5, 1916. Of the whole of the 650 miles of the Murman railroad, 30% is above the polar circle, making it the most northern railroad in the world. As soon as the last rails were joined traffic started, although unfortunately the allies had not felt that the road would be open so soon and had sent to Vladivostok most of the munitions, 750,000 tons of which never reached the front. As a result, the Murman railroad was idle until January, when the first steamer arrived at Murmansk. From that time, in the most busy month the average number of cars loaded with war goods was 120 a day, about the same number as was being loaded and shipped from Vladivostok, which is eight times further from the front than Murmansk. All munitions arriving at Murmansk were successfully transported to the front.

Construction of Piers at Murmansk

Most of the ports in Russia are similar to those of the German type, with long wharves or quays following the shore line and with warehouses, parallel to the tracks, for storage. In the design and construction of the port of Murmansk, the American system of separate piers at right angles to the shore line was followed. These piers are of timber construction built on piles; the tracks on the piers were located so as to bring the cars alongside the steamships. Most of the incoming cargo had to be unloaded by the aid of deck cranes on the ships and then transferred to the port warehouses by trains. For unloading heavy units a traveling locomotive crane of 20-ton capacity was used; for freight exceeding 20 tons a floating crane of 35-ton capacity was employed.

There are no warehouses on the piers, as the latter are intended only for transfer of freight from steamships to cars, or vice versa. In 1917 several piers were completed which provided unloading facilities and mooring space for seven ocean-going steamships.

There were excavated about 15,000,000 cu. yd. of earth; more than 50% of this excavation was transported to embankments, an average distance of about 3000 ft. Excavations in granite were blasted out by dynamite, and amounted to about 2,000,000 cubic yards.

Workers were gathered from all parts of Russia, Siberia and the Caucasus, and included Russians, Poles, Tartars, Armenians, Kirghes, Kalmuks and prisoners of of war—Hungarians, Germans, Turks, Austrians—and even Chinese, altogether more than 100,000 men. Many troubles arose because of the differences in customs, religions and races. Slavonic prisoners always fought with the Germans and had to be separated from them. The Tartars refused to use meat, as the cattle were not slaughtered according to their religious custom, and they carried their prejudice even to the point of refusing to use the meat brought in the same wagon as that used by the Christians. The Mohammedans in Murmansk refused to eat food, recently arrived from America, when, according to their religious rules they must fast until sunset, and as it was then summer, when the sun does not set in Murmansk, it was necessary to bring them to Kandalakcha where they saw the sun set behind the mountains, and thus their lives were saved.

There are great possibilities for engineering in Russia, which has only 43,300 miles of railways, while in America there are about 260,000 miles. Many towns are without public utilities and municipal improvements such as water-supplies, sewerage systems, electric-light and power stations, etc. Russia has immense quantities of various kinds of raw materials awaiting the reconstruction of her industries.

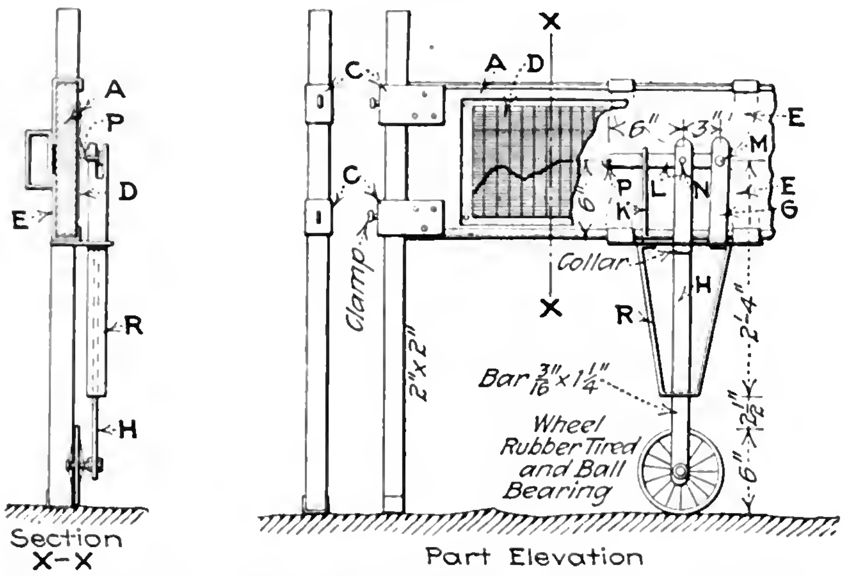
Contour of Pavement Traced to Exaggerated Scale

Device Measures Irregularities of Surface and Plots Profile With the Ordinates Multiplied by Three

MEASURING the irregularities in the surface of pavements and plotting them to an exaggerated scale on paper is performed by the instrument developed by F. A. Hermans, engineer of grade crossings, New York State Highway Department. While the method is somewhat similar to that described in *Engineering News-Record* of Oct. 17, 1918, p. 708, the exaggeration of the variations is said to be distinctly new. This feature should make it easier to study the results of a series of measurements where differences are small.

Referring to the diagram of the apparatus showing the details, A is a dressed plank of any desired length having two clamps, C, at each end. Through these clamps two square rods pass, which support the plank in a horizontal position. D is a suitably ruled piece of paper which is tacked to the plank. L is a lever pencil arm which is pivoted to the support at M and has a pencil point at P. A frame E buckles around the plank top and bottom and holds the support for the pencil arm and the guide for the vertical arm H. As the vertical bar attached to the wheel moves up and down, due to the irregularity of the surface, these irregularities are traced on the paper, three times their actual size. This results from the pencil arm being divided between the pencil and the fulcrum as 3 is to 6, by the point of connection with the vertical arm H.

When it is desired to map the surface of a pavement, the apparatus is set up at the proper elevation, and the



PIVOTED PENCIL ARM WITH UNEQUAL LEVERAGE EXAGGERATES VERTICAL VARIATIONS OF SURFACE

paper is tacked on at any desired height with reference to the pencil point at the point of starting. The frame E is then slid from one end of the plank to the other, the pencil marking out the profile. It is believed that a small knob would be better than the large 6-in. wheel, as it would register more truly the undulations of the pavement.

By setting up the device in connection with a bench mark, and placing the zero line of the paper horizontal and at the same elevation each time, seasonal variations may be measured and studied.

It is also asserted that the instrument is useful for studying variations caused by the shoving of asphalt surfaces due to traffic, the spreading of road crusts, and the amount of wear in a road under various concentrations of traffic.

Mileage of Main State Highways

State highways in the United States which come under the classification of main highways total about 203,523 miles, according to statistics just compiled by the American Automobile Association. Forty-four states have established definite systems of trunk highways, either by legislative action or action by state and local officials. It is pointed out that if the Federal Government takes over a system of from 50,000 to 75,000 miles it will cut the state systems by only from 20 to 25%, which would not affect materially the necessity for state highway departments.

The mileage of main state highways by states is given in the accompanying table that has been issued by the association:

State	Mileage	State	Mileage
Alabama	2,700	Nevada	1,400
Arizona	1,600	New Hampshire	1,390
Arkansas	3,000	New Jersey	3,147
California	3,000	New Mexico	6,250
Colorado	7,083	New York	12,287
Connecticut	950	North Carolina	3,356
Delaware	650	North Dakota	4,000
Florida	Not given	Ohio	9,880
Georgia	5,500	Oklahoma	10,700
Idaho	2,200	Oregon	4,805
Illinois	4,800	Pennsylvania	10,235
Indiana	2,000	Rhode Island	800
Iowa	6,000	South Carolina	2,550
Kansas	......	South Dakota	6,000
Kentucky	8,000	Tennessee	Not given
Louisiana	5,000	Texas	12,620
Maine	1,353	Utah	3,660
Maryland	1,300	Vermont	4,300
Massachusetts	1,200	Virginia	3,740
Michigan	4,500	Washington	3,374
Minnesota	12,700	West Virginia	4,600
Mississippi	......	Wisconsin	5,000
Missouri	7,500	Wyoming	3,100
Montana	2,400		
Nebraska	4,000	Total	203,523

Arizona Has New Water Code

By G. E. P. Smith
Professor of Irrigation Engineering, University of Arizona, Tucson, Ariz.

Arizona is to have a comprehensive water code, passed by the legislature just at the end of the session, although the opposition was so strong as nearly to defeat the bill. The main purposes of the code are the protection of vested and initiated rights to the use of water, protection of the interests of the public in the water-supplies, and encouragement for the highest possible development of such supplies.

Arizona, like 15 other Western states, will have one central office, where landowners and investors will be able to ascertain the extent of stream flow in any watershed and the existing rights to its use. The office of state water commissioner is created. Unusually great authority is centered in the commissioner, but provision is made for the right of appeal in all cases to the superior courts. The commissioner is appointed for a long term, six years, and it is hoped that the state water department will be and will remain absolutely divorced from politics for all time.

In the provision for the adjudication of all existing water rights, the code follows closely the Oregon method, which is based on the Wyoming law—but with certain fundamental improvements. After the accumulation of the data needed for the determination of water rights on a watershed, and after hearings of contests, the commissioner will prepare an order of determination, showing priority and extent of each water right. This order will be filed in the superior court, where additional hearings will be held before the order is affirmed by the court, but the order of the commissioner "shall be in full force and effect from the date of its entry in the records of his office."

Water Distribution Supervised

For supervision over the distribution of water, the state will be divided into water districts, each with a water superintendent and assistants. In general, the code permits the supervision to extend down to the individual water users, but on account of the opposition of certain valleys in which court decrees have already been obtained, all decreed rights are to be recognized *in toto*, and such rights will be incorporated into the orders of determination covering entire watersheds. The only objection to this is that in some cases excessive rates of flow have been decreed. The state water commissioner will divide the water of a river between the court water commissioners and such others as are entitled to its use.

The law provides for the approval of plans for dams and for inspection during construction, and for investigations of the water resources of the state. It contains the reciprocity clause of the Oregon code, providing for diversions in one state for use in another, and it contains the noncapitalization clause of the California law. It provides a special appropriation of money for the adjudication of the Gila River, exclusive of the Salt, and that will be the first work undertaken. The waters of the Gila are used in eight counties, and heretofore there has been no adequate legal machinery for determining relative rights in two or more counties.

The transference of water rights was the subject of much contention. As finally passed, the law permits

the transference of rights "if for any natural cause beyond the control of the owner it should at any time become impracticable to beneficially or economically use water for irrigation of any land to which water is appurtenant." In such case the right may be transferred "to other land under the same canal."

LETTERS TO THE EDITOR

Comment on Matters of Interest to Engineers and Contractors Will Be Welcome

Takes Exception to Classification of Railroad Engineers

Sir—The inclosed clipping [reproduced below] from the May issue of the *Monad*, published by the American Association of Engineers, should be a matter of concern to every technical engineer who regards himself as a professional man and looks forward to the day when an enlightened public shall accord him the recognition and esteem which his attainments warrant.

It is generally conceded, among engineers, that most of our present-day difficulties in securing recognition arise from our past failure to consider our own welfare, either as individuals or as a profession. Our sins have been of omission rather than of commission, and it is true that we have harmed only ourselves. It is just as true that we are beginning to see our mistake and are trying, to a certain extent, to go back and get a fresh start. A classification of railroad engineers such as this, emanating from such a source, sets a precedent which, if allowed to pass unchallenged, may prove a hindrance to our efforts. An exception to it, taken at this time, may rob it of much of its unintentionally harmful effect. As one engineer who hopes for a bright and useful future for his profession, I take that exception.

Cleveland, Ohio. ERNEST R. TAYLOR.

[The clipping referred to above follows.—EDITOR.]

JUST THE THING WE PROTEST

CLASSIFICATION OF ENGINEERS REQUIRED

(Supplement No. 15 to Circular No. 2—Rates of Pay, Men With Technical Training.)

It has been ruled by the Director, Division of Operation, that assistant civil engineers, draftsmen, or other men of technical training or experience who are not employed in the Maintenance of Way Department but are on the staff of the chief engineer, valuation engineer, or the general staff of the Mechanical Department, and are not classified as officials, should be classed as clerks and come within the application of either Supplement No. 7 (Article 6) or Supplement No. 8 (Article 2) to General Order No. 27.

Criticizes the Seelye Joint

Sir—In *Engineering News-Record*, of Mar. 20, 1919, p. 556, there is illustrated what is termed the Seelye joint. This is a method of joining wood timbers where under tension, as in roof trusses.

This joint is an adaptation of the old mortise bolt which is quite common in various kinds of wood framing but which has not been used in the particular manner described, for obvious reasons.

The Seelye joint, at the junction of the end rafter and the bottom chord, has no provision for vertical shear. The majority of roof trusses have a knee-brace near the end of the bottom chord, which brace exerts a vertical shear. There are also frequent loadings from the use of chain blocks or trolleys which exert vertical shear. To take up this shear, it is necessary to have the column cap, which Mr. Seelye illustrates as a part of the old-style truss. The cap should be placed under the Seelye truss and omitted in the old-style design. When the bottom chord of the truss projects beyond the end of the rafter, either an iron strap or a double timber dap will take up all the strain very nicely.

It is not economy to cut a vertical tie-rod in two pieces and make two mortise bolts, as Mr. Seelye illustrates in the vertical member of his truss.

No carpenter would consider making a clumsy tension joint in the bottom chord of a roof truss of the kind Mr. Seelye illustrates. If a tension joint is to be made it is customary to halve the two ends of the timbers for considerable distance back and introduce shear pins.

In general, the splicing of timbers for tension members is now nearly out of date. If a full-length timber cannot be obtained for the bottom chord of a roof truss it is preferable to use a built-up section. Five 1⅝ x 8-in. plank, surfaced on one side to uniform thickness, will make an 8 x 8-in. built-up chord, of which the tension value anywhere will be 52,000 lb., at an assumed tension value of 1000 lb. per square inch.

Los Angeles, Calif. MAX J. WELCH.

[This letter has been submitted to Mr. Seelye and he has made the following reply.—EDITOR.]

Sir—In reply to Mr. Welch's criticisms, I would submit the following explanations of the joint:

The vertical shear is taken entirely by the end post.

Loads, such as shafting, may be taken on the lower chord by the use of lagscrews or small bolts, as indicated in the original cut.

The purpose of the bolster in the old joint is to counteract eccentricity due to the fact that the lower chord transmits its tension to the end post three lugs in its top surface only.

As to economy, a contractor has recently adopted this detail for a large number of lower chord splices in preference to fishplates and laminated chord alternates.

Why should lower chord splices become "out of date" when our timber supply is decreasing in the large sizes available? ELWYN E. SEELYE.

New York City.

Quick-Release Keelblock Not New

Sir—The article appearing on p. 881 of your issue of May 1, entitled "A New Quick-Release Keelblock," is an example of the partial truth in the old saying, "There is nothing new under the sun." I do not wish to be understood as suggesting that the idea illustrated is not quite original in so far as Eugene Lantz is concerned, but I take this opportunity of advising you that similar wedge-blocks were used as keelblocks in repairing steamers for the Union Steamship Co. of New Zealand at its Wellington slipway and its dry dock at Port Chalmers, N. Z., as far back as 1901, and by the British Admiralty at the Calliope dry dock at Auckland, N. Z., about the same time. These instances are of my own personal knowledge.

Hans Berents, consulting engineer, of Shanghai, China, tells me that he used similar wedge-blocks in

the erection of the bridges for the Anhui Ry. in China in 1910. Mr. Berents points out the necessity for taking care that the tapered keys do not project at their small ends beyond the face of the block, so as to eliminate the danger of accidentally knocking the keys loose.

F. H. FRANKLAND,
New York City. Consulting Engineer.

Engineers' Estimates in Relation to Careful Bidding

Sir—Road-building is developing so rapidly that it promises to become one of the biggest industries in the country. Contractors who have heretofore done other work may engage in road-building before long. This makes careful and businesslike bidding exceptionally important, and leads me to venture a word of caution with respect to engineers' estimates of cost.

In states where bids must not go over the engineer's estimate it is very important that estimates be made high enough to allow making a reasonable profit. Otherwise the work will be improperly done by unscrupulous contractors, or small bidders will secure the work and carry it along very slowly and inefficiently—ultimately without profit to themselves and without satisfaction to the engineer.

Should the engineer give out his estimate? I have reluctantly concluded that he should not. Some contractors will bid on the engineer's estimate, which may or may not be prepared carefully. A contractor who guides his bid by the estimate may then easily get into debt; and, on the other hand, the contractor who has carefully investigated the work, and who should really build the job, has no chance in the competition. Several states, notably Pennsylvania, do not publish the engineer's estimate. The practice should be made general.

Kansas City, Mo. CONSTRUCTION ENGINEER.

Nomographic Chart in Cofferdam Design

Sir—In *Engineering News-Record* of Apr. 10, 1919, p. 708, was a very interesting article by F. R. Sweeny on the design of single-wall cofferdams. The author derives formulas for the spacing of the wales and the thickness of the sheeting, and shows how to apply these formulas by the use of a diagram and a chart accompanying the article.

The construction of the author's Fig. 2 and the table on p. 710 must have been quite laborious and time-consuming. A splendid opportunity is there afforded to show the superiority of the straight-line or nomographic type of chart over the ordinary rectangular coördinate diagram.

Fig. 1 is a chart for solving the author's Eq. 3.

$$D_N = 0.314\,\frac{d}{s}\sqrt{\frac{kb}{wc}}\ (\sqrt{N^3} = \sqrt{(N-1)^3}$$

A similar chart can readily be designed for Eq. 6.

In this diagram, every variable is provided for and a complete solution of each formula is obtained from the diagram, no table of correction constants being neces-

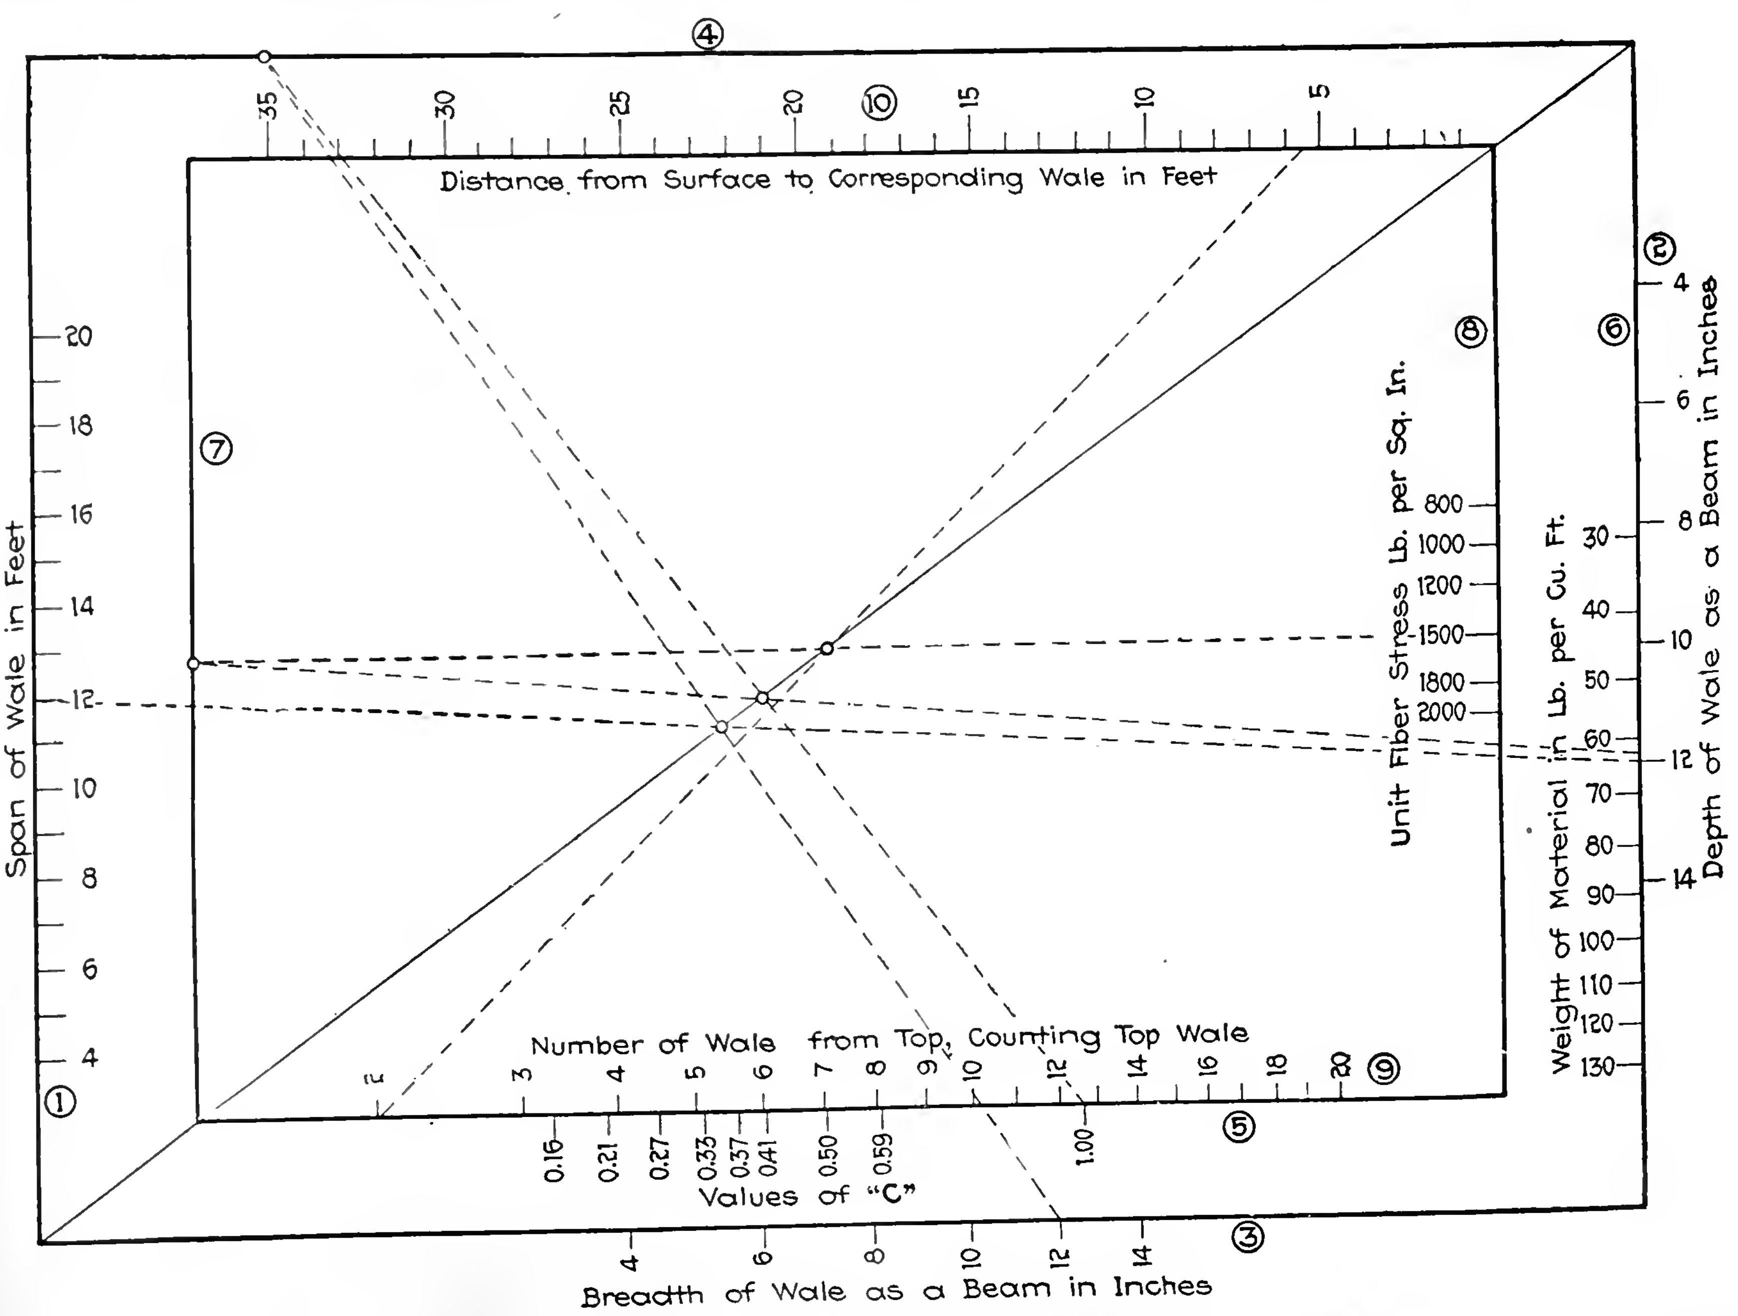


FIG. 1. NOMOGRAPHIC CHART DESIGNED FOR SOLUTION OF COFFERDAM SIZES

sary. All lines of the diagram are straight lines, which is a factor of great importance in all charts, both in construction and interpolation. The diagram can b constructed complete in less than two hours.

The method of using the diagram is as follows: Lay a straight-edge from the proper s on axis (1) to d on axis (2) and mark its intersection on the diagonal. Rotate the straight-edge about this last point and bring it to b on axis (3). Mark the intersection on axis (4). Rotate the straight-edge about this last point, and bring it on to c on axis (5), and then mark the intersection on the diagonal. Rotate about this point on the diagonal, bringing straight-edge on to w on axis (6) and then mark the intersection on axis (7). Hold this laast point and swing straight-edge about it to read k on axis (8), marking where the diagonal is crossed. Now by rotating the straight-edge about this intersection on the diagonal and bringing it to successive values of N on axis (9), the corresponding values of D and t may be read on axis (10). After a couple of solutions have been performed on the diagrams, the operation becomes almost automatic.

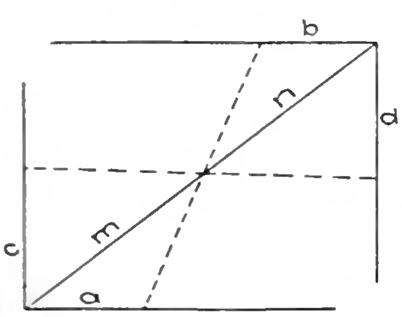

FIG. 2. BASIS OF CHART DESIGN

The chart is of the particular form of nomographs known as proportional charts and is based on similar triangles. In Fig. 2, $a/b = m/n$ and $m/n = c/d$, therefore $a/b = c/d$ where a, b, and c are certain functions laid off on the axes as shown to scales of S_1, S_2, and S_3 respectively. Then, if d is a fourth function laid off to scale S_4, where $S_1/S_2 = S_3/S_4$, the values of a, b, c, and d read on the axes will satisfy the equation $a/b = c/d$. This principle may be extended to more than four variables by an increase in the number of axes. Thus in Fig. 1 eight variables are handled.

The author's Eq. 3 may be written

$$3.18\,D = \frac{d\,k^{1/2}\,b^{1/2}\,P}{s\,w^{1/2}\,c^{1/2}}$$

where $P = (1/N^3 - 1/(N-1)^3)$. P is computed for different values of N and tabulated. Let $Q = \frac{d\,b^{1/2}}{s}$ and the equation becomes $3.18\,D/P = k^{1/2}Q/w^{1/2}\,c^{1/2}$. Then let $1/R = Qw^{1/2}\,c^{1/2}$, and the equation reduces to $3.18\,D/P = k^{1/2}/R$. Q and R are simply factors introduced to aid in the plotting. Each will have an axis but, since we are not interested in their numerical value, those axes need not be graduated.

Since $Q\,b^{1/2} = d/s$, if $b^{1/2}$ is plotted to a scale of 1/0.6, d to $\frac{1}{3}$, and s to $\frac{1}{4}$, the scale of Q may be found from $\frac{\text{scale of } Q}{\frac{1}{0.6}} = \frac{\frac{1}{3}}{\frac{1}{4}}$, from which the scale of $Q = 1/0.45$.

Then, since $w^{1/2}\,R = Q\,c^{1/2}$, if $w^{1/2}$ is plotted to scale of $\frac{1}{2}$ and $c^{1/2}$ to $\frac{1}{0.2}$, $\frac{\frac{1}{2}}{\text{scale of } R} = \frac{\frac{1}{0.45}}{\frac{1}{0.2}}$ from which scale of $R = \frac{1}{0.889}$.

P was plotted to a scale of 1/1 and 3.18 D to $\frac{1}{16}$ and from $\frac{1}{\frac{1}{\frac{1}{16}}} = \frac{1}{\frac{0.889}{\text{scale of } k^{1/2}}}$ the scale of $k^{1/2}$ was found to be 1/14.22.

Fig. 3 shows in diagrammatic form the layout for Eq. 3. This layout should always be made before construction of the actual diagram is begun. It is the key to the situation. The scales should be so chosen as to give a well balanced diagram and bring all the straight-edge intersections within the chart.

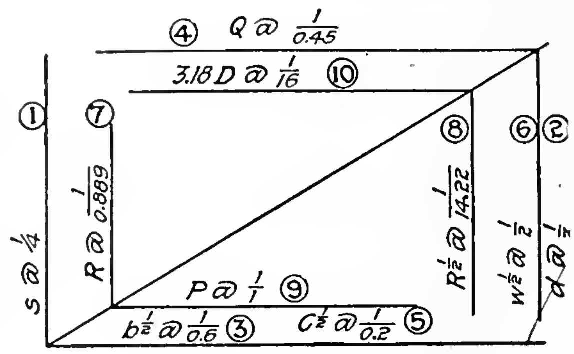

FIG. 3.

The solutions for the following values of the variables is shown in Fig. 1 by dotted lines; $s = 12$ ft.; $d = 12$ in.; $b = 12$ in.; $c = 1.0$; $w = 62.5$; $k = 1500$ lb. per square inch; and second wale. The values of D and t are found to be $D = 5.5$ ft. and $t =$ slightly over two inches.

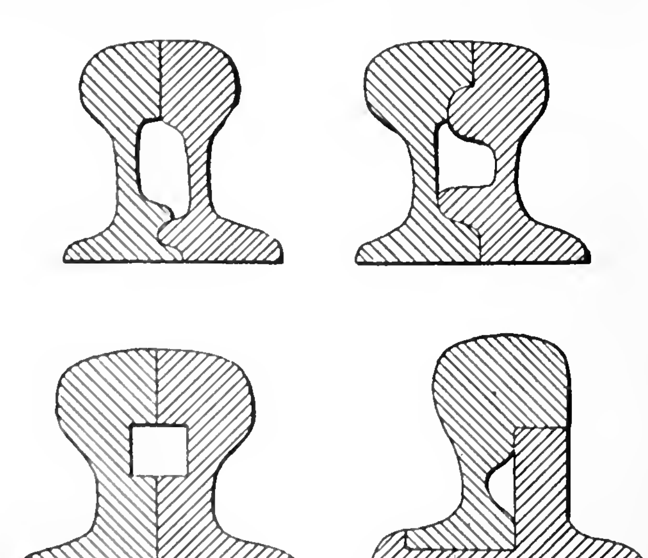
"Graphical and Mechanical Computation," by Professor Lipka, John Wiley & Sons, contains many valuable suggestions for the engineer in plotting charts of all kinds.

WARREN A. LYON,
Captain Corps of Engineers, United States Army.
Camp A. A. Humphreys, Virginia.

More on Old Compound Rail Sections

Sir—Compound rails of the type illustrated by the sections given on pp. 441 and 684 of *Engineering News-Record* of Feb. 27 and Apr. 3, 1919, were used to a considerable extent in the early days of railways. A paper by J. Elfreth Watkins on the development of rail and track, in the *Transactions* of the American Society of Civil Engineers, April, 1890, shows five such sections which were in use in New York State about 1855. These were of iron and weighed 65 to 75 lb. per yard. Three of them had the longitudinal joint in the middle of the head, while in the others the head was solid with half of its width supported on an L-shaped bar forming half of the web and flange. My impression is that similar sections were used on a number of old roads in the territory of the present Baltimore & Ohio Railroad.

Difficulty in maintaining splice joints with the old T-rails having pear-shaped heads is given as the reason



COMPOUND RAILS IN USE IN 1855

for the use of compound rails. They are said to have made good track at first, but in the absence of effective nut-locks it was difficult to hold the parts together rigidly, while in the divided head the wear was irregular, being especially severe on the inner section, thus causing rough track. An objection not mentioned in the paper is the tendency of frost to remain along the joint and thus cause the engine wheels to slip.

Mr. Watkins suggested the possibility that an improved compound rail made of steel and having secure bolted connections might be "the rail of the future," but, though there have been some modern designs, they have met with little consideration as competitors of the solid rail. RAILWAY.

Chicago.

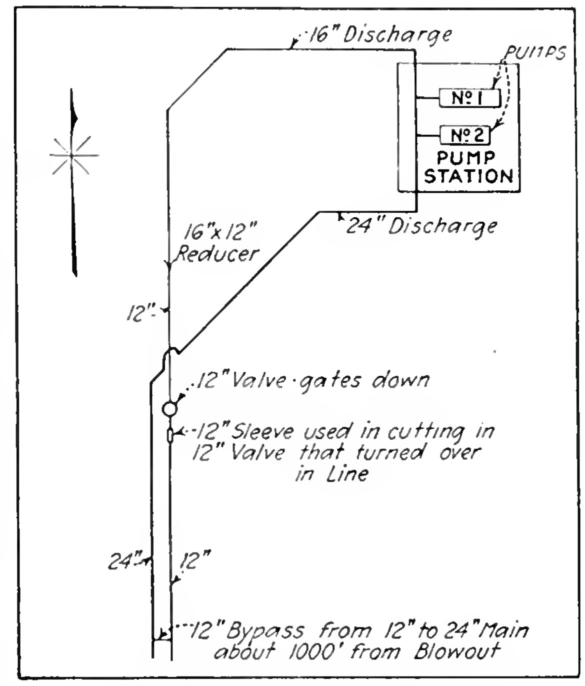
A Gate Valve That Turned in the Ground

Sir—The accompanying view shows the nearly horizontal position in which a 12-in. gate valve was found on digging down to it on account of a leak. The valve is on a force main near the water-works pumping station. The various connections are as shown in the sketch.

The valve was inadvertently left closed, and nothing was known of the fact until a blowout occurred. My explanation is that with the gate down and the nipple and sleeve on the discharge side of the valve, the pulsa-

VALVE TURNED TO A NEARLY HORIZONTAL POSITION

tions from the pumps tended to push the valve off the end of the pipe and to close the space in the sleeve, left there when the cut was made. The continued strain finally caused a leak to start somewhere in the valve or sleeve joints, and it was several days before an attempt to repair the leak was made. Meanwhile, the leak became so bad we could put off attention no longer, and upon attempting to close the valve to shut off the water we could not reach the head nut. So we went back to the pumping station and shut off the water on the 16-in. line. We noticed that there was a great amount of movement in the piping and valve, so much so that with a sounding rod put down against the main one could distinctly feel the movement of the sleeve and valve with each stroke of the pump. The closing of the 16-in. valve just outside the pumping station stopped the major portion of the leakage and all of the vibration, as this left just the return line from the bypass connection shown in the sketch. The fact that the top of the valve rested against a large, heavy valve box, which in turn rested against a granite curbing, is all that kept the valve from turning further around than it did. The soil was light, fine sand, and when it became wet from the first small leak there was practically no lateral resistance to the movement of the valve until it carried the valve box over against the heavy curbstone. No attempt was made to right the valve. It was left in the position shown in the view, and a chamber was built around it so that a hand wheel could be put on the stem in place of a head nut.



SKETCH SHOWING LOCATION OF GATE VALVE

In nearly 20 years' experience this is the first incident of the sort I have known. The pulsations of the pump are the only explanation of the turning of the valve that I can offer. The moral is: Never leave a valve closed on a main line if there is a chance that it will give way. McKEAN MOFFITT,

Superintendent of Water and Sewers.

Wilmington, N. C.

Latin and Greek for Engineering Students

Sir—The suggestion of Dean Cooley in your issue of May 8, 1919, p. 930, that Latin and Greek be incorporated into the engineering curriculum, once more opens the discussion between the so-called cultural and industrial arts. It was long held that the study of Latin, Greek and the allied finer arts made for breadth and depth of the intellect, while the study of the sciences served a utilitarian purpose only. A falser distinction never was made. Cultural studies are those which promote not alone intellectual happiness and contentment but physical comforts also.

I do not deny that the study of Latin and Greek is an enjoyable one. I enjoyed both. But today the sole result of such cultivation is that, in working on mathematical equations, I can express myself fluently in the Greek alphabet, while my less gifted brethren must restrict themselves to English. I have often felt that I would have enjoyed myself as much and paved the way for future intellectual enjoyment had I spent the time on the study of natural history and the political sciences. I would be now in a better position to appreciate what is taking place and what has taken place in the world.

It is time to stop decrying the engineer as a man inherently without culture. It is not true. If the engineer cannot find time to become a *dilettante* in the fine arts, it is because he is too poorly paid; not because he lacks the cultural training. Herbert Spencer pointed out long ago the cultural effects of the pursuit of the scientific studies and the illusory effects of the cultivation of the dead languages. It is not necessary to repeat his unanswerable arguments.

New York City. G. PAASWELL.

HINTS FOR THE CONTRACTOR

DETAILS WHICH SAVE TIME AND LABOR ON CONSTRUCTION WORK

Road-Construction Camp Rationing When Convict Labor Is Used

CONTRACTORS and others using convict labor for road and bridge work should give special attention to the proper feeding of the men in the construction camps, according to the biennial report of the State Highway Department of Arizona. It has been found that failure to supply satisfactory food will cause trouble more quickly than any other single item of complaint. It is believed that this will also be found to be the case in free-labor camps.

Other Articles in This Issue of Interest to Contractors:

On the work of the Arizona Highway Department the cooks and assistants were selected from among the prisoners. The rations were varied, and every effort was made to have them prepared and served in an attractive manner. In the desert regions it is necessary at times to use canned goods and dried fruits, but in general it is the aim to supply fresh fruits and vegetables in preference to all forms of canned goods. The accompanying table shows the kind and amount of food allotted to each convict during a period of one month at the Clifton camp, Arizona, having from 90 to 100 men:

RATIONS PER MAN PER MONTH

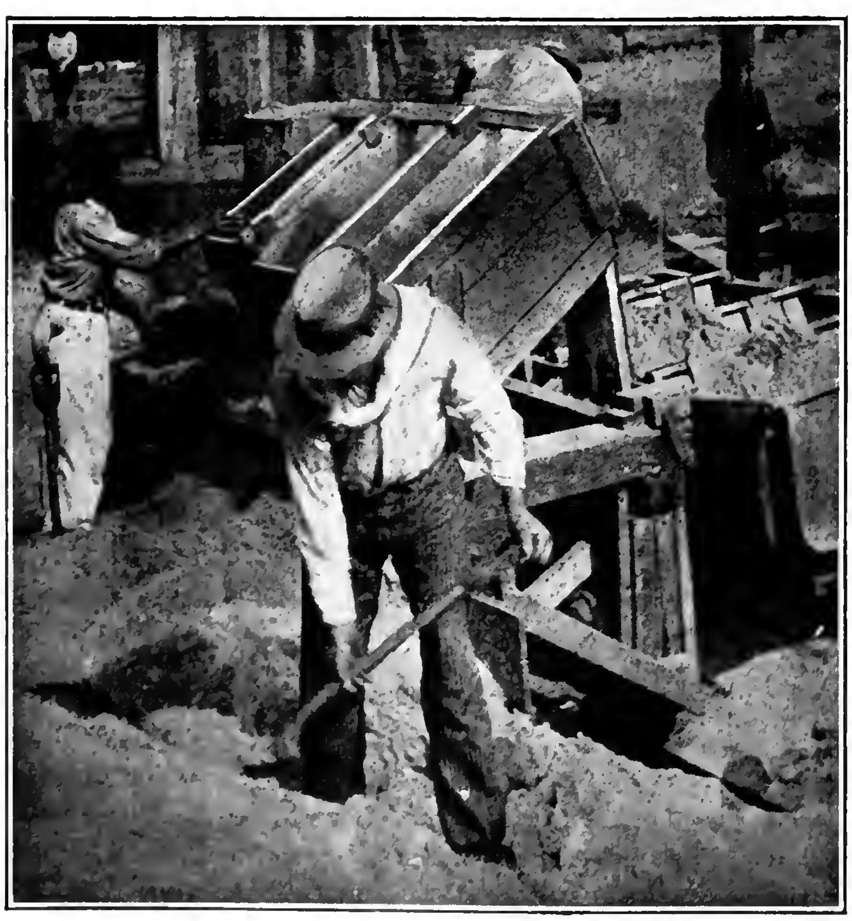
	Pounds		Pounds
Flour, wheat	12.0	Fresh beef, pork or mutton	23.5
Flour, milo maize	1.6	Flour, barley	2.0
Rolled oats	1.7	Cornmeal	22.0
Sugar	3.0	Macaroni	0.8
Prunes	1.5	Vermicelli	0.2
Canned peas	2.4	Dried apples	2.0
Dried peaches	0.1	Dried apricots	4.0
Canned tomatoes	4.4	Canned corn	6.0
Cottolene	4.0	Bacon	5.2
Beans	1.6	Ham	1.6
Onions	3.7	Lard	1.5
Velva syrup	5.0	Condensed milk	3.9
Coffee	2.6	Potatoes	17.0
Rice	1.7	Eggs	17.0
Cheese	1.0		

Properly Proportioned Batches Hauled to Mixer by Trucks

MOTOR trucks with specially arranged bodies were used to haul properly proportioned batches of concrete material to the mixer in building the Welsh-Mercer County Line road, in McDowell County, West Virginia. The stone and the sand were measured into specially constructed compartments on the trucks at the railroad siding, and hauled to and dumped directly into the concrete-mixer hopper, thus eliminating the extra handling which is necessary when materials are dumped upon the subgrade.

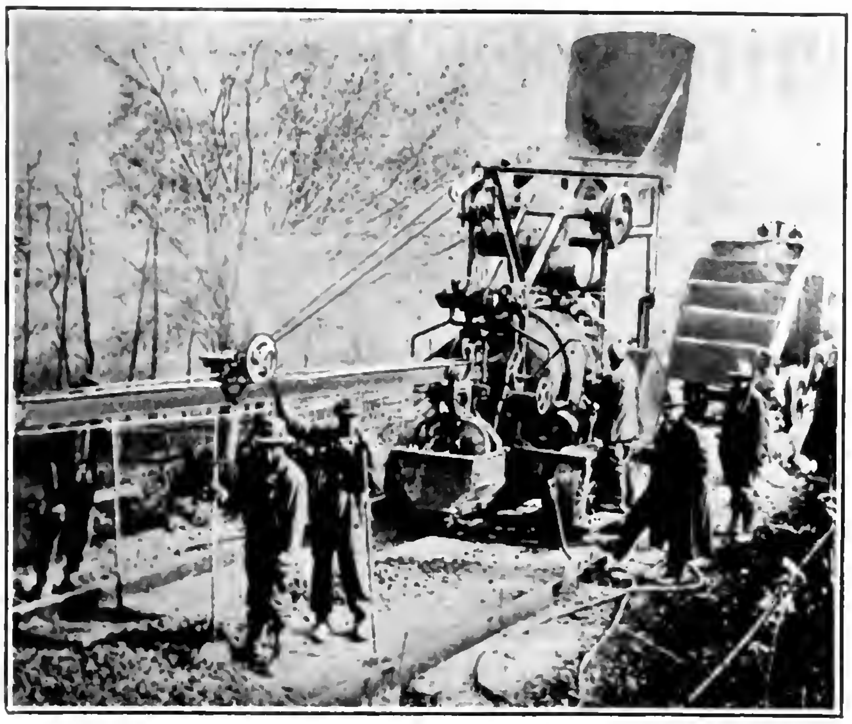
Ordinary motor trucks were used, the bodies being divided into four compartments by means of hinged trap-doors. The hinge edge of the door is formed of an ordinary gas pipe resting upon the top of the steel truck body and held in position by a strap-iron socket bolted to the frame. The lower edge of the door, which fits the bottom of the truck, is free except that it is attached to the front of the truck body by a cable to be released at the will of the truck driver. An illustration shows one of these trucks backed up at the mixer with one compartment dumped, and waiting for the hopper to drop and receive the next batch. The cables are so arranged that the batches can be dumped in succession.

Proportioning the concrete materials is accomplished at the railroad siding by the following method: The truck is run under the stone bin, and each compartment is filled with stone up to a mark which is painted upon the inside of the truck body. It then proceeds to the sandpile along the siding, where hinged measuring boxes are arranged on a small car running upon a narrow-gage track along the side of the sandpile, as



HINGED SAND-MEASURING BOXES ON CAR RUNNING BESIDE SAND PILE

shown. The sand boxes are placed the same distance apart center to center as the compartments in the trucks, and as soon as the trucks have reached their position at the side of the narrow-gage car the boxes which have been previously filled with sand are ended up by hand and dumped into the compartments. On



SECTIONAL TRUCKS USED TO DELIVER PROPORTIONED BATCHES OF MATERIAL

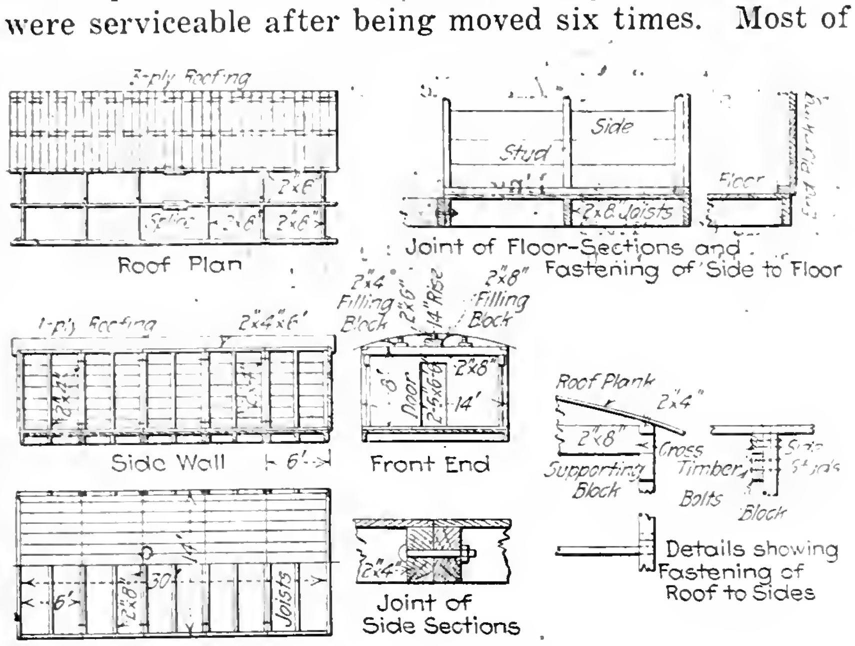
work having a sand as well as a stone elevator, this measuring could be done in the truck body.

The contractor for the work was the Harrison Engineering & Construction Corporation, Buffalo, N. Y.

Laborers Build Sectional Camp Houses

WOOD camp buildings built up in 6-ft. sections by laborers instead of carpenters as is usual, are shown in the accompanying drawings, the sections being put together with bolts through the abutting floor joists, side studs and roof beams. Each 6 x 14-ft. section is composed of floor joists, studs and roof-beams, with plank floor and sheathing. The roof is of the turtle-back type, composed of 16-ft. transverse planks bent over stringers blocked up on the roof-beams so as to give a rise of 14 in. At the eaves these planks are secured to sticks notched into the ends of the roof-beams. This roof planking is applied after the sections have been erected.

After erection the roof of the completed building is covered with three-ply roofing paper, fastened by nails and tin washers. Doors are provided in the ends, and a certain number of sections have windows framed into the sides. The sections are readily disconnected, packed for shipment and reassembled. Some of the buildings were serviceable after being moved six times. Most of



SECTIONAL CONSTRUCTION FOR CAMP BUILDINGS

the buildings are 30 or 36 ft. long, but shorter lengths are employed for such special structures as storehouses and camp hospitals.

These camp houses were built in sections at the site by laborers under the direction of a boss carpenter, as no carpenters for building the houses in the usual way were available. In two weeks 60 houses were built by about 20 men; one group of six men building the sections, a second gang of six men erecting the sections, and a third gang of eight men putting on the roofs and the paper sheathing. This was the average distribution; at first all the men were engaged in building sections, and toward the end most of them were applying the paper. One carpenter-foreman supervised the three gangs. The laborers were paid 40c. per hour.

These buildings are used by the Walsh Construction Co. on its work of double-tracking the Indianapolis division of the Cleveland, Cincinnati, Chicago & St. Louis R.R. (See *Engineering News-Record* of Mar. 13, 1919, p. 524). The drawings from which the illustration was made were furnished by T. E. Earle, resident engineer for the railroad.

Compressed Air Line Connected to Water Mains for Fire Protection

A "SCISSORS" expansion joint in a wrought-iron compressed-air line, and a connection of the same air line to a cast-iron water main, are features adopted at the shipbuilding plant of the Beaumont Shipbuilding & Dry Dock Co., Beaumont, Tex. E. B. Van De Greyn, chief engineer, considers the scissors expansion joint more efficient in construction work than the ordinary telescoping expansion joint. It also has the advantage of being home-made, requiring mainly only nipples and elbows.

For fire protection, a connecting pipe runs from the cast-iron water main to the air line, the valve in which is, of course, ordinarily kept closed, and no water enters the air line. However, in case of fire the many small air lines which go to all parts of the work are at once made available as water lines by simply opening this valve. Boxes with such connections are distributed at frequent intervals throughout the yard.

J. W. Link is president and general manager of the Beaumont Shipbuilding & Dry Dock Company.

Cracked Water Jackets Repaired by Rust Joints or With Steel Cement

RUST joints, familiar to every contractor, can be used successfully to repair cracked water jackets on tractor engines, when the crack does not exceed $\frac{1}{32}$ in. in width. Drain off the water and close the drain cock. Seal the outside of the crack with putty or tallow. Using a solution of 1 lb. sal ammoniac to 1 gal. of water, fill the water jacket high enough to submerge the crack, and let stand 30 minutes. Then drain the water and run the engine for a few minutes to warm the jacket. Refill the jacket with the solution, let stand, drain and reheat. Repeat this operation three or four times, and a joint will be formed which will not leak. Wider cracks can be closed with steel cement applied according to the directions printed on the containers. These recipes are vouched for by the International Harvester Companies.

News of the Week

New York, May 22, 1919

Civil Engineers' Society Plans for Convention at Minneapolis

At the American Society of Civil Engineers' forty-ninth convention, at Minneapolis-St. Paul June 17-20, the president, F. S. Curtis, will deliver the annual address at the opening meeting, at which Howard N. Winchell, president of the American Institute of Mining and Metallurgical Engineers, will also deliver an address on the "Mines of Minnesota," and F. C. Shenehon will speak on "Engineering Activities of the Twin Cities." The second day will be occupied by an automobile trip to various points of interest, and the party will be entertained by the Engineers' Society of St. Paul. The third day will be devoted to two all-day excursions, either one by trolley to Lake Minnetonka, or one by automobile (about 50 miles) to the Taylors' Falls plant, by invitation of the Northern States Power Company.

For the afternoon of June 20 an excursion to Duluth and the Missabe range iron mines is scheduled. On arrival at Duluth the party will be the guests of the Duluth Association of Members of the American Society of Civil Engineers and the Duluth Engineers' Club on an evening trip by steamer on the Duluth-Superior harbor. On Saturday morning a special train will be taken to the mines at Hibbing and, under the auspices of the Engineers' Club of Northern Minnesota, the party will then proceed by automobile 30 miles along the iron range to see the development of the Mesaba open pit mines at Eveleth. From there the party will proceed to the ore-shipping port of Two Harbors, where the ore docks will be inspected.

More Units of 23rd Engineers Scheduled for Early Return

The War Department has announced that three additional companies of the 23rd Engineers (highway engineers) have been placed on the priority list to be returned to the United States from France. The three companies are G, H and I. The Washington representative of *Engineering News-Record* reports that it is expected that additional companies of the 23rd will be ordered home from day to day.

Shipyards Authorized To Take Foreign Orders

Orders issued by President Wilson May 13 allow American shipyards to build ships for foreign account in so far as the work will not interfere with the building program for American registry. It is understood that all such foreign contracts will be placed under the supervision of the Shipping Board.

Employment Bureaus

Engineering Societies' Employment Bureau, 29 W. 39th St., New York City.

American Association of Engineers, 29 S. La Salle St., Chicago. Service to members only, but Army or Navy Engineers in uniform who are eligible to certified membership may join without payment of entrance fees or dues while in uniform and for six months after discharge.

Engineers' Service Bureau, 57 Post St., San Francisco. Only applications by mail or wire will be considered.

Professional and Special Section, United States Employment Service, 469 Fifth Ave., New York City.

Reëmployment Committee of New York City for Soldiers, Sailors and Marines, 233 Broadway, New York City.

Committee Appointed To Coöperate With Bureau of Public Roads

Appointment of a committee of state highway officials to coöperate with the Federal Bureau of Public Roads in carrying out the provisions of the Federal-aid road act and its amendments has been announced through the Department of Agriculture. A. R. Hirst, state highway engineer of Wisconsin, and president of the American Association of State Highway Officials, made the appointments, as follows: George P. Coleman, state highway commissioner of Virginia; S. E. Bradt, state superintendent of highways of Illinois; Charles J. Bennett, state highway commissioner of Connecticut; W. S. Keller, state highway engineer of Alabama, and Ira R. Browning, state road engineer of Utah. The committee will act in an advisory capacity to the bureau.

Fast Work Done in Building of 8800-Ton Ship

Built in 27 working days, the 8800-ton steamship "City of Eureka" was launched at Portland, Ore., May 8 by the Columbia River Shipbuilding Corporation. In building the ship work was carried on continuously, in three shifts. The performance established a new shipyard record for the Pacific Coast.

A. A. E. Convention Features Pay and Employment

Society Inter-Relations Considered, and Proposed Laws Affecting Engineers To Be Published

Salary schedules, employment problems and opportunities, proper compensation, and society inter-relations were the main features discussed at the annual convention of the American Association of Engineers May 12-13 in Chicago. Ninety delegates from 13 of the chapters and three clubs were present, although the attendance was 186 at the largest session.

Changes made in the constitution are as follows: A national practice committee is authorized, to report on questions of ethical policy and conduct. a grade of candidate junior is added; chapters are to recommend grading of candidates; junior members may now vote but not hold office; the latest past-president is to be a director; the board is authorized to make mutual agreements with other societies. (This is in confirmation of the affiliation plan carried out with the Cleveland Engineering Society.) The warmest discussion of the convention was over the proposal to fix the entrance fees at \$5 or \$10. The present by-law was retained; entrance fees, therefore, will continue to increase automatically by \$2 for each 500 members above 1000, the count to be made in December and fixed for a year. Apprehension that the fees would be so high as to keep out younger members gave way to the idea of the increased service that could be rendered through the larger income.

Following an explanation of the similarity in work of the Engineering Institute of Canada with that of the association, by Fraser S. Keith, secretary of the former body, it was voted to leave the Canadian field to the institute and to coöperate fully with it. An indication of the desire of other organizations to enter into some agreement was a telegram from the Oregon Engineering Society asking for a proposal either to enter as a chapter or to make joint membership possible.

A. M. Van Auken, chairman of the committee on compensation of the Chicago Chapter, presented a comprehensive 19-page report, containing schedules, which had been made to the chapter on May 3. (See page 1005 of this issue.) Adoption was not asked for, but it was recommended that the national body use the data and schedules in a nation-wide study and seek to formulate a more comprehensive schedule.

A recommendation was adopted pro-

viding that abstracts of all laws applying to engineers and surveyors, which degrade and hurtfully affect the engineer, should be collected, published along with suggestions for better laws in the interest of the public and the good of the profession, and should receive the widest publicity. The St. Louis Chapter presented a schedule for the municipal engineers of that city, which was indorsed.

H. G. D. Nutting, in his paper on "Ways and Means of Obtaining Proper Compensation," indicated five ways which may be used to help the man who cannot develop sufficient initiative along selling lines. His suggestions were: Increase the demand; limit the number by license; limit the number of technical graduates (questionable); union methods (questionable); limit the fake correspondence school courses; limit the fake employment agencies with alluring offers.

F. H. Myers, speaking on the employment department, indicated that 10% of the dues is now spent on this activity. From 300 to 350 members are on the list to receive the bulletin of positions open. Circular letters to employers get 5% returns. For the week ending May 10, twenty-one men were placed in positions averaging $150 per month, at a cost of $45. Had these men gone to employment agencies the cost would have been $1890.

The next annual convention will be held in St. Louis. The results of the letter ballot for officers are as follows: President, F. H. Newell; vice-presidents, W. W. DeBerard and F. A. Evans; new directors, W. W. K. Sparrow, P. E. Harroun, R. Burnham, F. D. Richards, A. A. Matthews and E. F. Collins.

New York Governor Vetoes Water-Power Commission

Governor Smith of New York has vetoed the Sage Water-Power Commission bill which appropriated $100,000 to ascertain the cost of development, transformation and distribution of water-powers and urge upon the Federal Government the state's right of full control of boundary waters. Apparently the Governor did not think it desirable to spend more money in investigatory work and is in favor of some definite legislation which will permit immediate state water-power development.

State Purchase of Interstate Toll Bridges

A law approved by Governor Sproul of Pennsylvania, May 15, provides means for coöperation of the state with New Jersey in purchasing toll bridges over the Delaware River. The Board of Public Grounds and Buildings is to act for Pennsylvania in conjunction with a similar body designated by New Jersey. Purchase may be by agreement or under condemnation, but in fixing the fair value of the bridge and its approaches the commission must take into consideration the value of the franchise.

New President of American Association of Engineers

Dr. F. H. Newell, head of the department of civil engineering, College of Engineering, University of Illinois, was elected president of the American Association of Engineers at the annual meeting in Chicago last week. He has had an active part in reform movements in the engineering profession in the past few years, and has served as president of the Committee on Engineering Coöperation from its organization in Buffalo in 1915 to the present time. He was one of the founders of the Washington Engineering Society and served as its president.

Elected President of American Association of Engineers

F. H. NEWELL

Dr. Newell served as the first chief engineer of the United States Reclamation Service from 1902 to 1907, and from 1907 to 1914 he was director of the Service.

He is a member of the American Society of Civil Engineers, the American Society of Mechanical Engineers and the Western Society of Engineers, and is one of the original members of Engineering Council.

Preliminary Program of Concrete Institute Annual Meeting

At the annual meeting of the American Concrete Institute, to be held at the Hotel Traymore in Atlantic City, June 27-28, special attention is to be paid to the subject of concrete ships and of the developments which have arisen in their design and construction. Thus, there are two papers of particular interest to general concrete construction: "The Effect of Vibration During Placing on the Strength of Concrete," by Prof. D. A. Abrams, and "An Investigation Into the Economic Possibilities of Light-Weight Aggregate in Building Construction," by A. W. Stephens. There will be, besides, four papers on concrete ships proper: "Construction of Concrete Barges," by S. C. Hollister; "Layout and Equipment of the Government's Concrete Shipyards," by A. L. Bush; "Problems in the Design of Concrete Ships," by J. Glaettli, Jr., and "Problems in the Construction of Concrete Ships," by R. J. Wig. Special tests made in the investigation of concrete ships are to be treated in a paper entitled "Results of Investigation on Shear, Impact, and Bond Made for Concrete-Ship Studies," by W. A. Slater, and the development of the new strain measurer to determine the stresses in ships is taken up in a paper by F. R. McMillan entitled, "The Strainagraph and Its Application to Concrete Ships." Other important papers are: "Fire Tests of Concrete Columns," by W. A. Hull; "Temperature Cracks in Chimneys," by J. G. Mingle; "Concrete Work on the Brooklyn Army Base," by A. C. Tozzer; three papers on fuel oil tanks, by H. B. Andrews, H. B. Walton, and J. C. Pearson and G. A. Smith, and "Concrete Railroad Tracks," by A. C. Irwin. On June 27, at 8 p.m., a joint session will be held with the American Society for Testing Materials.

Mining Engineers to Hold Fall Meeting in Chicago

The fall meeting of the American Institute of Mining and Metallurgical Engineers will be held in Chicago Sept. 22-26, according to present arrangements. It is planned to make the meeting of considerable importance to the industry, and subjects of vital concern to iron and steel interests will be discussed. In addition to technical papers, a program of excursions to various points in the Chicago district will be arranged, including trips to the steel mills at Gary, oil refineries at Whiting, and to the La Salle district, where there are cement, coal and zinc industries.

New York Removes Motor Truck From Personal Tax Class

Through a provision in a revenue bill just signed by the Governor of New York, motor trucks are removed from the personal-property classification and are placed upon the same basis in this respect as the passenger vehicle. The only revenue levy that can now be collected from the commercial truck is the regular license fee.

No change was made in the license fee which has held for the past two years. This provides that a truck of one-ton gross weight or under shall be taxed $10 per year, and that $5 shall be added for each extra ton of gross weight. Thus the license fee for a five-ton truck whose gross weight would be about 2000 lb. would be around $55. The bill provides that this license fee shall cover all taxes whatsoever; thus cities and other Governmental units would be prohibited from levying taxes or requiring special licenses. Provisions have also been made for increasing the license fees on passenger vehicles, which means a tax up to $60 for the larger and higher-priced cars

Annual Meeting of Highway Traffic Association

Discusses Regulation of Motor Express and Traffic Control on Feeder Roads—Officers Elected

The organization and the development of highway transport, as well as the proper construction and control of the highways made necessary by this development, were the subjects of discussion at the annual meeting of the National Highway Traffic Association held at the Automobile Club of America, in New York City, May 14. The program, announced in *Engineering News-Record* of May 8, 1919, p. 938, was followed very closely. The subjects which brought out the most discussion were regulation of the motor express service and the control of traffic on feeder roads.

During the afternoon session practically every speaker touched upon the subject of the desirability of enfranchising motor express companies. It was stated that the principal reasons why motor express companies are failing are (1) Ignorance as to the cost of operation, and (2) inability to raise prices on account of cut-throat competition even if costs are known. It was the general opinion that legislation should be passed to limit the number of companies operating over any one route. Some, however, felt that franchises should not be given to motor transportation companies, and they suggested a campaign of education as to the cost of operation.

In the evening session, after the presidential address by Arthur H. Blanchard in which he defined the subjects to be followed in the study of "Highway Transport Engineering," and addresses on "The Townsend Highway Bill," by H. G. Shirley, secretary, Federal Highway Council, and "Highway Requirements," by W. G. Thompson, state highway engineer of New Jersey, a discussion of the control and construction of feeder roads was opened by E. J. Mehren, editor of *Engineering News-Record*, followed by George H. Pride, president of the Heavy Haulage Co., of New York. This discussion showed a wide difference of opinion as to the feasibility and desirability of restricting heavy traffic on side roads. It was pointed out that a very large percentage of present highways will not stand up under motor-truck traffic such as is proposed, with an allowed maximum load of 28,000 lb. However, no solution of the problem of keeping trucks off the feeder roads was reached. The fact was brought out that even legislative regulations at present in force are constantly broken, and it seems almost impossible to make the regulations effective. At the close of the session an instructive educational film for the promotion of good-roads sentiment was shown by the Universal Film Manufacturing Co.

The following officers were elected for the ensuing year: President, Prof. Arthur H. Blanchard; vice-presidents, David Beecroft and John T. Stanton; secretary, Elmer Thompson; treasurer, George H. Pride. The following directors were elected: Gen. T. Coleman du Pont, of Delaware; William P. Eno, of the District of Columbia; William P. Beatty, of Illinois; Charles Henry Davis, of Massachusetts; Walter R. Addicks, of New York; R. J. Corbitt, of North Carolina, and Philip A. Koehring, of Wisconsin.

Highway Bond Issue Vetoed by New York State Governor

Governor Smith of New York has vetoed the proposed state highway bond issue for $20,000,000. The funds from this bond issue were to be used largely in meeting the allotment of Federal-aid moneys to the state. He approved an appropriation of $25,000 for the employment of prisoners on state and county highways.

The ground given by the Governor for disapproving of the bond issue was that the bill was so framed that the manner in which the money is to be used would be determined by the legislature. He stated that in the past money so distributed had been treated as political patronage, and that highways were designated, not with the idea of serving the greatest number of people, but with the idea of benefiting the men with the most political influence. While this money was to have been used in combination with Federal aid, it is hoped that some other means may be found to supply the necessary funds, so that the work will not be delayed.

California to Vote on Highway Bond Issue for $40,000,000

A special election has been ordered by Governor Stephens, of California, for the purpose of submitting an amendment to the constitution providing for the issuance of $40,000,000 in highway bonds. This bond issue, which is in addition to several made in recent years, is for the purpose of making extensions to the state highway system.

Good-Roads Sentiment Strong in California

That good-roads sentiment is strong in California is evidenced by the vote upon a bond issue for $4,800,000 in Fresno County. Although this bond issue is larger than that voted by some states, it was carried by a majority of 7 to 1. Seven precincts voted unanimously for the bonds. It is felt that this is an indication of the vote which will be recorded in favor of the forthcoming state bond issue for $40,000,000.

Plan $5,000,000 Water Bond Issue in Tulsa

At a meeting of the Allied Civic Committee in Tulsa, Okla., May 9, which was called by W. C. Steger, chairman, final plans for holding a city election for the purpose of voting $5,000,000 in bonds for building a new water-supply system from Spavinaw Creek to Tulsa were formulated.

Cement Companies Combine for Foreign Trade

Ten Manufacturers, Taking Advantage of Webb Act, Organize Cement Export Company

Portland cement manufacturers have just formed a company for foreign sales only, under the provisions of the Webb act. Ten companies have already joined the organization, which is known as the Cement Export Co. and has offices in New York City, and invitations to participate in the new organization have been extended to all Eastern cement manufacturers.

The following were elected directors of the company: Emil Loeb, Coplay Cement Manufacturing Co.; J. Brobston, Dexter Portland Cement Co.; J. A. Horner, Nazareth Cement Co.; L. C. Morton, Phoenix Cement Co.; George F. Bayle, Glens Falls Portland Cement Co.; J. W. Fuller, Allentown Portland Cement Co.; Frank H. Smith, Lawrence Cement Co.; Charles F. Conn, Giant Portland Cement Co.; Morris Kind, Hercules Cement Corporation, and F. W. Kelley, Helderberg Cement Company.

It is announced that arrangements are under negotiation with the Bureau of Standards to test all cement delivered by the export company and to certify that the cement fulfills all the requirements of the standard specifications of the American Society for Testing Materials.

As portland cement for domestic shipments is almost entirely delivered in paper or cotton sacks, and as most export shipments are called for in wooden barrels, the matter of cooperage is of great importance. Tentative plans have been outlined for the erection of a barrel-manufacturing plant at tidewater, with a large storage warehouse equipped with barrel-packing machinery in connection therewith. By having a large stock of cement in storage at tidewater at all times, the company, it is believed, will be able to take better advantage of the present somewhat limited shipping facilities to South American countries. While the Cement Export Co. expects that its activities will largely be confined to Latin-American countries, it will be in a position to supply cement to European countries if conditions make this desirable.

Feeder Cables a Factor in Bridge Fire

A small fire that broke out on an emergency footwalk on the Williamsburg Bridge over the East River, New York, May 18, led to a heavy short-circuit of electric feeder cables strung directly under the walk. A short length of the walk and a considerable amount of cable were destroyed, and one steel track stringer was damaged enough to require replacement. Because of the part played by the feeder cables in this accident, Public Service Commissioner Nixon has undertaken to provide ducts or other inclosure for the cables.

Disintegrated Sewer Concrete Requires Repairs

Stretch of Sewer in a Chicago Industrial District Breaks Down Below Water Line

Disintegrated concrete appears over nearly one-eighth of the inside area of a 63-in. concrete sewer built in Chicago in 1908. Extended investigation of the faulty structure by one of the editors of *Engineering News-Record* disclosed the following remarkable conditions: In many places the disintegration reaches entirely through the shell. The concrete at these places is rotten; it can be dug away and picked apart with the fingers. When excavated and hoisted to the surface in the process of repairing the sewer few pieces of this spoiled concrete are as large as a man's fist, and much of the débris is as fragmentary as was the original gravel aggregate.

The faulty sewer is a portion of the eight-mile sewerage system of the Clearing Industrial District, located in the southwestern outskirts of Chicago. These sewers are not a part of the Chicago city system; they were built and are owned by the district. Of the total system, only Sec. 7, which is the sewer on 63rd St., exhibits disintegration. This section is 7924 ft. long and is a monolithic concrete sewer 63 in. in diameter, with an 8-in. and 12-in. shell. It was built in 1908; it was the last of all the sections, and it was built as a separate contract.

Portland-cement concrete was employed. The cement was given the usual tests by a reliable commercial testing laboratory and was passed by the laboratory as satisfactory. The sand and gravel were from pits which have furnished aggregate for many successful concrete structures, and both passed inspection. The proportions were 1 : 2½ : 5. All concrete was machine-mixed. A fairly dry mixture was employed. Construction methods followed ordinary good practice. The invert concrete was placed first, then forms were set up, and the remainder of the concrete was placed from the top. There were no longitudinal construction joints. The trench was in stiff clay, giving excellent backing for the structure.

Disintegration affected the whole length of the section. It is more severe in some stretches than in others, but there is no regularity in the alternation of the more and the less damaged stretches. The damage is confined to the bottom and to the sides below the horizontal diameter. It is mostly at the normal water line. Above this level on the sides there is an occasional bad spot. The roof is invariably hard and sound. Disintegration often extends through the shell. Where it exists it is complete; the concrete has no coherence or strength. The extent of the damage is indicated by the amount of repairs entailed in the 1300 ft. of sewer on which work has been completed. Repairs were necessary on 79% of the length and on 11.8% of the internal area. Indications are that these proportions will be less as the work proceeds toward the head of the section.

In this connection attention should be called to the disintegration of the concrete in one of the Chicago stockyards sewers, reported in *Engineering News* of Sept. 14, 1916, p. 486. In that case, however, the sewage was notoriously putrid, and the disintegration was practically entirely in the arch above the water level.

The sewage in the Clearing district is the waste of industrial plants, house sewage and storm water. Only the wastes from the Commercial Chemical Co. can be suspected. The disintegration is as prevalent in the sewer 600 ft. above the point where the chemical wastes enter as it is below this point, and is no greater near the entrance than it is at more distant points. Furthermore, the disintegration ceases where Sec. 7 joins Sec. 5, constructed at another time. All the system, it should be noted here, except Sec. 7, was built of puzzolan cement and at a previous date, and none of its length shows any disintegration. It is only the 2000 ft. of Sec. 7 which is not in perfect condition.

The damaged sewer is being thoroughly repaired by its owners. Samples of the disintegrated concrete are being submitted to a number of experts for analysis and tests. When these are completed the results will be available for whatever they may be worth.

Benjamin G. Lamme Recipient of Edison Medal

Benjamin G. Lamme, chief engineer of the Westinghouse Electric & Mfg. Co., received May 16 the Edison medal awarded by the American Institute of Electrical Engineers for "invention and development of electrical machinery." The Edison medal was founded by an association composed of friends and associates of Thomas A. Edison, and is awarded annually for meritorious achievement in electrical science, electrical engineering or the electric arts. The award of this medal is one of the highest honors that can be conferred upon an American or Canadian electrical engineer. and among those who have received it are George Westinghouse, Elihu Thomson, Frank J. Sprague, Alexander Graham Bell and Nikola Tesla.

This honor to Mr. Lamme follows closely his appointment to membership on the Naval Consulting Board, which also emanated from the recommendation of the American Institute of Electrical Engineers.

Among the achievements of Mr. Lamme in the engineering field may be mentioned the development of the alternating-current motor, the "harnessing" of Niagara Falls, the design of the equipment used in the electrification of the New York, New Haven & Hartford R.R., the Pennsylvania, the Norfolk & Western and other railroads.

Civil Service Examinations

United States

For United States civil service examinations listed below, apply to United States Civil Service Commission, Washington, D. C., or to any local office of the commission, for form 1312.

Engineer in forest products, $1860-$3000 per year; assistant engineer in forest products, $1200-$1800 per year, Forest Products Laboratory, Madison, Wis., May 27. File applications before May 27.

Chief of road survey party, $1800 to $2100 per year, transitman for road surveys, $1200 to $1800 per year, highway draftsman, $1200 to $1800 per year, Bureau of Public Roads and Rural Engineering, May 29. File applications before May 29.

Senior engineer and senior architect, Interstate Commerce Commission, $1800-$2700 per year, June 10. File application before June 10.

Valuation engineer, $3600-$4800 per year, and assistant valuation engineer, $2500-$3600 per year; technical staff, income-tax unit, Bureau of Internal Revenue, Treasury Department. No date specified.

Engineering Societies

Calendar

Annual Meetings

NATIONAL CONFERENCE ON CITY PLANNING; 19 Congress St., Boston; May 26-28, Niagara Falls and Buffalo.

AMERICAN WATER-WORKS ASSOCIATION; 47 State St., Troy, N. Y.; June 9-13, Buffalo, N. Y.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS, 29 W. 39th St., New York; June 16-19, Detroit.

AMERICAN SOCIETY OF CIVIL ENGINEERS; 29 W. 39th St., New York; June 17-20, St. Paul-Minneapolis.

AMERICAN SOCIETY FOR TESTING MATERIALS; University of Pennsylvania, Philadelphia; June 24-27, Atlantic City, N. J.

AMERICAN CONCRETE INSTITUTE; 6 Beacon St., Boston; June 27-28, Atlantic City, N. J.

The Pittsburgh Chapter of the American Association of Engineers will give a banquet and ball at the William Penn Hotel in honor of the engineers of the Army and Navy who have returned from the service. **The Engineers' Society of Western Pennsylvania** and **the Pittsburgh Association of Members of the American Society of Civil Engineers** have been asked to coöperate in the program.

The Portland, Ore., Chapter of the American Association of Engineers recently elected the following officers: President, W. H. Marsh; vice-presi-

dents, A. H. McKeen, T. W. Saul and O. Laurgaard; secretary, R. W. Barnes, and treasurer, C. F. Thomas. A committee was appointed to consider the Oregon law for the licensing of engineers, as well as a committee to report on the pay of technical engineers in railroad service.

The Detroit Engineering Society held a joint meeting, May 16, with the Detroit-Ann Arbor Section of the American Institute of Electrical Engineers. The meeting was addressed by Col. R. A. Millikan, of the Council of National Defense, Washington, D. C., and professor of physics, University of Chicago, who spoke on the "Influence of the War Upon Scientific and Engineering Development in the United States."

The Society of Engineers of Eastern New York elected the following officers at the annual meeting held in Albany, May 12: President, James G. Blunt; vice president, John H. McElroy; secretary, Arthur Bibb, and treasurer, Edgar Croasdale.

The Tri-State Water and Light Association of the Carolinas and Georgia will hold its ninth annual meeting at Greenwood, S. C., June 17-19. W. F. Stieglitz, Columbia, S. C., is secretary-treasurer.

The Engineers' Club of Cincinnati held a joint meeting with the Cincinnati Chapter of the American Society of Mechanical Engineers, May 15. The meeting was addressed by Ernest F. Du Brul, on "Trade with South America."

The Rochester, N. Y., Engineering Society will hold its annual meeting June 13.

The Western Society of Engineers was addressed May 12 by E. M. Haas, of the Austin Co., who spoke on "Modern Tendencies in Engine-House Design."

The Colorado Society of Engineers held a special meeting May 13, at which resolutions were adopted opposing measures providing for a board of control of Denver and creating a public service commission.

The Rochester, N. Y., Society of Technical Draftsmen will be addressed May 29 by Maurice A. Wilder on "Application of Mathematics in the Drafting Room." The annual meeting of the society will be held June 26.

Personal Notes

HOMER L. FERGUSON, president and general manager of the Newport News Shipbuilding & Dry Dock Co., Newport News, Va., has been elected president of the Chamber of Commerce of the United States, having been a member of the Board of Directors since 1914. He was born in 1873 and was graduated from the United States Naval Academy in 1892 and from Glasgow University in 1895. For 11 years he was a constructor in the United States Navy, and in 1905 became general manager of the shipbuilding company of which he is now president. He is a member of the Society of Naval Architects and Marine Engineers, the Society of Naval Engineers, the Engineers' Club of New York, and the Army and Navy Club of Washington.

BRIG. GEN. DOUGLAS MCARTHUR, 42nd Division, U. S. A., has been appointed superintendent of the United States Military Academy. During the first three months after this country entered the war General McArthur served as chief of the Army censorship in this country, with the grade of major, Corps of Engineers. He then sailed with the Rainbow Division as chief of staff, with the rank of colonel. He was engaged in much of the actual fighting and has received decorations from the American, British and French Governments. Previous to the entry of this country into war, General McArthur was on regular station duty with the Corps of Engineers.

WILBUR H. JUDY, who since 1914 has been connected with the water-impounding system and has served as chief inspector of the operating department of the City of San Diego, Calif., has been appointed manager of operation of the city. His first engineering work was with the Allis-Chalmers Manufacturing Co., Milwaukee, and he was later employed on the hydro-electric project of the Pacific Electric & Power Co. near Fresno, Calif.

EDWARD H. BOUTON and MAJ. EZRA B. WHITMAN, of the firm of NORTON, BIRD & WHITMAN, consulting engineers, New York City and Baltimore, former water engineer of Baltimore, who has recently been on duty at Camp Meade, Maryland, sailed from New York, May 17, for England, whence they expect to proceed to Poland to investigate the field there for the establishment of public utilities, such as water and sewerage systems, railroad and highway improvements. They do not expect to leave England for Poland until after the peace treaty is signed.

MAJ. CHARLES H. MILLER, Engineers, U. S. A., has returned to this country and has resumed his work in the firm of the Miller-Butterworth Co., Inc., engineers and contractors, Little Rock, Ark. He received his commission as major of engineers in June, 1917, and was sent to Deming, N. M., as constructing quartermaster of Camp Cody. He was later assigned to the command of the 2nd Battalion, 23rd Engineers, which sailed for France in the month of March, 1918.

M. MANCUSI-UNGARO and L. R. GILBERT have become associated under the firm name of UNGARO & GILBERT, civil engineers and architects, with offices in the First National Bank Building, Bound Brook, N. J. Mr. Ungaro was previously engaged in private practice in Newark, N. J., until entering Government work at Bound Brook. Mr. Gilbert was connected with the Calco Chemical Co. and previously with the New York State Engineering Department.

W. J. DOUGLAS, who recently resigned as engineer of maintenance, Panama Canal, and vice-president of the Panama Railroad Co., in which positions he has served since June, 1918, has returned to New York City and will resume his work as a member of the firm of Barclay Parsons & Klapp, consulting engineers. In the absence of Governor Harding during the past twelve months, Mr. Douglas was acting Governor of the Canal Zone.

C. GRADY CATES, for the past four years chief engineer of the Roanoke Iron & Bridge Works, Inc., Roanoke, Va., has resigned to become chief engineer and assistant general manager of the American Truck Body Co., which has recently been organized, with factory at Martinsville, Va.

MAJ. EDWARD STUART, Sanitary Corps, U. S. A., who recently received his discharge from the service after returning from the Balkans, where he was detailed as sanitary adviser to the Serbian Army and Government, has sailed for France as a member of the Tuberculosis Commission of the Rockefeller Foundation.

D. L. REABORN, for the past four years superintendent of the Mt. Rainier National Park, Washington, and formerly division engineer, Los Angeles aqueduct, has resigned as superintendent of the park to become chief engineer of the Western Willite Road Construction Co., with headquarters in Los Angeles.

LIEUT. E. B. STEARNS, Air Service, U. S. A., who was recently discharged from the service, has been appointed sales manager for the H. K. Ferguson Co., engineers and contractors, Cleveland. He was formerly associated with the Pitt Engineering Co., Pittsburgh.

CAPT. EDWARD STEIDLE, formerly 30th Engineers, U. S. A., and more recently attached to the First Gas Regiment, Chemical Warfare Division, has returned to this country and will resume his connection with the Carnegie Institute of Technology, in mining and field work.

J. W. HOWARD has finished his work in the Ordnance Department of the Army and has resumed the practice of engineering, specializing in roads and pavements, with testing laboratory in Newark, N. J., and offices at 1 Broadway, New York City.

J. D'ESPOSITO, assistant chief engineer of the Chicago Union Station Co., has been appointed chief engineer, succeeding THOMAS RODD, who, it is understood, will become consulting engineer. During the period of the war

Mr. D'Esposito served in the Emergency Fleet Corporation, wooden ship division, as assistant to James O. Heyworth.

BRIG. GEN. WILLIAM H. ROSE, U. S. A., director of purchase, Division of Purchase, Storage and Traffic, has resigned from the service and has become associated with Lockwood, Greene & Co., industrial engineers, as manager of the New York office. General Rose was a major in the Corps of Engineers.

CAPT. C. R. TWISS, for the past 14 years city engineer of Vicksburg, Miss., has resigned to become associated with the I. R. Packard Construction Co., Chicago, and will be in charge of the company's contracts in Arkansas.

EDWARD B. HAROLD, formerly of the New York sales office of the Universal Portland Cement Co., has been made manager of the highway department of the Clinton Wire Cloth Co., with office at 949 Broadway, New York City.

MAJ. A. C. KING, Construction Division, U. S. A., who has been in charge of the electrical section, has resumed his work as one of the chief officers of the Illinois Appraisal Co., with offices in Washington and Chicago.

R. L. SCHMID has been appointed assistant division engineer, Nashville, Chattanooga & St. Louis R.R., with headquarters at Nashville, succeeding J. L. FERGUS, appointed assistant engineer, as noted elsewhere.

FREDERICK A. RHODES, consulting engineer, San Diego, Calif., has been appointed city engineer. He is 39 years old and is a graduate of the Cogswell Polytechnic School, San Francisco.

H. E. TURNER, formerly assistant division engineer, Denver & Rio Grande Ry., Utah Lines, with headquarters in Salt Lake City, has become resident engineer in charge of concrete-highway construction, State Road Commission of Utah.

MARCH F. CHASE, formerly director, explosives division, War Industries Board, has become consulting engineer for the Leonard Construction Co., New York City. The offices of the company have recently been moved to 6 Church Street.

FRED J. DEUTSCHMAN, Aurora, Ill., has been appointed city engineer of Mitchell, S. D., succeeding S. H. Smith, who recently resigned. Mr. Deutschman was previously city engineer of Belleville, Ill.

RAY S. BLINN, formerly city manager of Westerville, Ohio, has been appointed city manager of Lapeer, Mich. He was previously director of public service of Mount Vernon, Ohio.

MAJ. CHARLES S. PILLSBURY, U. S. A., who has been attached to the Aviation Section of the Signal Corps in France in charge of construction work since 1917, has been made a member of the Legion of Honor by the French Government. Major Pillsbury was formerly assistant general sales manager, Chicago Bridge & Iron Works, Chicago.

LIEUT. JAMES R. COMLY, Engineers, U. S. A., has received his discharge from the service and has returned to the engineering department of the San Diego & Arizona Railway.

ALLEN H. STUBBS, formerly of the Department of Engineering, University of Nebraska, has become manager of the Kansas City office of HEDRICK & HUFF bridge engineers.

OLIVER G. SHAFER and ROBERT W. HANSON have become associated under the firm name of SHAFER & HANSON, general contractors, Caldwell, Ohio, successors to Oliver G. Shafer, highway contractor.

ELBERT M. CHANDLER, chief engineer of the Naches Selah Irrigation District, has resigned to become first chief engineer for the Washington State Reclamation Service, with headquarters at Olympia.

D. E. COUNTS, superintendent of bridges and buildings, Nashville, Chattanooga & St. Louis R.R., whose headquarters have previously been in Atlanta, is now located at Chattanooga.

ALBERT T. CANFIELD, assistant engineer, architectural department, Union Pacific R.R., with headquarters at Omaha, has resigned to become associated with the SHERMAN ENGINEERING Co., Kansas City.

CAPT. H. E. DARTON, formerly of the 162nd Depot Brigade, Camp Pike, has been appointed first assistant state highway engineer of Arkansas, succeeding JOHN P. HARPER, resigned.

J. L. FERGUS, assistant division engineer, Nashville, Chattanooga & St. Louis R.R., with headquarters at Nashville, has been appointed assistant engineer.

SAMUEL A. GREELEY, hydraulic and sanitary engineer, formerly at 64 W. Randolph St., Chicago, has removed to 39 W. Adams Street.

J. C. CORCORAN, assistant engineer, New York Central R.R., with office in Albany, has been appointed chief signal inspector, east of Buffalo, with headquarters at the same point.

FREDRICK W. CARPENTER, of Flushing, N. Y., has been appointed executive officer of the Wilmington, Del., Bridge Commission.

ENSIGN BERTRAM B. MOORE, U. S. N. R. F., has received his discharge from the service and has resumed his work with the engineering bureau of the City of San Diego, Calif.

MAJ. ARTHUR M. SHAW, Corps of Engineers, U. S. A., announces that upon his release from active duty about June 1 he plans to reopen his office in New Orleans for the private practice of engineering and will engage in hydraulic, railroad, industrial plant and river and harbor work.

F. J. BACHELDER, consulting engineer, Chicago, announces the opening of a new office in Washington, D. C.

WALTER DEUTCHER, acting city engineer of Aurora, Ill., has been appointed city engineer.

W. C. DICKEY, for the past six years city engineer of Conneaut, Ohio, has resigned to become associated with A. E. Vrooman & Co., Painesville, Ohio.

PHILLIP L. MINOR, engineer, National Tube Co., Pittsburgh, has been appointed borough engineer, Ellwood City, Penn.

JOHN ABERCROMBIE, for many years county surveyor, Alexandria, Minn., has opened offices at that point for the private practice of engineering.

OBITUARY

EMIL SWENSSON, consulting engineer, Pittsburgh, died in that city, May 13, at the age of 61. He was born in Sweden in 1858 and was educated in the public schools of Halmstad in a scientific course. He was graduated from the Technical Institute at Gothenburg, Sweden, in 1878. He came to the United States in 1880 and engaged in engineering work. In 1885 Mr. Swensson entered the service of the Phoenix Bridge Co. as draftsman, and two years later became connected with the Keystone Bridge Co., afterward the Carnegie Steel Co., of which he was made assistant to the chief engineer and later superintendent of the Keystone Bridge Works. Leaving the Carnegie Steel Co. about 12 years ago Mr. Swensson entered private practice, and since that time has been engaged in a large number of important works.

H. C. ALLEN, state highway engineer of Idaho, died at Sprague, Wash., May 4. He was appointed to the position of state highway engineer a year and a half ago. Previously he was city engineer of Great Falls, Mont. From Great Falls he went to Spokane, Wash., and laid out the irrigation system for the Hercules ranch. He was later employed as an engineer for the Day Bros. mine at Wallace, Idaho, and was also engineer at the Tamarack and Custer mine, at the time of his appointment as state highway engineer.

DOUGLAS W. TAYLOR, highway engineer of Multnomah County, Oregon, died in Portland, May 3. He was a son of the late D. W. Taylor, who for some years served as city engineer of Portland. Mr. Taylor was born in 1885 and was graduated from the University of Oregon in 1906. Since then he was engaged in engineering work in northwestern Oregon.

Rates for Industrial Insurance in State of Washington

The State of Washington has a monopoly of the industrial insurance business in that state. The advocates of this plan assert that it is the only method by which compensation benefits can be extended to all classes of risks which would be excluded by private corporations. The employers are protected by a state fund, and it is said they are well satisfied with the system. The accompanying table gives the rate per year per $100 of payroll for the various classes of industry. The information was furnished by Frank W. Harris, C.E., statistician for the Industrial Insurance Department, Olympia, Wash. Detailed information will be furnished on request by the industrial department.

COST OF WASHINGTON STATE INDUSTRIAL INSURANCE PER YEAR PER $100 OF PAYROLL*

Class	Industries	Cost
1	Tunnels, sewers, drilling wells, etc.	$2.64
2	Bridges and trestles, mill-wrighting, tanks, towers, etc.	4.19
3	Canals, piledriving, breakwaters, etc.	4.76
5	Carpenter work, plastering, roof-work, etc.	1.91
6	Conduit work, electric power plant, etc.	1.41
7	Railroad construction, logging railroad, etc.	2.82
8	Concrete paving, roadwork, etc.	1.20
9	Shipbuilding, etc.	1.36
10	Logging, sawmills, etc.	2.01
12	Dredging, etc.	1.43
13	Steamheat or power plants, etc.	1.34
14	Street and interurban railways	.95
15	Telephone and telegraph	.86
16	Coal mines	3.15
17	Quarries, gravel pits, etc.	3.16
18	Smelters, rolling mills, etc.	1.44
19	Gas works	.58
21	Flour mills, grain elevators, etc.	.85
22	Laundries and dye works	.34
24	Paper and pulp	.99
29	Cooperage, sash and doors, boxes, etc.	1.24
31	Building material, cement manufacturing, etc.	1.77
33	Fish canneries	1.01
34	Auto repair, foundries, machine shops, etc.	.76
35	Brick and tile, briquettes, etc.	1.02
37	Breweries, bottling works, etc.	.84
28	Textiles, cordage, etc.	.33
39	Foodstuffs, bakeries, etc.	.36
40	Condensed milk, creameries, etc.	.23
41	Lithographing, printing, etc.	.10
42	Longshoring, etc.	2.07
43	Packing houses, tanneries, etc.	.98
44	Cold storage, ice plants, etc.	.87
45	Moving pictures, theatres, etc.	.16
47	Creosoting piles, etc.	.77
48	Elective adoption	.35

*Averages for years 1913 to 1917.

Record Gyratory Crusher Built at Allentown, Pennsylvania

What is reported to be the largest gyratory stone crusher ever built has just been completed in the shops of the Traylor Engineering & Mfg. Co., at Allentown, Penn. The machine, which is shown set up in the accompanying view, is to be used for crushing limestone for chemical purposes, flux, etc. It has two jaw openings each 60 x 190 in. and an estimated capacity of 2500 tons per hour, reducing to 8 in. The crusher complete weighs about 800,000 lb., is 17 ft. 8 in. high from foundation to top of hopper and has a shaft 21 ft. long and 40 in. in diameter.

GYRATORY CRUSHER WITH OUTPUT OF 2500 TONS PER HOUR

In the view herewith, where it is set up in the shop, the enormous size may be well gaged by the men who are standing on the ladder.

Business Notes

The Railway and Power Equipment Co., Woolworth Bldg., New York City, which was recently incorporated to take over the business conducted during the past 20 years by Charles F. Johnson, in New York, Buffalo, Cleveland, Philadelphia, Chicago and Toronto, announces that it is receiving many foreign inquiries for machinery and equipment. It proposes to conduct a world-wide business in all kinds of new steel products, steam, electric and hydraulic machinery, railway equipment, machine tools and contractors' equipment. The engineering and construction departments will design and construct, and aid in financing, important enterprises at home and abroad.

The Westinghouse Electric & Mfg. Co., of East Pittsburgh, Penn., announces the appointment of A. E. Hitchner as manager of the mining section of the industrial sales department. Mr. Hitchner has had extensive experience in handling mining machinery, having been in charge of the Wilkes-Barre office of the company, and in his new position will manage the sale of apparatus for use in the mining industry.

The Blaw-Knox Co. of Pittsburgh has taken over the manufacture and field operation of the Uni-Form system of reinforced-concrete floor and roof construction, and has incorporated it in the steel forms department of the company. Nils F. Ambursen, chief engineer of the Ambursen Hydraulic Construction Co., will assume the duties of chief engineer of the building form department, and W. L. Church, formerly of the Westinghouse Church Kerr Co. and of Lockwood, Green & Co., engineers, is retained as consulting engineer on the operation of the Uni-Form system.

The Canton Culvert and Silo Co., of Canton, Ohio, announces that Judge F. E. De Haven, of La Grange, Ky., has resigned his position as judge of the fiscal court of Oldham County to become their company's traveling salesman in Kentucky. It is also announced that L. W. Hurley, of Lansing, Mich., has accepted a position as representative in Michigan.

Daniel T. Pierce, formerly assistant to the president of the General Asphalt Co., has just returned from more than a year's service in France, and is temporarily established at Room 1031, 120 Broadway, New York City. Mr. Pierce will represent certain Franco-Italian interests and will also act for American manufacturers seeking business in France and other European countries.

The Northern Waterproofing Co., the Waterproofing and Construction Co., Inc., and the Standard Surfacing Co. give notice that they have amalgamated, with business address at 195 Lexington Ave., New York City. While these companies have combined, they will conduct business under their respective names.

The Minneapolis Steel & Machinery Co., Minnehaha Ave. and 29th St., Minneapolis, announces the extension and development of its New York office at 154 Nassau St. to facilitate the handling of domestic sales in the East. J. A. Teach, contracting, mechanical and construction engineer, is now making his headquarters at the New York office. C. W. Hadden will continue his duties as export manager.

Trade Publications

The following companies have issued trade publications:

The C. H. & E. Manufacturing Co., Inc., Clinton and Mineral Sts., Milwaukee, Wis.; folder, 7½ x 11 in., four pages, illustrated; describes the C. H. & E. expansion joint for pipe lines and its installation, with piping system.

The Truscon Steel Co., Youngstown, Ohio; folder, 8⅜ x 11 in., four pages, illustrated; describes the use of "mesh" and "rib" metal for reinforcing concrete roads.

The Portland Cement Association, 111 W. Washington St., Chicago, Ill.; booklet, 6 x 9 in., 19 pages, illustrated; contains "Facts About Concrete Roads."

A Consolidation of Engineering News and Engineering Record | McGraw-Hill Company, Inc.—JAMES H. MCGRAW, President

ENGINEERING NEWS-RECORD

DEVOTED TO CIVIL ENGINEERING AND CONTRACTING

E. J. MEHREN, Editor | CHARLES WHITING BAKER, Consulting Editor

Volume 82 | NEW YORK, THURSDAY, MAY 29, 1919 | Number 22

Government Tax on Information

ON AND after July 1 it will be necessary to charge subscribers of ***Engineering News-Record*** living west of the Mississippi River an extra $1 per year to cover partially the increased cost of postage.

Zone rates of postage, adopted as a war measure, became effective on magazines July 1, 1918, thus reestablishing a system abolished as obsolete in 1863. The zone rates, however, are to persist after the war, and are to increase in four successive steps, reaching their maximum July 1, 1921. The publishers had hoped that the law would be repealed, and for that reason bore the burden themselves for the first year. On the first of next July, however, when the second increment becomes effective, it will be necessary to add a postage charge for zones farthest from the point of publication.

The postage on a copy of ***Engineering News-Record*** under the old law was about 72c. a year to any point in the country. In the year beginning July 1, 1919, it will be $2.38, $2.90 and $3.16, respectively, in the sixth, seventh and eighth zones, in which the states west of the Mississippi lie. When the zone rates are fully effective these rates will become $3.94, $4.98 and $5.50, respectively, so that further increases in subscription price to cover added postage seem inevitable.

In studying the law, when first passed, it was proposed to add a postage charge in each zone, but the clerical difficulties introduced were so great that it was found necessary to lay a flat increase on the greater distances. The added amount for postage decided on for the sixth zone was adopted also for the seventh and eighth zones, thus covering all the territory west of the Mississippi.

Therefore, with all subscriptions, new and renewals, sent in on and after July 1 from points west of the Mississippi River an extra $1 should be added for zone postage.

The publishers greatly regret the necessity for taking this step. It has been forced upon them by legislation which places information in the same class as merchandise and penalizes the educational efforts of those who live in the most distant parts of the country. Progress in postal matters has always been marked by a change from the zone system to a flat basis; throughout the world the theory is accepted that there should not be a distance tax on education and enlightenment. Under that theory a 5c. stamp carries a letter to Guatemala, to South Africa or to Japan.

We have no doubt that when the restrictive and sectionalizing character of this legislation becomes apparent the people will demand its repeal.

THE PUBLISHERS.

Septic Tank Patent Settlement in Sight

THE proposed settlement of the Cameron septic tank patent litigation, noted on p. 1084, promises to bring to an end a long and stubborn contest in which many engineers and municipalities have coöperated to resist what they believe to have been invalid claims. The sum to be paid, in which any alleged infringer may join and thus be freed from possible litigation, is so small as to seem like a virtual confession of either the weakness of the case or else of exhausted resources on the part of the claimant. Nevertheless, the remarkable league of states, cities, companies and individual engineers who have stood united in the long fight is presumably wise to accept the compromise, on the ground that the expense will be trifling and the freedom from further annoyance worth while. Those interested in joint civic and private action to defend patent claims will be repaid for obtaining the printed information summarizing this settlement agreement.

Exhibit Promoted by Engineers

WHILE we have been talking about the need for fuller realization by engineers of their local civic responsibilities, an example has been set which deserves hearty commendation. We refer to the industrial exhibition recently held in the 23rd Regiment Armory in Brooklyn, N. Y., under the auspices of the Brooklyn Engineers' Club. Beginning with a few loans shown at the club house, the exhibition reached such a size that only the largest armory in Brooklyn could house it. The main object sought by the club was to place the industrial importance of the Borough of Brooklyn before its citizens in a clear light, with a view to creating and maintaining an active public interest and a pride in Brooklyn's manufacturing progress. The club long ago realized that engineers should take a larger part in civic matters and that a great power for good can be secured from the coöperation of responsible engineering bodies, manufacturers and business men in bringing about civic improvements. An engineering society which shows so keen an appreciation of the responsibility of the engineer in the present age of industrialism as did the Brooklyn Engineers' Club in this case should be congratulated and emulated.

Organization in Lumber Camps

WHEN the Spruce Production Division was organized, and sought to secure a greater rate of production in the Northwest woods, the first obstacle was the labor problem. Labor was in a sullen, ugly mood throughout the Northwest camps. Efficiency was way below par, and there were dissatisfaction and grievance on the part of employer and employee. How General Disque brought employer and employee together on the common ground of loyalty is one of the

important chapters of war-time production. It has a significance now in the fact that the Loyal Legion of Loggers and Lumbermen, the organization 110,000 strong which grew out of General Disque's plan, has elected to continue permanently. In other words, the benefits of a common or joint council as the ruling body in the great industry were so patent to all that the workers themselves voted to continue the organization even after the pressure of war-time necessity had been removed. There is excellent example for other industries, and food for thought for both employer and employee, in the operating plan of the Loyal Legion of Loggers and Lumbermen.

Wanted—A Cheap, Acceptable House

ENGINEERS have not had much to do with building dwelling houses. The single house is so obviously the architect's field that when the number is multiplied, and whole villages are built at once, it is the architect who dominates the design and construction of the houses themselves and leaves to the engineer the public utilities alone. Such was the case with the Government housing program carried out during the war. In consequence, we find that practically nothing valuable was developed by this forced work, in the way of novel or economical house design. The engineer is accustomed to multiple production, to the reduction of pieces and effort by the repetition of the unit. The architect, on the other hand, is concerned with the general effect, and concentrates on the perfection of the unit itself. Much was saved in the Government housing by the development of contracting methods such as are outlined by Mr. Meltzer on another page, but the impression cannot be avoided that some cheaper, and equally pleasing, form of multiple housing could have been developed than the succession of suburban villas which look so delightful in the architect's perspective but which lend themselves so little to economies of production. War emergencies have passed, but the housing shortage is worse than ever. Engineers cannot escape their duty of entering this field. Can they not impress their ideas on the design of the house itself, so that there may result that only solution of the present deadlock between high prices and necessity for shelter—reduced unit costs due to efficient design as well as efficient management of construction?

America's Legacy

IN THE concluding sentence of his address before the National Machine Tool Manufacturers' Association, Charles F. Lang, president of the Lakewood Engineering Co., expressed the thought that, whereas Greece had given us art and Rome law and organization, America would give to the ages a solution of the problem of the "proper distribution of wealth and happiness and education among the masses." Certainly, there is warrant for thinking at the present time that America will make real progress in these directions. Back of Mr. Lang's thought, however, is something very much larger than he had room to develop in that sentence. There is something spiritual, and in that lies all the hope for America's thinkers and America's industrial leaders doing their utmost to reach a real solution of the industrial problem. Mere spreading of wealth will not of itself bring a social order of which we would be proud. A better spreading of the world's goods would be but the means to a geater end. The fullest spiritual development of the individual will come when a qualitative standard again becomes the object of human endeavor, replacing the quantitative standard which has debased our industrial age. That thought is inherent in Mr. Lang's expression when he speaks of happiness and education, for happiness does not consist in the enjoyment of purely material things, nor can education be worthy of the name if it be nothing more than a surface polish, leaving below an undeveloped soul and a weak character. The thought expanded, as it lay in Mr. Lang's mind, is indeed an idea worthy of a great people. It will come only through sacrifice by those who control and direct our destinies, and through an awakening of the nation as a whole to a realization of how our industrial structure ramifies through and vitally affects the life of every individual.

Human Side of Labor and the Engineer Must Be Recognized

CONSIDERATION of the laborer in his human and personal relations rather than as merely an impersonal physical machine is becoming increasingly necessary. That this is being recognized by engineers who have to handle labor was shown by opinions voiced at the recent meeting of the American Railway Engineering Association, as noted in *Engineering News-Record* of Apr. 10, 1919, p. 698, the subject coming up in a discussion of plans for camp buildings and boarding cars, as submitted by the committee on economics of railway labor.

Much of the attention to the physical welfare of laborers has been based upon improving the human machine as an asset of the employer, and has been confined largely to housing and feeding. But there is a growing recognition of the fact that the employer or superior must be willing to consider the worker as an individual and to assist his development in his own—the laborer's—personal interest. In doing this he will help to make the men better citizens, besides cultivating a spirit of loyalty and coöperation instead of indifference or perhaps antagonism.

Higher efficiency is the demand of the time, but in the discussion noted it was pointed out by R. H. Ford, Rock Island Lines, that at present there is low efficiency of common labor as employed on railway construction and maintenance. This condition he attributed largely to the poor grade of housing and feeding that the railways have been content to provide, because they have failed to appreciate even the benefits resulting to themselves from better care of their men. In Mr. Ford's opinion, the great improvement made in recent years in this respect is but the beginning of a much broader improvement. Regard for the human element in the problem, for the benefit of the laborer rather than the employer, was emphasized by J. L. Campbell, of the El Paso & Southwestern R. R. He urged that it is necessary to recognize the fact that the laborer—like any other man—has ideas and aspirations of his own, beyond his mere daily needs and his employment.

Perhaps one reason for the shifting habits of common labor is the fact that welfare methods ordinarily do not go beyond the housing and feeding of the men. Under such conditions there may be no particular inducement for them to stay in any one place. The next employer or job or camp may be better, or if it is worse there is another further on. Checking oppor-

tunities for such casual movement may have some effect, but a better solution seems to be in considering the men as individuals and fellow human beings. This does not imply the babying or coddling of the men, but simply a square man-to-man treatment that will benefit not only the laborer but also the employer and the community.

While the discussion mentioned had relation to common labor, particularly on railway work, the same conditions apply to the skilled laborer and the engineer employee. That employers have shown slight regard for the human aspects of the young engineer and technical beginner is probably a large cause of the unrest and dissatisfaction among the men from whom the engineering profession of the future must be recruited. A new attitude toward and a new sense of responsibility for the technical man and the workman, on the part of the employer, promoting a different relation between employer and employee, may be foreseen among the coming changes.

Scrapping Tons of Good Highway Bridge Metal Because of Local Corrosion

SEVERAL recent cases of highway-bridge repair call attention to the abnormal liability to deterioration of steel at the level of the decking and in certain locations under the floor. The life of many bridges is determined by loss of strength at these points, though elsewhere the full initial strength remains. Facts of experience amply justify the statement that the life of a steel highway bridge is unlimited if trouble at points of special corrosion is taken care of—and, of course, provided cleaning and painting are not neglected. For this reason the engineer's aim must be to eliminate local troubles.

In one case serious loss of strength resulted from corrosion of the web members of a through truss at the point where they pass through the wooden decking. Dirt and moisture, accumulating in the slots cut in the decking for the passage of the posts and diagonals, cut into the metal like a chisel. With concrete deck the same thing would have happened, the members passing through the floor by similar openings (or even much larger ones.) There was also abnormal corrosion at certain points under the floor, as where spiking pieces rested on stringer flanges so that moisture could be retained between the contact surfaces, and where floor planking came so close to the top of a floor-beam that dirt could pocket between them. These conditions are in all respects typical. They establish very definitely the fact that past highway-bridge practice has not given sufficiently careful attention to the protection of steel at and under the floor.

Studies for repairing a Chicago viaduct over railway tracks recently brought out the same general truth, in a totally different set of circumstances. Locomotive gases (acting below the deck level) were the corroding agency in this case. They weakened the bottom chord and stringers so that only half their original strength remained, while the rest of the structure was as good as new; emergency repairs were the only means of avoiding immediate replacement of the entire structure. Enough was known of locomotive-blast corrosion, at the time this viaduct was designed, to enable the after-history to be fairly well foreseen. Yet, with a hopefulness out of all experience, the designer, following the precedent set by many other bridge designers, counted on paint protection to resist this corrosive action. On the occasion of the repair work, however, the engineer who analyzed the case could not escape the broadly general conclusion that highway bridges over tracks should have no part of their steel structure located below the floor.

This is a very sweeping recommendation. As such, however, it is welcome evidence of bold and decided thinking in the matter of the local-corrosion problem. No progress has been made in the past under the plan of letting local corrosion take care of itself, but progress may result if we will face the facts and use every available expedient in the effort to prevent the undesired destruction.

Floors suspended below the truss chords, and so designed as to curtain the smoke away from the steel, would require some interesting modifications of typical design details. A concrete floor slab or a suspended ceiling would have to be used, and in the case of timber-floor highway bridges, as in the case first mentioned, the application of the principle might prove difficult. But any solution of the local-corrosion problem is worth discussion. Under past practice many tons of highway bridges have been thrown into the scrap heap because a few pounds of metal were eaten away by local corrosion.

Care in Foundation Work

NEGLECT in the examination of foundation conditions or in the design or construction of a substructure is sure to cause trouble sooner or later. This trite warning needs constant reiteration in view of the recurrence of failures. The settlement and failure of the Minneapolis armory described in this issue is a new instance. Two months ago the settlement brought to light a peculiarly prominent example. An equally remarkable case in another field was the failure of a drawbridge pivot pier because grossly faulty construction and inspection resulted in making the base only half as large as the body of the pier, as described in *Engineering News-Record* of Sept. 13, 1917, p. 484. Shortly before that time, water-works construction contributed a similar example in the Cleveland filter-house difficulties.

Piles of inadequate number and length in a deep bed of soft mud were responsible for the settlement that wrecked the Minneapolis building. Apart from the question of whether the soil conditions had been considered, it is clear that improper construction and inspection were factors in the case. The piles sank a foot or more under the final blow of the hammer, yet a heavy structure was built on them. The settlement that was to be looked for began even during construction, but apparently nothing more was done about it than leveling up the irregular floor with additional concrete.

Experience thus gives ample warrant for the caution that foundation work preëminently demands zeal and care—too much rather than too little. This applies equally to preliminary investigation, to design and to construction and its supervision. Failures have occurred in spite of all care, but that is an added reason for special thoroughness. The responsibility rests on the engineer; in case of a failure, even if he is blameless, the public is likely to place the blame upon him and the engineering profession.

How One Contractor Went About a Housing Job

Building 450 Small Dwellings for Shipyard Workers in Limited Time Required Organization of Forces and Planning of Operations in Different Manner From That of Usual Large-Contract Job

By Joseph Meltzer
Of Joseph Meltzer & Co., Contractors and Engineers, Boston, Mass.

LARGE-size housing operations involve as much material and labor as the ordinary construction job of similar cost, but the wide area over which the work is done, and the multiplicity of small similar units it involves, make them quite different in many ways from the usual contract operation. The problems in one such war-time job, Project 62 of the United States Housing Corporation at Quincy, Mass., for the workers of the Fore River shipyard, were both engrossing and difficult. First and foremost came the problem of grouping operations and sections of the work and arranging them in sequence for all classes of labor; second came the problem of obtaining the material and delivering and storing it in a way which would eliminate double handling and delay in the work; third came the proper coördination of field and office-organization help; fourth, the problem of grouping labor units under foremen and subforemen so that shirking and idling would be cut down to a minimum.

The project consisted of 256 houses, one-third of which were single six-room houses, and two-thirds double houses with four rooms in each part. Most of them were of common frame construction, with brick first floor, and a few were entirely of brick. The foundations were built entirely of concrete, using the run of the bank for the concrete aggregate, with no waterproofing or exterior finish except for surfacing with a thin grout above the grade line. The frames of the houses were of the ordinary type, with a 2 x 4-in. studding, 4 x 6-in. corner posts, clapboard or shingled as was required by the architect, with double floors throughout, and with mineral-coated asphalt shingles for most of the roofs and slate for others.

The entire project was divided into three tracts, the Arnold St., River St. and the Baker Basin tracts. The first and last tracts were further subdivided into three areas each, thus making seven areas with about 36 houses to an area. The landscape architecture suggests a well formed design throughout, with a logical and systematic layout, taking advantage of the natural grades for economy. The houses were designed for permanence, the rooms were well formed, giving plenty of closet space and suggesting compactness, neatness and economy. The color schemes of the exterior walls and the roofs will present a very pleasing effect when completed. The United States Housing Corporation, through its architect, its landscape architect and the city engineer, designed the houses, laid them out in proper coördination and designed the public utilities. These plans were all ready when the contractor made up his estimate.

HOUSES OF SAME INTERIOR LAYOUT WERE VARIED IN EXTERNAL APPEARANCE

The detailed estimate, with its fine subdivisions into every kind of material that goes towards the making of a single house, was such that at a glance the entire aggregate of commodities could be taken off from a list. This was no small part of the job. As there were 28 different types of houses in the project, each commodity—such as concrete, boarding, rough framing, brickwork, shingles, etc.—had to be itemized per type of house and summarized both for the group of houses and the total number of houses. This was accomplished with the help of the corporation's field cost engineer. As a general rule, a contractor, in bidding on any construction project, does not go into minute detail but rather bunches groups of work. It was therefore a departure from the ordinary methods of the contractor's estimating department. As an example of the fine subdivisions, the rough framing had to be divided in the different sizes and different lengths and spread over the 256 houses, giving the number of pieces of each length for each type number.

The contractor's organization of forces followed the axiom that a triangle is safer standing on its base than on its apex. In other words, the scheming of the contractor's organization was done in such a way as not to make it top-heavy.

The construction work was commenced Sept. 9, 1918, four days after the award of the contract and four weeks before the contract was signed. Excavation was begun immediately after a tent was pitched, emergency equipment and material were brought in by trucks, and first small gang of 15 men started. The contractor's force then consisted of a few labor foremen, one office man and the assistant works manager. From that day on the field organization as well as the office organization began to form.

September and October were the most trying times for a contractor in which to organize a working force. The weather was bad, extremely bad. The influenza epidemic in the neighborhood was on the upward climb,

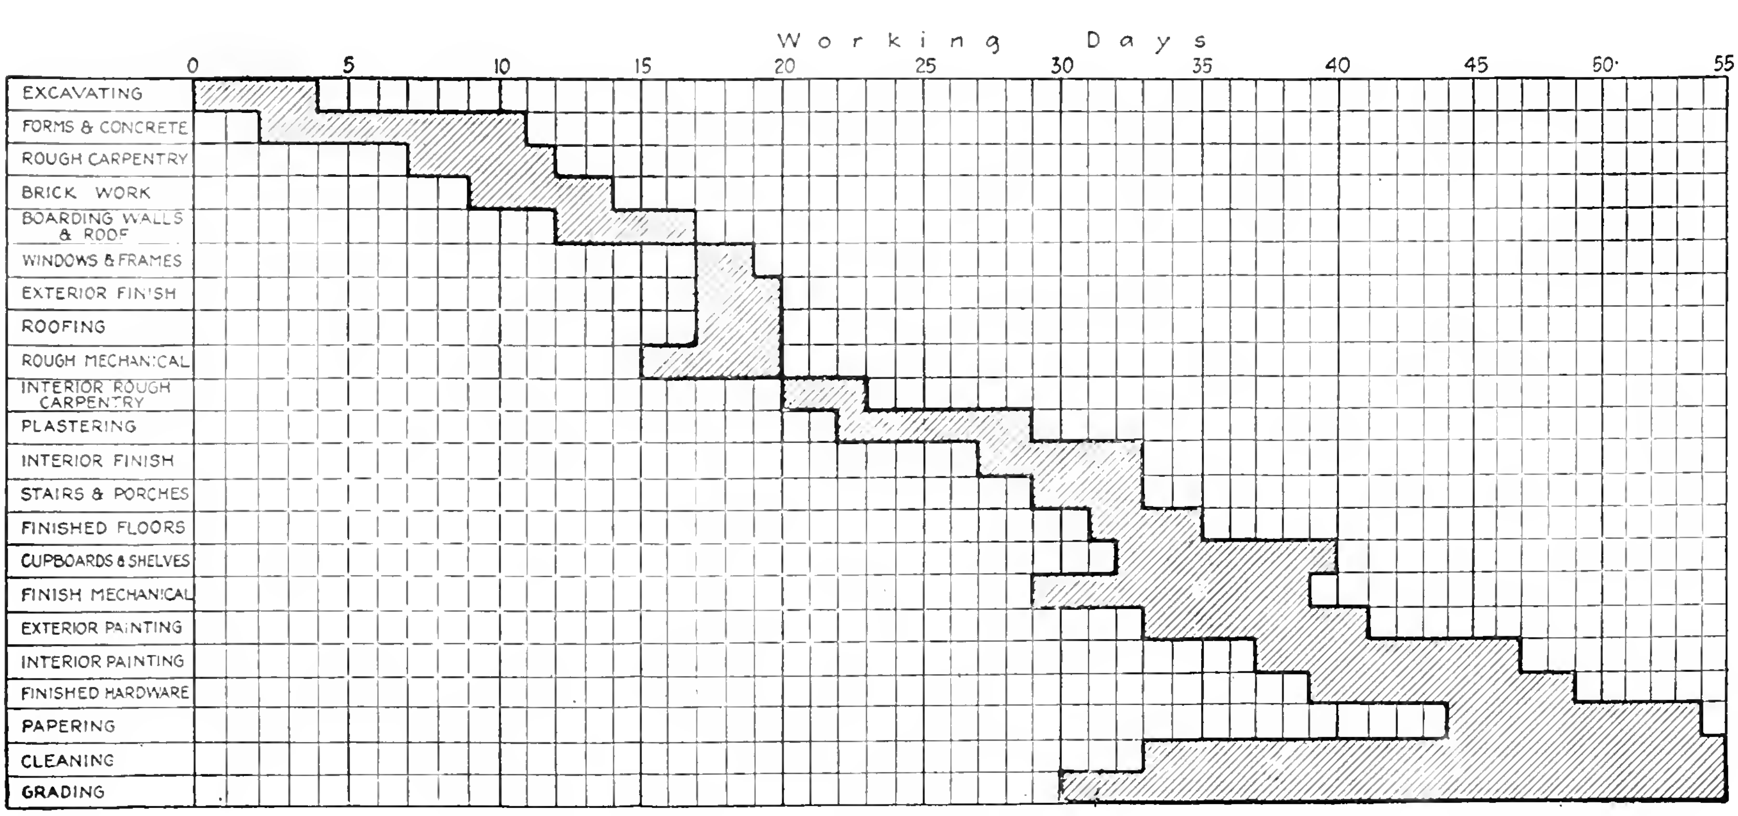
SHOWING RUNWAY OVER HOUSE FOOTINGS IN FOREGROUND TO FACILITATE OPERATIONS

taking its victims where least expected, and it took every ounce of energy to persuade the laboring class to go to the Quincy job at a wage scale that offered no inducements. However, in spite of all these difficulties, in three weeks' time an office organization consisting of approximately 30 employees and a field organization approximating 500 were gathered and put into working order toward a definite goal—rapid work, economical construction and efficient handling of labor.

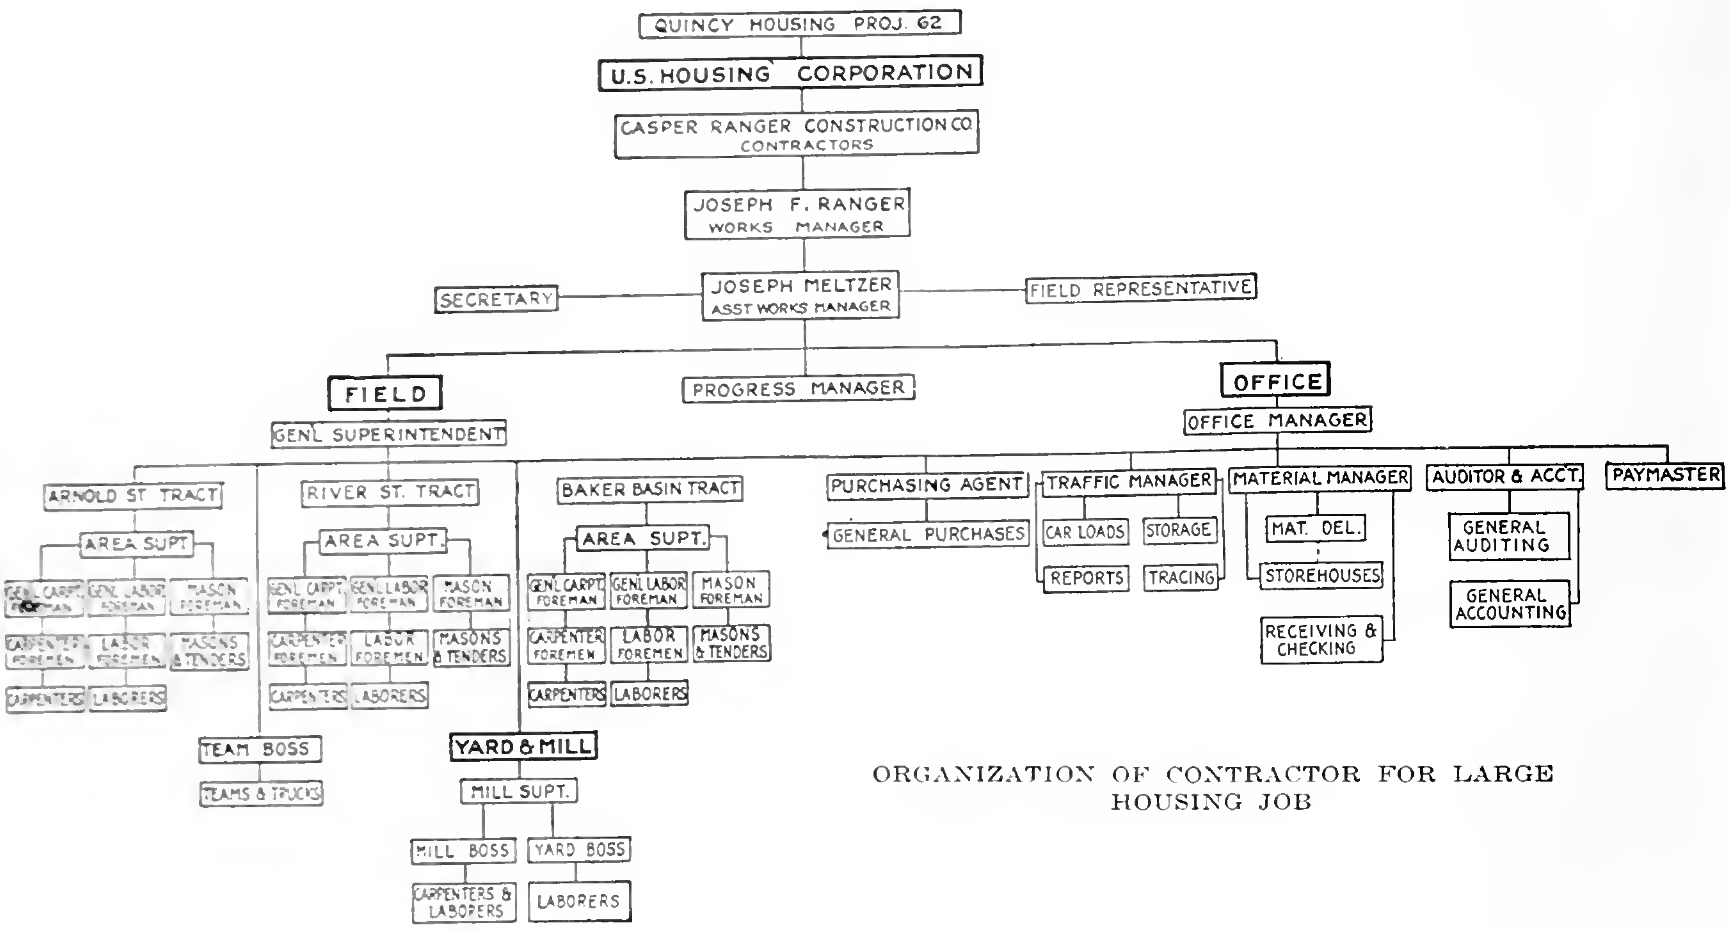
Gangs were organized to do excavation, other gangs were organized to do concrete work and still others were organized to place forms and to strip forms. These gangs followed one another in series, so that very little time was lost betwen movements. As soon as it was possible to remove the forms, the framework was started and brought to completion in very short time. Usually between eight and 10 men constituted a gang for placing the concrete work and from six to eight carpenters constituted a gang for putting up the framing and boarding.

The excavation on two of the areas was accomplished by horse scrapers and hand shoveling. On the Baker Basin tract, however, as well as in one or two instances on the Arnold St. tract, steam shovels were used.

Particular attention was paid to the top soil and subsoil with a view to saving every available square yard for planting and seeding around the houses. This was accomplished by using two horse scrapers and piling up the top soil and loam between the houses so that double handling would be avoided. The pressure of time, the inability to obtain the required amount of labor, and the rapidly approaching cold weather, hampered



HOW WORK WAS PLANNED ON ONE GROUP OF 15 HOUSES



ORGANIZATION OF CONTRACTOR FOR LARGE HOUSING JOB

the contractor in handling the top-soil excavation in the most efficient manner. However, taking everything into consideration, very little rehandling of the top soil was necessary. The excavation, which consisted in the main of gravel and sand in a proportion suitable for concrete aggregate, was effected by scrapers, plows and hand shoveling. Every possible bit of gravel that was fitted for concrete work was saved and used for that purpose.

Just as soon as a cellar would be completely excavated, the concrete footings for the walls were placed, mixed by hand or machine, and forms for the concrete walls were immediately set. Square-edged spruce and hemlock boards were used as well as tongue-and-groove North Carolina pine, although the writer prefers square-edged material. The concrete for the walls was mixed in one-batch gasoline-operated mixers mounted on wheels, which proved very economical. These machines were easily moved from one cellar to another and runways were quickly set up. At times two or three cellars would be poured from a centrally located mixer. Each mixer would pour the foundation of a double house in one day.

The framing for the entire project was handled from central mill located on the Arnold St. tract; all of it was cut and framed, numbered, marked and shipped to the various houses. When the concrete forms were partially stripped gangs of carpenters were organized, usually from six to eight to a house, to place the ready-cut framing, do the rough boarding and lay the rough flooring, all in one operation. These gangs were kept moving from house to house, from four to eight gangs being used on each area.

As soon as the rough framing was completed and interior studding placed, the plumber would organize a gang of two for each house to do the roughing-in work, between two and eight gangs being used on each area at different times. The electrical subcontractor organized similar gangs, working in conjunction with the plumbers and getting the houses ready for lathing and plastering. The sequence of operation after the lathing was in place—such as plastering, hanging sash, interior finish, finish flooring, etc.—was kept up systematically, so that each gang followed another with very little loss of time.

The public utilities being handled under a separate contract and installed by a different contractor, it was in most cases done in such a way as not to hold up the work. The public-utilities contractor used a large steam trencher for excavation for his sewer and water pipes throughout the job. In only a few instances was hand shoveling used. His work embraced the sewer, water and gas piping, and road work from subgrade to finish grade and granolithic sidewalks.

A difficult problem presented itself in the proper scheduling of the material so that commodities would all arrive consecutively and as needed. As the project was situated, all the material necessarily arrived by rail. The contractor scheduled his material so that no more than 15 or 16 cars would come in one day, and in such quantities as were needed weekly, in order to eliminate unnecessary rehandling. Shortly after the award of the contract the War Industries Board organized to purchase all material on Government contracts. This immediately upset all the contractor's material schedules, and material began to pour in at the Quincy station very rapidly, as many as 35 cars coming in one day; in a very short time, due to labor insufficiency, the yard was greatly congested, holding as many as 105 cars at once. It was necessary to build storehouses for the cement, the lime, the interior finish and other material which could not be exposed to the weather, and also to rent several storehouses to accommodate interior trim and other material.

The unloading of all material, especially the lumber, was a somewhat slow process, as the Government officials insisted on a very close check. At the beginning of the job all material was checked by both the contractor's checker and the Government checker. This was later eliminated and brought down to a more businesslike

basis by employing experienced lumber surveyors, and on the whole the unloading was considerably speeded up. All the material was delivered by motor trucks, and all the lumber except lumber for forms was delivered to the mill lumber yard and distributed in piles according to sizes and lengths, as is customary in lumber yards. The cement and the lime were stored in temporary and rented storehouses when these materials arrived in larger quantities than were immediately needed on the different areas. However, whenever possible these perishable materials were delivered directly on the job from the cars, to fill requirements. The other material, such as shingles, roofing, brick, etc., were delivered directly to the house lots in the quantities called for on the official estimate. All standing finish, doors, sash, etc., which had to be protected from the weather, were temporarily stored and then distributed to the different house lots to fill requirements. The central mill was equipped with electrically operated equipment, among which were the following: Two cut-off saws, three band saws, four circular saws, one bed planer, two buzz planers, one miter and other apparatus to make the mill complete. As a necessary adjunct the mill was equipped with a saw setter's outfit, grinders, emery wheels, etc. The mill proved a very profitable unit and decreased considerably the cost of framing and handling. The entire framing for each house was properly scheduled by an experienced man, thus eliminating the duplication of effort and the possible waste of lumber.

FACSIMILE OF PROGRESS COST RECORD, SHOWING FINE SUBDIVISIONS

Unqualified Men Called Themselves Carpenters

One must remember that the laborer who applied for a job during the months of October and November was not a building laborer. Owing to the second Army draft men of all classes and of all occupations sought Government employment so that they might be classed as employed in an essential industry. The project at one time was overrun with tailors, waiters, farm hands and quarrymen, a class of labor which had to be sifted. The turnover on the job, therefore, was immense. In the carpentry line such difficulties were not encountered, but, owing to the many cantonment jobs that were in operation during the previous 15 months, many helpers classed themselves without right as carpenters, which only necessitated their expulsion after a few days' trial.

All this necessarily made for higher cost of construction, and it was only through the careful watchfulness of the individual foremen that the cost was held down to the lowest possible margin.

The progress department would report progress each day on each individual house, also the kind of work performed each day on each individual house. The same department kept a perpetual chart showing the gradual progress. These reports were submitted to the assistant works manager, who would chart each day's work graphically and numerically. By this method constant watch was kept on the cost of the job, the size of the organization, the progress of the job and the ratio of output to cost. In a word, it was the intention and aim to follow up the work as if the entire job was a big machine shop where maximum output and minimum cost are the aim.

In order to create coöperation and friendly feeling between the heads of the departments and a high *esprit de corps*, weekly organization meetings were called. At these meetings the results of the past week's work were discussed, criticisms were made promptly, and everybody present was urged to clear himself of all difficulties confronting him. Thus, each head acquired a view of the workings of the other departments and a proper perspective as to his place in the organization and the necessity for working in harmony. These meetings proved very beneficial to the job.

Among the Government's representatives were H. G. Ganson, traveling superintendent, and Walter H. Cook, project manager. Both proved to be of material help not only in their practical advice but in their hearty encouragement. The architect for the job was James E. McLaughlin of Boston. The landscape architect was Herbert J. Kellaway, and Ernest W. Branch was the engineer. The Casper Ranger Construction Co. was the general contractor, for which the writer acted as assistant works manager, having complete charge of the operation until Jan. 1. Joseph F. Ranger acted as the works manager. The entire work was done on the basis of actual cost plus a fixed fee. The approximate estimate of the cost of the work was $1,600,000, or about $3500 per house. This did not include the utilities such as water-supplies, sewers, streets and sidewalks, which were let under a separate contract to Dennis E. Crowley of Quincy, Mass.

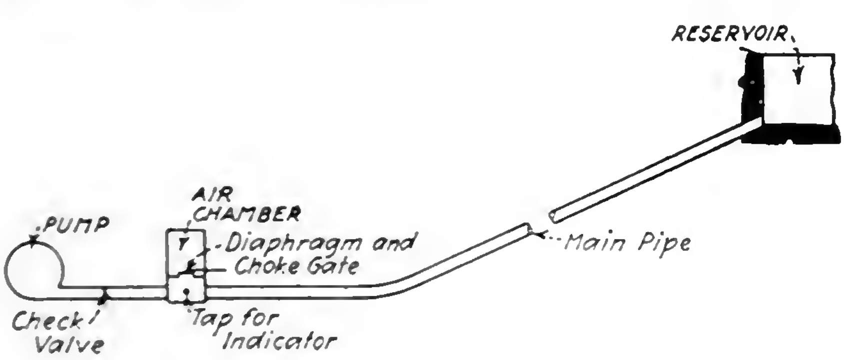
Graphical Records of Surge Pressures in Pipe Lines

Tests Made to Determine Effect of Varying Air-Chamber Conditions and Changing Choke Gate Area

By Ralph Bennett
Los Angeles, Calif

NUMEROUS curves showing the actual effect of varying the conditions on two pipe lines equipped with air chambers have been made by an apparatus which produced a time-pressure record of the variations which took place at shut-down in these pumping lines. Results of a series of surge tests on these 18-in. and 24-in. lines are given. As originally installed, the 18-in. line was equipped with a plain air chamber, while the 24-in. pipe was without any protection against shock. The test results for the 18-in. line were used to design the air chamber for the 24-in. line.

In order to secure a continuous record of actual pressure variations, the pencil mechanism of a steam indicator was so arranged that it produced its mark on a strip moved by the clockwork train taken from a high-speed recording voltmeter. The machine, though difficult to set up, gave sufficiently accurate records for the purpose. It was subject to the usual disadvantages of the steam indicator when used on water. Thus, it is probable that the shoulder seen on the trailing end of the waves is due to piston lag, since at that point in the stroke the piston would have been riding quietly in the



GENERAL ARRANGEMENT OF TEST APPARATUS

cylinder and so may have stuck slightly. Minor variations in the paper speed also occurred, as the indicator pencil dragged more on the chart than did the original voltmeter pen.

Inasmuch as the energy stored in an air chamber is a function of the volume and pressure of the contained air and not of the shape of the chamber, the volume has been used in referring to the air effects. Sufficient data as to the conditions are given to permit of translating to other units.

The curve-tracing device was connected at the base of the air chamber, as is shown in the accompanying sketch, the reading being the pressure of the line. In one case the instrument was transferred to a point above the diaphragm to obtain a record of tank-pressure changes. This has been superimposed on the pipe-line record in an otherwise similar test (Fig. 9.) The curve is very interesting in that it shows graphically the time and intensity relation of the internal and external pressures when an almost perfect damping is attained in a single swing.

The vertical scales shown on the curves are those corresponding to the spring used. Owing to indicator friction as well as secondary pressure disturbances, the

RESULTS OF TESTS OF 18-INCH PIPE LINE

Volume of air, cu.ft.	Pressure wave amplitude from starting pressure plus Lb. per square inch	minus	Time of half wave Sec.
0	—	—	2.36*
14	36	25	3.12
20	32	23	3.65
35	26	19	4.75
50	23	16	5.83
75	19	12	6.5
100	16	11	7.4
118	16	9	7.0

*This figure is calculated; all others are observed values.

actual peak values may vary considerably from the curve value. The horizontal scale of time must be averaged, as minor irregularities of drum movement affected the record. The time given for the waves is that of the half wave after shut-down is complete and the column is vibrating as a free but loaded pendulum.

The lines were supplied by motor-driven centrifugal pumps, directly in line with the main pipe and but a few feet beyond the air chamber, and equipped with squirrel-cage motors controlled by oil compensators. As the rotating elements of such units are very light, the shut-down caused by opening the oil switch was as nearly instantaneous as can be obtained. The pumps had check valves which closed at about the point of flow reversal.

Tests were first made on the 18-in. line, and from them the necessary data for a proper tank on the 24-in. line was secured. This 18-in. line was of riveted steel, as follows: 0.0625 in. thick, 971 ft.; 0.078 in. thick, 816 ft.; and 0.1094 in. thick, 1400 ft.; average thickness 0.087 in., total length 3187 ft. The maximum head was 240 ft. (104 lb. per square inch) and the grade uniform, with no sharp bends nor obstructions. No laterals were open during the test. The pipe terminates in the bottom of a reservoir 150 ft. across and 12 ft. deep.

The air chamber at the pump is 36 in. in diameter and 10½ ft. long above the line, which passes directly through it. The two-stage centrifugal pump, delivering by test 954 gal. per minute, gave a line velocity of 1.2 ft. per second. A swing check valve was used.

Shutdown tests were made on this line, using varying quantities of air in the chamber. No provision for contracting the entrance to the air chamber was available, and it was not possible to vary the flow in the line.

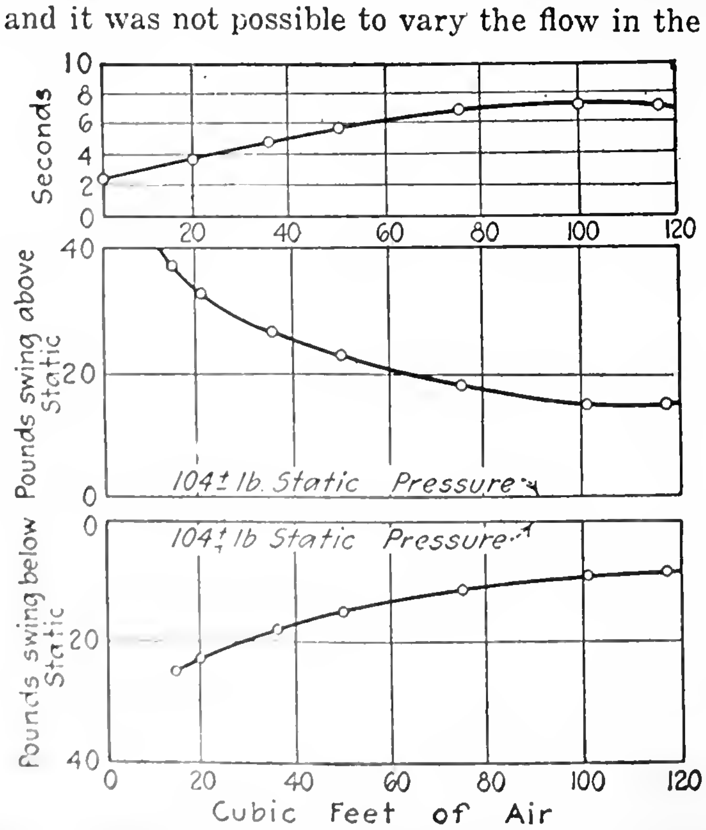


FIG. 1 PRESSURE VARIATION WITH AIR VOLUME—18-INCH PIPE TESTS

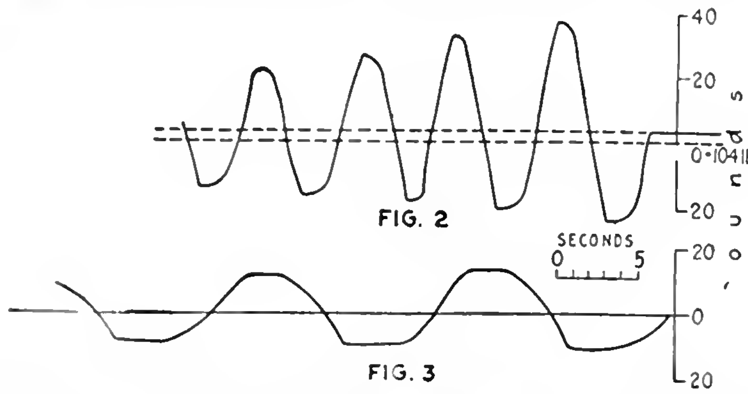
The results of these tests are given in the table and by the curves in Figs. 1, 2 and 3.

The data on the 24-in. riveted-steel pipe line are as follows: 0.078 in. thick, 4757 ft.; 0.109 in. thick, 1954



FIGS. 2, 3. GRAPHS FROM TESTS OF 18-INCH PIPE LINE
Fig. 2, air, 14 cubic feet; Fig. 3, air, 118 cubic feet.

ft.; and 0.172 in. thick, 80 ft.; average thickness, 0.086 in., total length 6791 ft.; maximum head 160 ft. (70 lb. per square inch, including friction); grade uniform and without sharp bends or obstructions; no laterals open during test; pipe terminates on the bottom of a reservoir 100 ft. in diameter and 10 ft. deep.

The air chamber is 48 in. in diameter, with 15 ft. effective height, connected to the line through a rectangular opening in a plate diaphragm which can be closed by a slide. Water is supplied by a two-stage centrifugal pump delivering by test 1881 gal. per minute and producing a line velocity of 1.33 ft. per second. The check valve on this pump was an egg-shaped plunger controlled as to speed of closing by a bypassed plunger.

The free action was as rapid as that of a swing check. Most of the curves were obtained with little or no retardation of this valve. Experiment proved that delayed action resulted in additional shock if the water column had reversed before the valve acted.

Tests on this line were made for numerous volumes of air, using also many different choke openings. The calculations had shown that the 24-in. line could be held to a rise of less than 10% of normal by an air chamber having an air space of about 65 cu.ft. connected to the line through an opening of 30-sq.in. area.

Fig. 4 shows the card obtained with 67 cu.ft. of air and a 25.87-sq.in. choke. Under this condition, the fall of pressure at shutdown is very severe, and the oscillations die down very quickly. The condition desired is one in which the greatest possible absorption of energy occurs across the choke from the instant of shutdown. The best condition occurs when the first half wave (in this case negative) is the one in which the greatest loss occurs. The ability of the line to stand reduction in pressure will frequently limit the possible control.

Note on this curve the great distortion of the fundamental wave by the shock from the check valve. This superimposed pressure may at times become very serious, but, as stated above, any attempt to control it by slow valve action is a move in the wrong direction. Better results would be obtained by a loaded valve.

Fig. 5 was obtained with the same air content, 67 cu.ft. and a 32-sq.in. choke. The check-valve disturbance is much as before. The indicator was put on the line before the pump was started, and the entire cycle from standstill to standstill is shown. Note that the shock due to the rapid start of the pump is more severe than is that due to the shutdown surge.

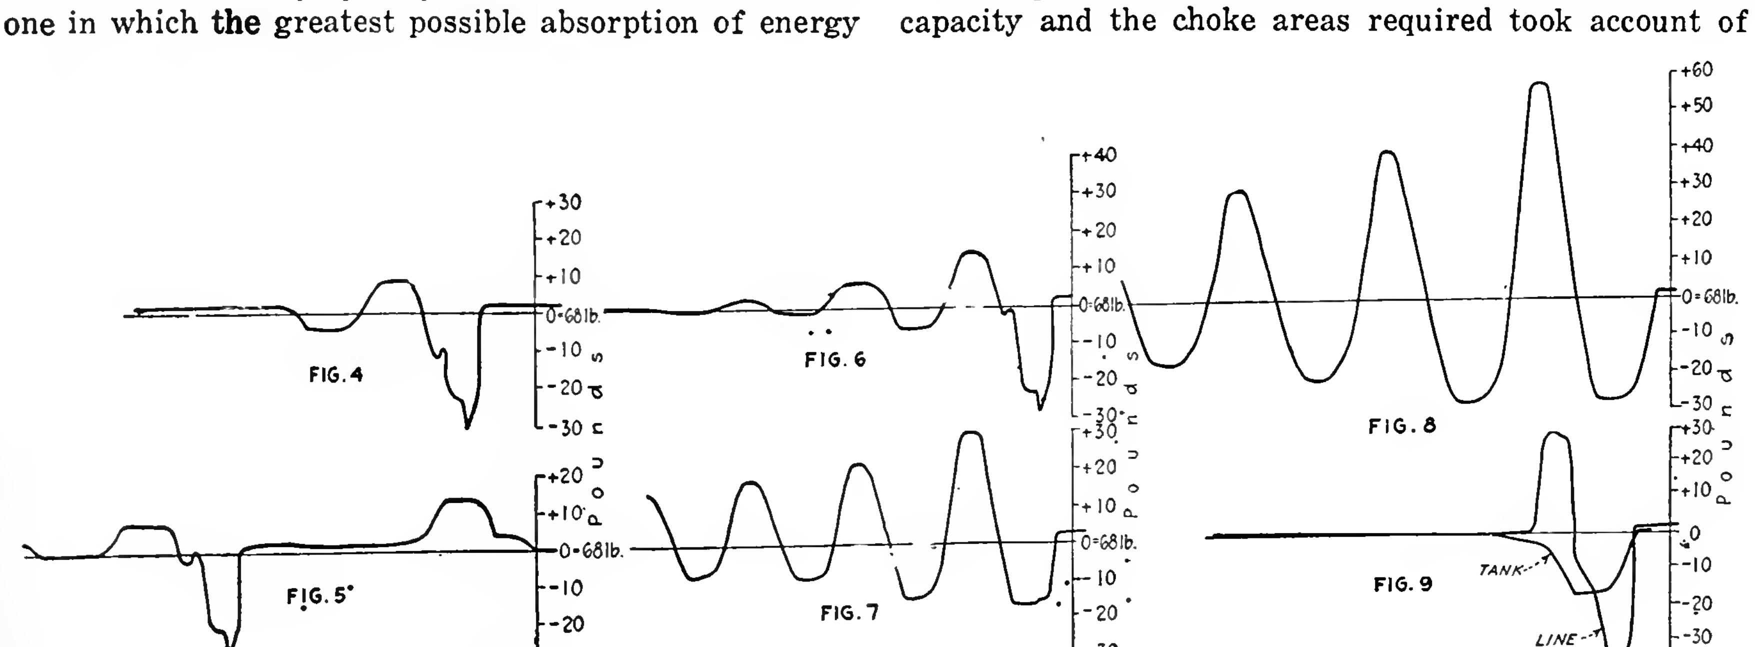
The quantity of air and the closeness of the choke can be varied within limits with about the above results but any considerable decrease in the amount of air reduces the ability of the tank to absorb energy and increases both the pressure peaks and the number of undulations required for full absorption of the energy in the water. Curves in Figs. 6 and 7 show these effects very clearly. Fig. 6 shows good control with 35-cu.ft. air and a 25.8-sq.in. choke, while Fig. 7, with the same volume, produces an excessive shock.

If the tank contains ample air but is too freely connected to the line, a condition results similar to that shown in Fig. 8, which was taken when the air supply, 90 cu.ft., was more than ample for full pressure control but with an excessive opening, 68 square inches.

Inasmuch as the commonest danger to ordinary pumping lines and to most water-wheel lines is due to excess pressure, most attention is directed to the effect of the upward surge. But the pressure limiting work is most effectively done in the first downward swing, as noted above, and the safe reduction in pressure is the usual limit to the control.

While the condition of full-load shutdown is more apt to occur in pumping lines than in wheel-penstocks, yet the effect of governing is of vital importance in the latter case, and a choke air chamber will be beneficial on any change of velocity.

The equations used in working up the air-chamber capacity and the choke areas required took account of



FIGS. 4 TO 9. GRAPHS FROM TESTS OF 24-INCH PIPE LINE
Fig. 4, air, 67 cubic feet; choke, 25.9 square inches. Fig. 5, air, 67 cubic feet; choke, 32.0 square inches. Fig. 6, air, 35 cubic feet; choke, 25.8 square inches. Fig. 7, air, 35 cubic feet; choke, 45.0 square inches. Fig. 8, air, 90 cubic feet; choke, 68.0 square inches. Fig. 9, superimposed tank and line pressures.

the elasticity of the water and of the pipe, but not of the effect of internal friction in the air. It is probable that large and important tanks would have to be figured with due allowance for all losses.

The lines tested were connected with plants supplied with energy by the Southern California Edison Co., and the company's apparatus was used in making the tests. R. J. C. Wood of the company acted with the writer throughout the work, and to his unusual ability in this class of work are due the results obtained.

Coming Status of the Employee in Industry

Advantages of Stock Ownership by the Workers—Duty of Industry to Society in Developing and Protecting the Men

The following paragraphs on the future status of the worker in American industry are taken from an address by Charles F. Lang, president of the Lakewood Engineering Company, before the annual convention of the National Machine Tool Builders' Association in Atlantic City, May 12. He points out the advantages of stock ownership by the employee, and credits the employee with the ability to exercise a salutary influence upon the management of the company. He also points out the duty which industry bears to society for the "health, mentality and welfare" of the worker—EDITOR.

WITH the financial inflation which this war has made necessary, with the world-wide shortage of labor, with the shelves of the world empty, America, with one-third of the world's gold, with her finances in splendid shape, with her tremendous productive capacity, with her marvelously productive labor, and with a less acute labor shortage than any other country in the world, can and should and will face the future with absolute confidence, for it cannot be doubted that she is entering upon a period of unusual prosperity and opportunity such as has never before come to any nation. One of the first things Noah did after the flood was to get drunk. And America's greatest danger for the future is that she may become drunk with power. She must enter this new era with certain principles and ideals or she will not realize her opportunities, and one of the greatest of these ideals is that there shall be such a distribution of wealth among all her citizens as will make for the happiness and well being of all her people.

Profit Sharing to Be Universal

Far-seeing men have already sensed this opportunity, and these ideals are being expressed—yes, and carried out—by business men in their relations with their employees in a spirit of coöperation not dreamed of a decade ago, and I predict that coöperation between employer and employee—profit-sharing, if you please, will become a universal rule of business with all successful concerns in less than another decade, and, I believe, with profit to all concerned, invested capital as well as labor, executive as well as laborer.

No real national policy of this kind has yet been developed, but toward the formation of such a policy leaders of thought in capital and labor must give their attention.

I am proud of the spirit of the present generation which is so earnestly thinking along these lines. The present form of corporation so readily lends itself to securing this coöperation that it is rapidly becoming a habit for American business concerns to encourage their employees to purchase stock in the company, but I fear the employees are not as rapidly as they should accepting this opportunity to share in the profits of the business for which they are working. But I believe the time is rapidly approaching when there will be a real partnership all the way down the line, when the stockholders of many of our business concerns will be the employees, and those sharing in the profits of the business (the more thrifty, of course, to a greater degree than the careless and shiftless) will be the men working for the concern. I see no dangers in the development of such a system. It is a well known, but nevertheless interesting, fact that your average stockholder never shows up at a stockholders' meeting unless his dividends are cut, and I don't believe the employee-stockholder will be a very much different kind of an animal, except that if he does become alarmed because his dividends are cut he will try to find the reason why, and may discover that he himself, because of the kind of service he has rendered his company, is one of the reasons for this, and that a lot of his fellow workmen are others of the reasons, and that between them they will try to discover a way, by more efficient service, to avoid a repetition of the unfortunate circumstance. It has never seemed very difficult for the American people to select the right man as their chief executive, and it is remarkable how few mistakes have been made in this direction in American history. In the democracy of business I think just as few mistakes will be made by the stockholding employees in the selection of various executives. In other words, peculiar fitness for particular responsibilities seem to be quickly and intuitively recognized by the American people, whether in their national affairs or in their business affairs. (More particularly, perhaps, in their business affairs, for I am inclined to agree with an official of the Chinese government who was over here not long ago and who raised the question as to why we did not require our congressmen to take an examination as to their qualifications to serve before we elected them.)

Advantages of Employee Stockholders

I submit that a system whereby the employees are stockholders might be far better than the present one, where, perhaps, an individual owning the majority of stock will keep himself in office and in responsibility long after his usefulness to the organization has gone, for he himself is always the last man to see this and to resign voluntarily. As the president of a large corporation recently said to me: "I am not a majority stockholder in my company and don't want to be. I do, however, own quite a block of stock, and when the time comes that I am no longer fit to be president of the company the other fellows will find it out before I do, and by asking me to get out will save for me the investment I have in the company; whereas, if I wait too long, I might lose my whole investment as well as my job."

I do want to say one further word as to coöperation between business and society as a whole. I cannot see how the American business man today in the conduct of his business can avoid his responsibility to society, for the health, mentality and welfare of the men employed in his institution. And I do not say this with any paternalistic idea in mind; it is, rather, a patriotic duty, and not a fatherly kindness. For, if all our men

are kept in health and happiness, due to proper and pleasant working and sanitary conditions, their productivity is increased, thereby increasing the national wealth and comfort.

Again, getting down to fundamentals, every workman dying before his time, because of the unhealthful or unsanitary conditions under which he is compelled to work, and leaving behind him a family for which he has been unable to provide a competence, merely represents another one of those losses which must be borne by society as a whole, which means that each individual member of it must bear his proportion. This is entirely aside from the sentimental and humanitarian side of the problem.

Again, it is the duty of the employer as well as the employees to compel such of the employees who neglect to do so, to live and bring up their families under clean and sanitary conditions of both mind and body—of both *mind* and body—for no employee has the right to endanger the health or happiness of his fellow employees, however careless he may care to be about his own.

These remarks apply with greater force to the the development of the mentality of the men. Low mentality makes for social unrest. We Americans are too apt to complain of the ignorance and lack of judgment of workmen, when, as a matter of fact, the responsibility for that ignorance is upon ourselves.

America Can Solve Industrial Problem

The Chaldeans, I believe, were the inventors of books; the Greeks left us a heritage of art; Rome gave to the world standards of law and organization which are still followed; the daring navigators of western Europe carried through a marvelous period of discovery; Germany, with all her faults, has given to the world many wonderful advancements in science. I cannot but feel that America will leave as her heritage a solution of the problem of the proper distribution of wealth and happiness and education among the masses; in other words, will show to the world how a government can truly be a government "of the people, by the people, and for the people," because the people are capable of making it that kind of a government.

Iowa Assembly Had 25 Occupations Represented—No Engineers

Although 25 different occupations were represented in the late General Assembly of Iowa, there was not a single representative of the engineering profession among the legislators. This fact was ascertained from J. H. Dunlap, who compiled the list of occupations in the course of the campaign for the passage of the engineers' registration bill. The professions and trades represented were as follows: Bankers, farmers, manufacturers, merchants, lawyers, druggists, coal and ice dealers, lumber dealers, investment salesmen, grain dealers, school principals, publishers, stockmen, auditors, physicians and surgeons, college presidents, editors, students, real-estate dealers, insurance agents, commercial travelers, teamsters and switchmen. In Professor Dunlap's opinion, the fact that no engineer's name appears reveals the common lack of interest in community affairs which the engineer is just beginning to realize is responsible for much of what he is criticizing in his present professional position.

A. A. E. Compensation Committee Report

In a report on compensation made at the recent annual convention of the American Association of Engineers the following conclusions, on which to base a salary schedule, were reached:

1. That the profession of engineering, taken as a whole, is insufficiently paid, or is not paid in proportion to the high degree of responsibility entailed or the technical training required to perform the work.
2. That the principle of a square deal for everybody should underlie all rules of compensation, and that technical men must demonstrate their worth both to their employers and the public before they receive the compensation due them.
3. That this demonstration should be made by individual salesmanship, and by proper methods of publicity directed by this association to establish coöperation between employers and employees and to insure proper recognition of the services of the engineer by the public.
4. That while salesmanship may produce results in individual cases, it is necessary to operate collectively for the rank and file of engineers, and desirable that some forms of grades for engineering services be adopted with a minimum rate of pay for each grade.
5. That the rates suggested herein are not the maximum standards, but rather indicate the rate of pay of anyone who can perform the line of work, and that individual effort should be encouraged to the fullest extent and be paid accordingly.
6. That in the determination of a just compensation, consideration must be given to the effort or cost of the educational training; the years and character of experience in the particular line, as well as total years experience; length of time in employer's service; character and personality; degree of efficiency and special qualifications.
7. That the uncontrolled law of supply and demand is not a just method by which to determine the compensation for valuable services. Therefore, steps should be taken to control its operation so that it may not become oppressive especially in the lower grades of service.

The following specific recommendations were made:

1. That the hours of employment for technical men of grades 1, 2 and 3, hereafter defined, should not exceed eight hours per day or 48 hours per week.
2. That overtime in above grades should be paid for at an increased rate.
3. That no one in charge of engineering or construction forces should be paid less than any man for whose work he is responsible.
4. That when by a superior's orders an employee is shifted to a point requiring him to change his place of abode, the employer should bear the entire expense of moving him and his family.
5. That employees should be given national holidays and not less than one day's vacation for each month employed during the year, and that provision should be made for disability due to the hazard of employment.

California Road Repairs and Vehicle Fees

A large part of the money for maintaining the California state highways is derived from motor-vehicle license fees, which are, in general, on the basis of 40c. per horsepower per annum, with an additional fee based on weight for those trucks which use other than pneumatic tires. The fees collected are used first to pay the expenses of the motor-vehicle department, after which the balance is equally divided between the state and the several counties, to be used solely for road work. The half going to the counties is apportioned among them on the basis of the amount received from the residents of each county. In California at the beginning of the year there was a total of 300,000 motor vehicles, or one for every 10 persons.

Motor Equipment of United States Army Engineer Corps

Motor Truck Adapted to Many Purposes — Portable Carpenter, Machine, Blacksmith and Printing Shops and Searchlights

WHILE it is well known that motor trucks have been adapted to many purposes by the Corps of Engineers of the United States Army during the war, ocular demonstration of the facts had been largely withheld in this country until the recent parade promoting the Victory Loan in New York City. Devices exhibited in this parade demonstrated the great flexibility of the motor truck as a tool and suggest similar adaptations in civil pursuits. Such equipment might easily be of service on any widely scattered construction or maintenance operation, where it would be advantageous to make repairs *in situ*, rather than convey the part to and from machine shops. Portable tool trucks and sleeping quarters for small maintenance and construction gangs are also suggested.

The pictures given herewith are fairly representative of the various uses to which trucks were put. Beside those shown, other applications of the truck to war purposes may be mentioned, as follows: Water-purification plants; airplane transportation trucks; motor kitchens; motor bath-houses and ice machines.

FIG. 1 PORTABLE CARPENTER SHOP WITH SIDE OPEN

In addition to the devices named there are, of course, the transportation trucks and the fighting machines such as tanks and artillery tractors, which may be considered as motor-transportation features developed by the war.

That efficiency as well as flexibility characterized practically all the motor apparatus used in France may be seen from the following statement made by Maj. George A. Green, assistant chief engineer of the tank corps of the British Army and, before the war, chief engineer of the Fifth Avenue Coach Co., of New York City. He stated before the first semi-annual motor-transportation conference held at the Colt-Stratton Building, New York City, that during 18 months' service in France, all of which was in the forward fighting area, he had not seen a single motor truck broken down from other causes than ditching and direct hits by shells.

Already many special peace-time motor installations have been developed, particularly in municipal and

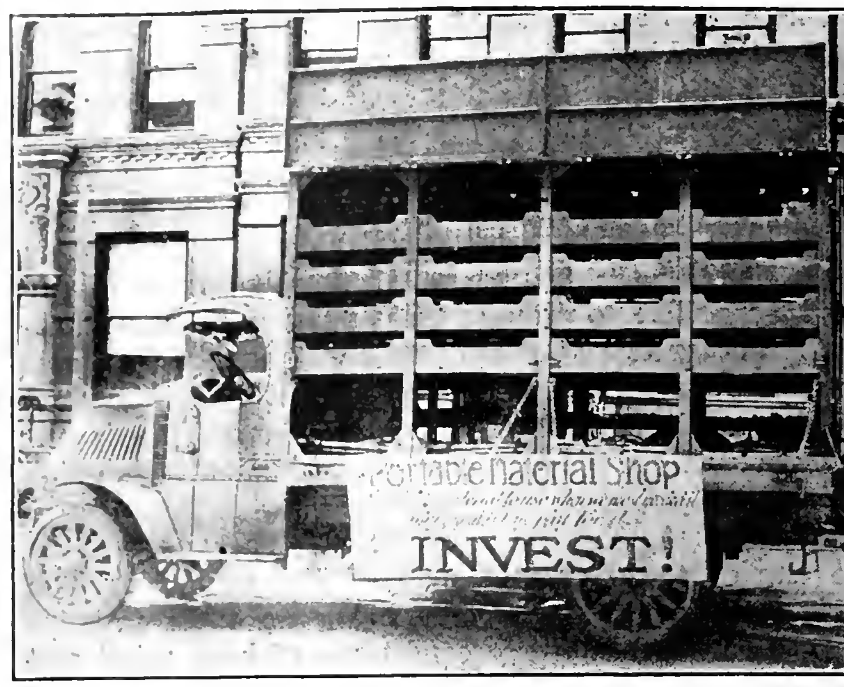


FIG. 2. MATERIAL TRUCK CONTAINS 600 ITEMS OF TOOLS, SUPPLIES AND OTHER EQUIPMENT

street work. It is thought that the successes along this line in warfare will stimulate additional experimentation in the use of trucks for special purposes.

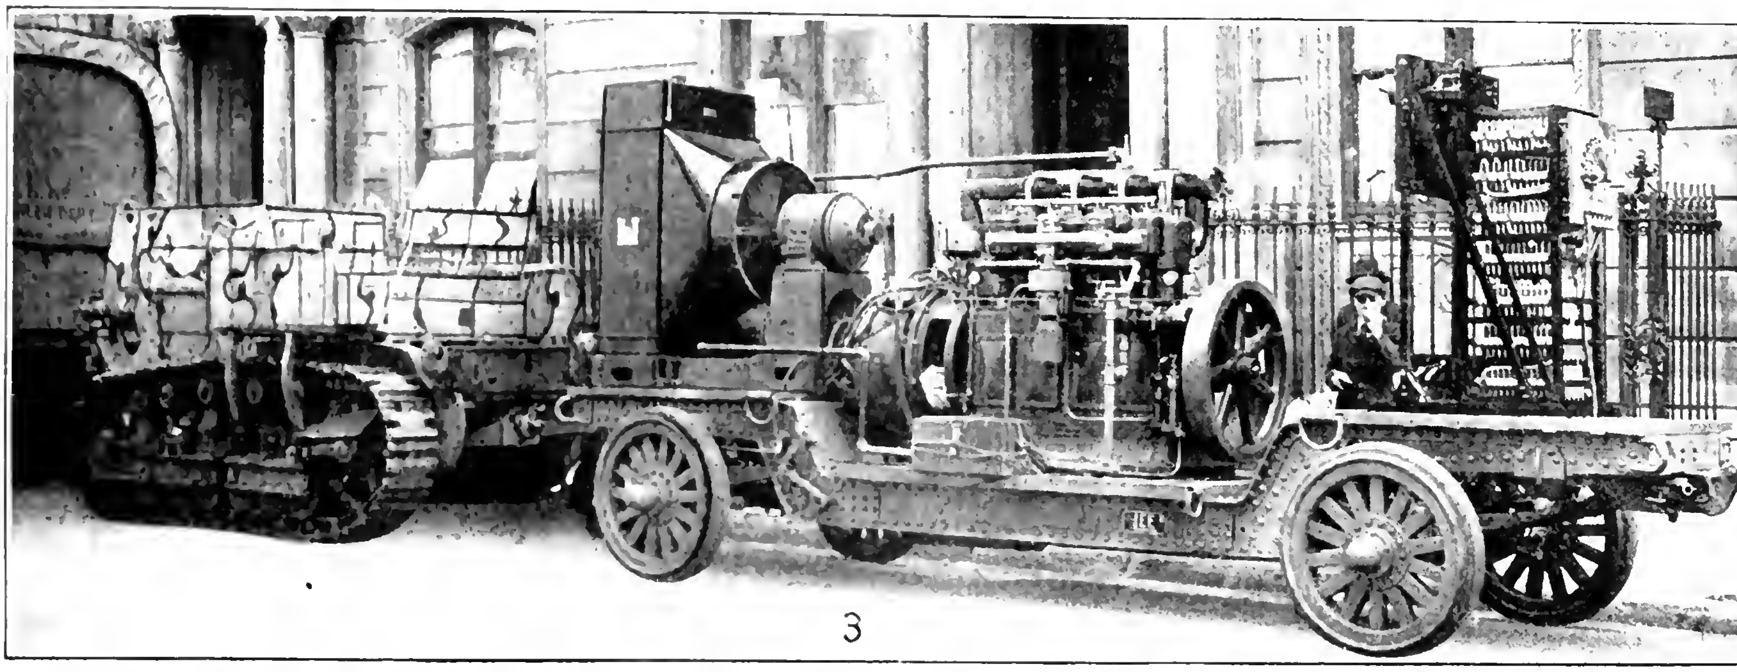
In all the special trucks developed by the Corps of Engineers, compactness is the chief characteristic. The necessity for this may be seen when it is stated that some of the portable shops contained as many as 10 different pieces of machinery, while the complete list of machine tools and supplies ran as high as 800 pieces. To get this all on one truck required the utmost economy in arrangement. When the war ended there were 95 of these portable shops in the service and 30 material trucks. The chassis for the shops and material trucks were of 5½-ton capacity.

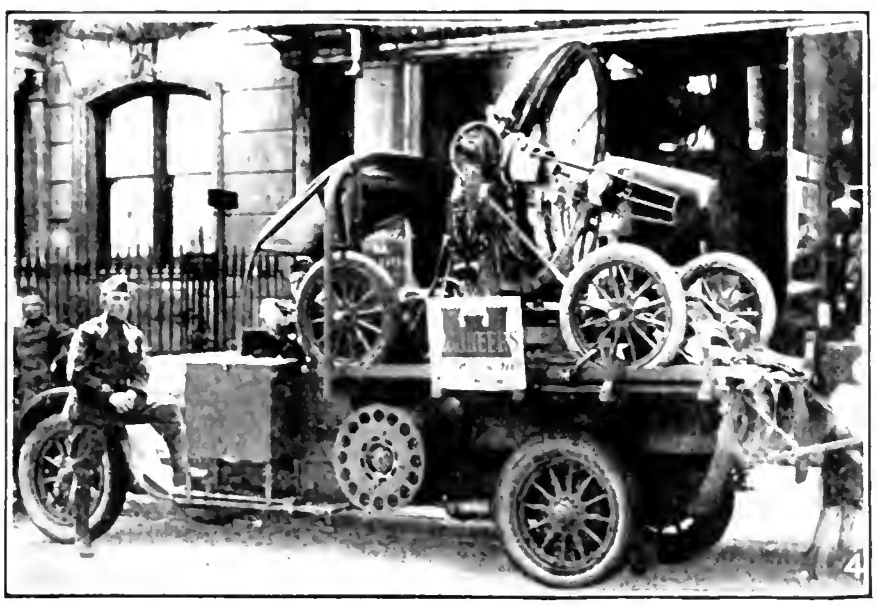
Among other devices developed by the corps, but which were not in service when the armistice was signed, is a small crane, for hoisting materials, mounted upon a motor truck so that it can move from place to place, and a portable pile driver which it is thought will be useful in highway and other construction where it is necessary to drive piles. The pile driver was designed to be drawn by horses, but it could easily be mounted upon a motor truck. While the pile driver is being transported, the leads, which are 30 ft. in height with a spread of 17 in., are folded up. The driver is operated with a 25-hp. gasoline engine, and can be placed in operation within 15 min. after arrival.

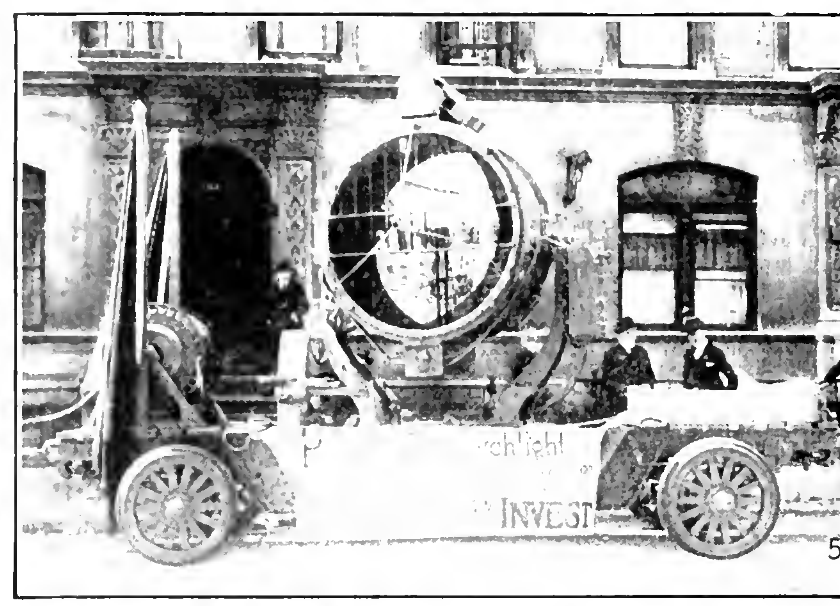
Referring to the pictures: The carpenter shop, Fig. 1, is arranged to do all light wood work. As shown, the side is let down and the curtain at the upper part is pulled up for working. It contains a boring machine, a drill press, a bench grinder, a work bench, a saw bench, a double-purchase winch, and a power plant and switchboard, besides the necessary tools and supplies. It costs, complete, about $8500.

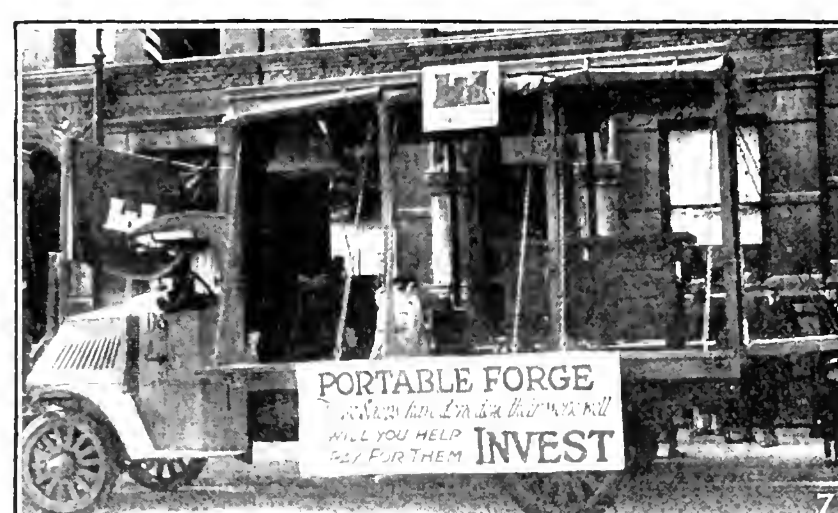
Fig. 2 shows a material truck with the side opened up for removing tools. Each truck contains about 600 items of tools and supplies. The height appears greater in the view than it actually is, because the upper portion of the sheet-iron side is folded up at the top. The sides are arranged so that they may be securely locked. The cost is about $8000.

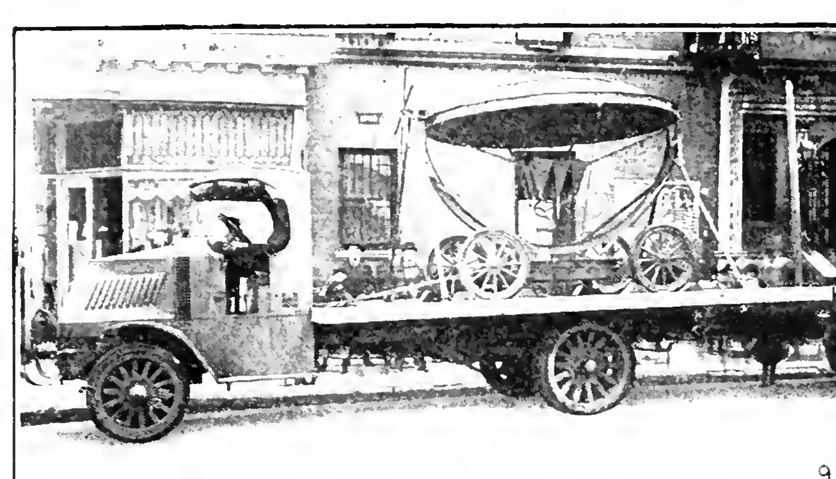
Of the other portable shops, the machine shop, Fig. 6, contains a work bench, a drill press, a portable electric drill, grinders, an electric hammer, a 14-in. lathe, an











FIGS. 3-9. 3. TRACTOR AND SEARCHLIGHT POWER PLANT. 4. OPEN-TYPE 60-IN. SEARCHLIGHT ON TRUCK. 5. SIXTY-INCH BARREL TYPE SEARCHLIGHT, WORKS WITH APPARATUS SHOWN IN FIG. 3. 6. MACHINE SHOP. 7. BLACKSMITH SHOP. 8. PRINTING SHOP. 9. PARABOLOID SOUND-RANGING APPARATUS

oxyacetylene welding outfit with a power plant and necessary tools and supplies. The complete shop costs about $9500. The blacksmith shop, Fig. 7, is also used in handling plumbing and tin-shop work when necessary. It contains a work bench, a forge, hoists, a pipe-threading machine, a shear and punch, vises, a welding and cutting outfit and power plant tools and supplies. The cost is about $8000.

Fig. 8 shows a portable printing shop used in making maps. During the parade this shop was turning out two-color posters, 20 x 30 in. in size, advertising the Victory Loan. All the shops are electric-lighted.

Figs. 3, 4 and 5 show the various searchlight appliances used for detecting airplanes. Figs. 3 and 5 go *en train*, the tractor hauling the power house and the searchlight to any desired location. The searchlight is of the 60-in., high-intensity, barrel type, developed by the Corps of Engineers. It has a turntable base which is hidden behind the Liberty Loan sign. By means of 500 ft. of cable the light can be operated anywhere within that radius from the power plant. The power plant consists of a gasoline engine directly connected with a dynamo, and, like the searchlight, is permanently mounted on a trailer.

Fig. 4 shows a 60-in. open, high-intensity type of searchlight, which is mounted upon rubber-tired wheels, so that it can be removed from the small truck and operated within a radius of 500 ft. from the same. The power for running this searchlight is mounted in the truck back of the cable roll. This searchlight has 2,500,000 candlepower. Tests of the searchlight used in detecting airplanes have shown a 43% visibility at 15,000 ft. and an 85% visibility at 12,000 feet.

The paraboloid sound-ranging apparatus shown in Fig. 9 was merely mounted upon this truck for the purpose of the parade. It is used in testing the location of artillery by the sound of the explosions.

Colleges Should Play a Part in Highway Program

Weakness of Road-Engineering Courses Compared With Great Need for Trained Road Engineers and Material Inspectors

By R. L. Morrison
Professor of Highway Engineering, Agricultural and Mechanical College of Texas, College Station, Tex.

There is no single line of activity to which more public attention is being directed at present than to the development of highways. During the war the amount and importance of highway transportation greatly increased, but new construction was practically at a standstill and even maintenance was reduced to an absolute minimum. With the ending of hostilities and the removal of legal restrictions upon road work, plans were immediately made for an era of roadbuilding such as this country has never known before. What part are the colleges to play in this road-development program? Are they leading or directing the movement? Are they doing extensive research work on highway problems? Are they training highway engineers to spend economically and efficiently millions of dollars?

Speaking generally, these questions must be answered in the negative. Of the 126 engineering schools of college grade, probably not more than a dozen devote as much as five term-hours to highway engineering, or have their highway course given by teachers with any practical experience as highway engineers. Practically every leading engineering school has at least one specialist in railway engineering, in sanitary engineering, and in structural engineering, but the highway specialists are conspicuously absent. Is there sufficient reason why colleges should offer more than a two- or three-hour course in highway engineering, or why the instructors should have any broader knowledge than can be obtained by a study of the textbooks used by the students, when the colleges are already criticized for specializing too much in undergraduate work?

The branch of engineering which most nearly resembles highway engineering is railroad engineering. When a young engineer in employed in railroad work after taking a college course which usually includes several courses in railway engineering, he works under the immediate supervision of, say, a trained and experienced resident engineer, and no matter how limited the young man's knowledge of practical railroading may be, he has every opportunity to learn and cannot go far wrong.

Untrained Men in Charge of Work

On the other hand, the 2,500,000 miles of public roads in this country are very largely in charge of men absolutely untrained and inexperienced in highway or any other engineering work, and who are constantly changing as a result of political changes. That there is enormous waste of money spent on roads is known to everyone. Comparatively few roads are adapted to the traffic which they are called upon to bear, improper materials are often used, and the standardization of methods and types is just beginning. The young man entering highway work may be employed as a county engineer within two or three years after graduation, with no experienced superior to guide him, or he may be in charge of work for a state highway department and located miles from his superior. In the latter case the engineer under whom he is working may be as new at highway work as he is.

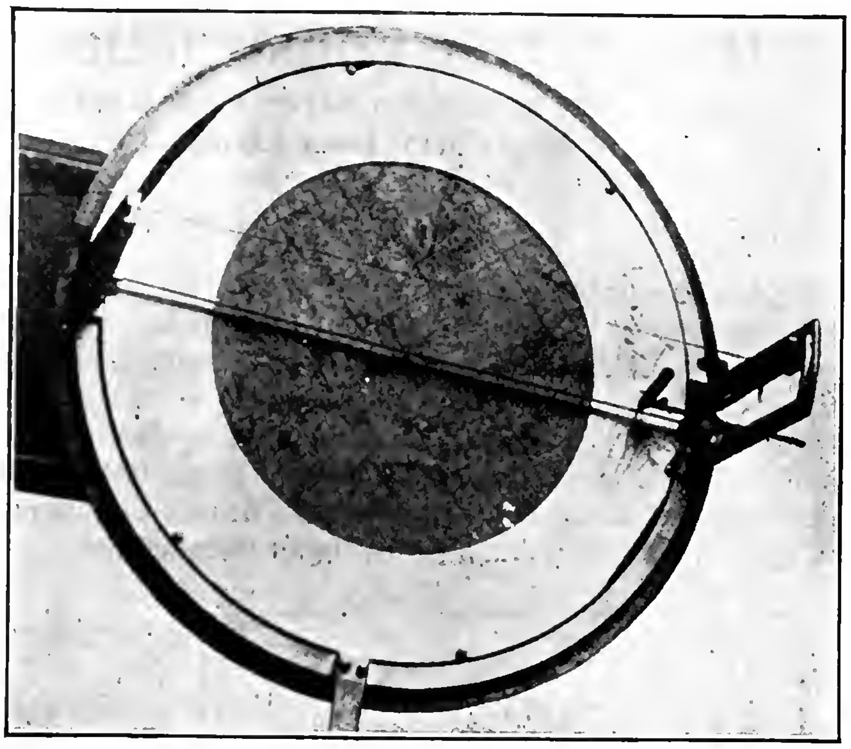
In no other field do so many engineers get responsible positions without previous experience in the work they are undertaking, and there is probably no other field which is attracting so many engineers at the present time. It would seem that this combination of circumstances alone is sufficient to justify the colleges in specializing in highway engineering.

Although there are of course many engineers all over the country who are thoroughly versed in all the details of highway work, there is also a large number who are called upon, for instance, to use large quantities of bituminous materials without having had any opportunity to make a study of such materials. They find that this is an extremely difficult subject to master without an instructor, so they use the materials by trade names only, or else they are forced to copy specifications which they do not understand and which may not be applicable to their particular conditions. If they wish to have intelligent laboratory control of their bituminous work, where they can find the necessary testing engineers? How many colleges are equipped to given adequate classroom and laboratory instruction in the subject of bituminous road materials? And if the colleges cannot train testing engineers, where do they come from? The answer is that as a rule they do not come.

In addition to training engineers, there is an opportunity for the colleges to be of great public service by giving "short courses" for local road officials who are not engineers. A few institutions have accomplished a great deal along this line, especially in coöperation with state highway departments. Valuable missionary work can also be done, especially in those states having the fewest good roads, by means of public lectures, bulletins, press articles, exhibits, etc. thus educating the public to appreciate and demand not only good roads but also proper methods of construction, maintenance, financing, and administration in general.

With this great opportunity before them, it is to be hoped that the engineering colleges will decide to do something more than turn out young men who are prepared to learn something about highway engineering, provided they can find someone to teach them.

"Fire Finder" for Lookout Stations of Forest Service



AN INSTRUMENT DEVELOPED BY THE FOREST SERVICE, TO LOCATE FOREST FIRES

AN INSTRUMENT combining some of the functions of the plane-table and the transit has recently been developed for locating forest fires from the mountain lookout stations of the United States Forest Service. Enough of the instruments were manufactured in Portland, Ore., early in 1918 to equip many of the important lookout stations in the Northwest, and it is reported that they gave satisfactory service last summer. In some cases fires were accurately located at a distance of 50 miles. Acting on the good record in actual use of the instruments, the Forest Service has recently adopted it as standard. It is known as the Osborne fire finder, as it was developed by William B. Osborne, Jr., of the Portland office of the Forest Service.

The instrument head consists of two parts, a lower iron plate equipped with leveling screws and lock nuts, and an upper iron plate of 24-in. diameter which pivots on the lower plate and bears on its periphery a circle graduated to 15 min. To this upper plate is fitted a heavy iron ring which can be revolved independently and which carries front and rear sights and a vernier for reading the horizontal circle. The vernier is graduated to read to 15 min. The sights are of brass, the rear sight being slotted as in a surveyor's compass, with the addition of a fixed peephole, the front sight being open with a vertical horsehair. The apparatus for measuring the vertical angle of the line of sight is attached to the front sight, and consists of a perforated brass belt running vertically on spiked wheels and controlled by a milled wheel and pinion. This belt carries a pointer and an indicator set horizontally at right angles to the line of sight.

The indicator slides over an etched tangent graduation attached to the outer face of the sight and reading to minutes. The same pinion which moves the belt and pointer carries a cogged wheel for moving a pencil-bearing rack forward and backward across the upper plate of the instrument, but along the line of sight. This enables the observer to sketch the panoramic profile, the sketch being made on a ring of heavy white celluloid, 21 in. in diameter and 4½ in. wide, which is placed on the upper plate of the instrument. The pencil is held in contact with the celluloid by a spring, and the profile is sketched by the observer looking through the peephole in the rear sight, keeping the pointer and horsehair of the front sight on the skyline or other line to be sketched, and slowly rotating the sight-bearing ring.

A map of the country under observation is fastened to the upper plate, beneath the celluloid ring before mentioned, the center point of the map representing the observation point. The instrument rests on a track mounted on a 1½-in. baseboard 28 in. long. The observer can move it along this track without disturbing the orientation or level, thus avoiding the posts of the lookout cabin that might obstruct the view.

In operating the instrument, the observer looks through the fixed peep of the rear sight and brings the pointer of the front sight to bear on the fire. The instrument being already oriented, he reads the azimuth of the line of sight on the horizontal circle and the vertical angle of the line of sight on the front sight graduation. He then obtains on the map of the locality a projection of the line of sight by means of a graduated steel tape which extends from the rear to the front sight. The zero of this tape is at the center of the map, and by the platting pencil he obtains the position of the fire on the panoramic profile.

The location of the fire is then determined by (1) platting the intersection of the lines of sight when the fire is reported from two stations; or (2) by using the vertical angle to plat the intersection of the line of sight with a profile or cross-section of the country along that line of sight; or (3) by estimating the location of the fire from its apparent position relative to other points which are platted on the map; or (4) by estimating the location of the fire from the position indicated for it on the panoramic profile, which latter estimate may be made at night when the features of the landscape are not visible.

Increase of Highway Costs in California

Highway costs in California did not change much in the period between 1912 and 1916, according to state highway officials, when the average cost of the standard concrete pavement, which was 4 in. thick and 15 ft. wide, amounted to $6200 per mile, exclusive of grading and culverts. In 1917, however this cost rose to $8400, and in 1918 the average was $10,800 per mile.

Design and Construction of Navy Concrete Oil Barges

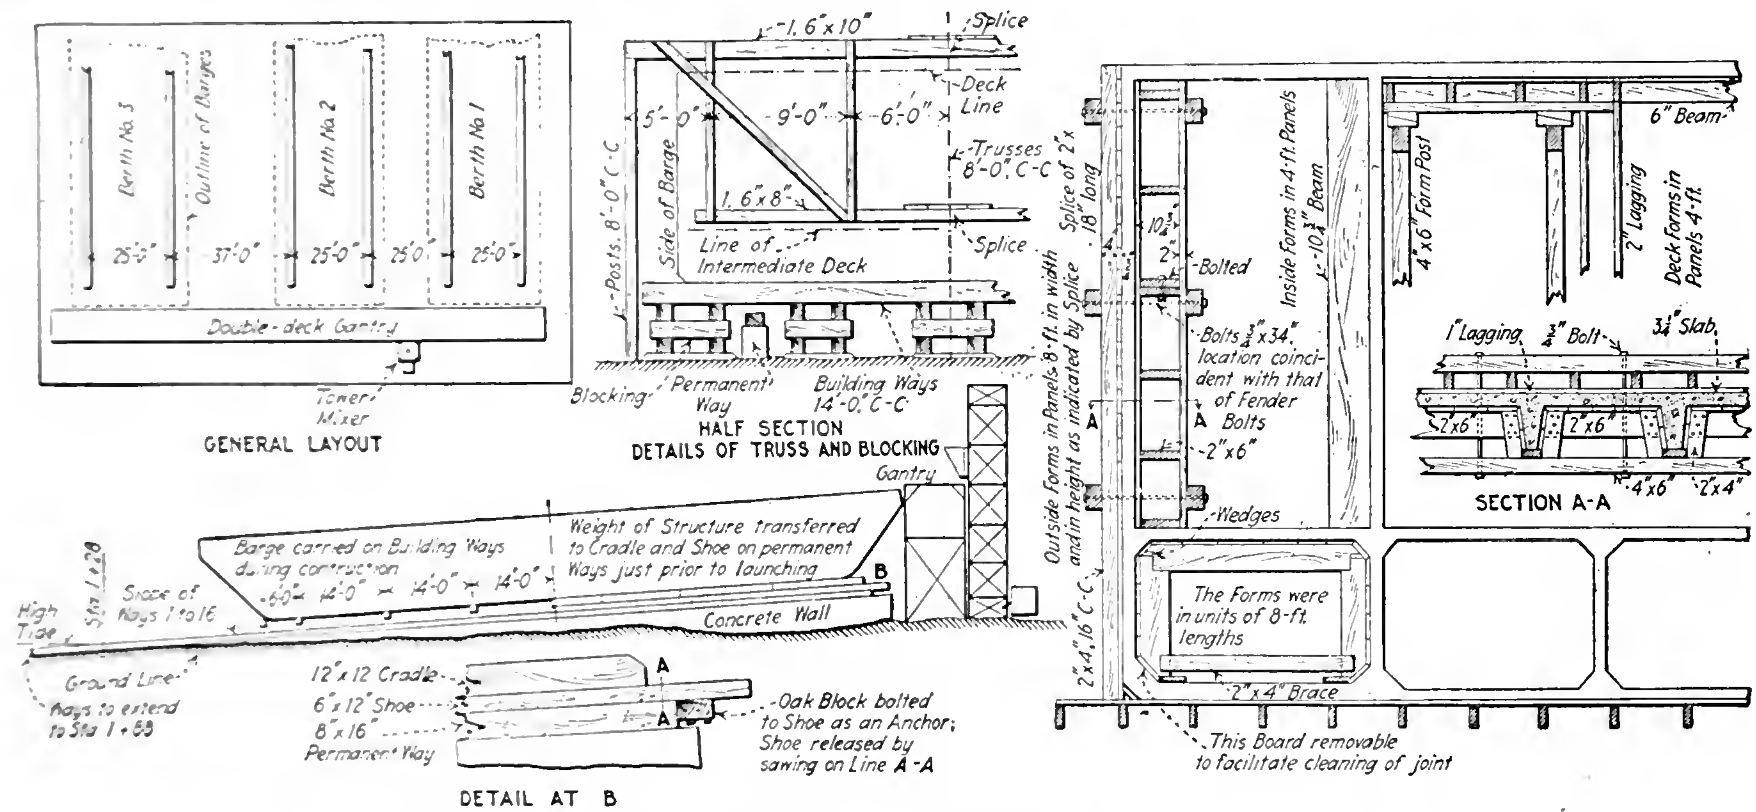
Boats Built at Hudson River Yard Have Oil Holds Protected by Air Compartments and Also May Carry Deck Loads—Concrete Poured From Trestle at Rear of Boats

By R. M. Burkhalter
Engineer, Louis L. Brown Company, New York City

THREE concrete oil barges for the United States Navy were successfully built and launched last season at the Hudson River yard of the Louis L. Brown Co., at Verplanck, N. Y. These vessels were designed in general outline by the department, but details were supplied by the contractor. They are being used as oil carriers, and differ from the common design of concrete barges in that they have below-decks compartments for 3000 bbl. of oil and a deck capable of carrying a 500-ton cargo, although both loads cannot be carried at the same time.

The principal dimensions of the barge are: Length 112 ft., beam 35 ft. and depth 13 ft. 4 in. As shown in one of the drawings, the barge has an intermediate deck below which six fore and aft bulkheads run the entire length of the barge. Above this intermediate deck are four fore and aft bulkheads which provide three spaces for oil compartments and two outboard compartments without cargo. By this arrangement an air compartment is everywhere provided between the oil compartments and the skin of the barge. There are, in addition, three transverse bulkheads above and below the intermediate deck, making a total of 32 separate compartments in the barge. The amount of cargo space and of air space below deck are practically equal.

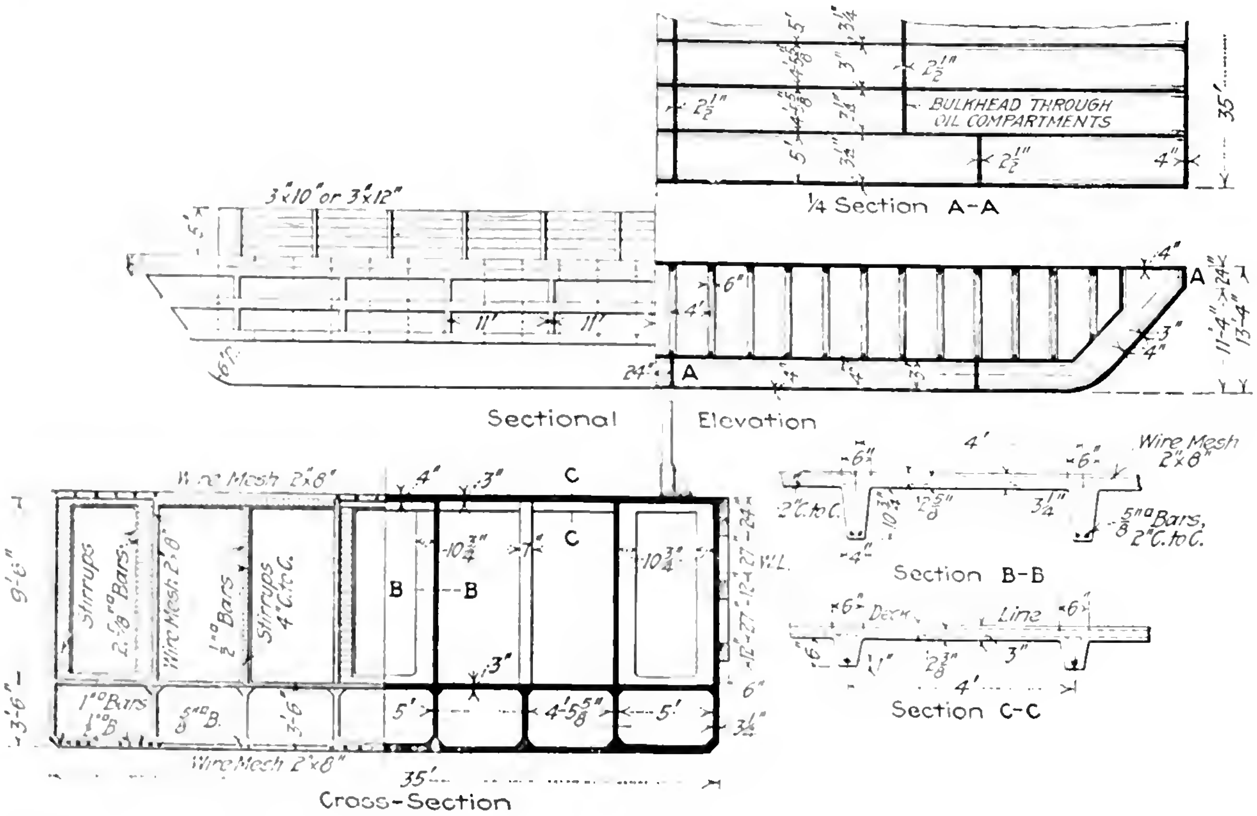
The transverse frames, above the intermediate deck only, are 4 ft. c. to c. They consist of vertical beams of 10¾-in. depth and horizontal beams of 6-in. depth so placed that the frames formed rectangles, three of which appear in the cross-section of the barge. The vertical members of these rectangles are beams receiving, through the slab, oil pressure or water pressure. The top members of the rectangle serve as deck beams and as struts between the two verticals; the bottom members serve as struts only. Thus there is produced a strong, rectangular frame which serves to transmit the deck load to the hull and to stiffen the boat transversely, corresponding to the strong frames in the usual marine design. Longitudinal strength is obtained by using fore and aft bulkheads. These bulkheads are 3 in. thick, stiffened every 4 ft. by vertical beams which extend down to the intermediate deck. Stiffeners were not considered necessary below the intermediate deck, since the unsupported height was only 3 ft. Rods placed in the hull and deck slabs below and above these bulkheads. cause the structure to conform to the requirements of a plate girder. By placing reinforcement on both hull and deck either flange is capable of taking tension; that is, the girder is effective as a plain or as a cantilever beam, so that it can take care of hogging and sagging strains. Actually, the vessel could be supported at its two ends only or by its middle third without overstressing the members.



FORM AND YARD LAYOUT FOR NAVY OIL BARGES BUILT AT VERPLANCK, N. Y.

The slabs in the bottom are 4 in. thick and in the side 3½ in. The reinforcement used is welded wire and deformed bars. In the slab the reinforcement was entirely of mesh, of which two layers were used in order to provide for the negative moment. Rods were used for beam reinforcement. In addition, a number of rods were placed to take care of the strains induced by hogging and sagging action. Much care was used in the choice of concrete materials, and the final choice was a special mixture of limestone screenings and ⅜-in. crushed limestone. The virtue of this product is the perfect grading of materials from the fineness of portland cement to the ⅜-in. aggregate.

In the design the stresses used were 12,000 lb. per square inch in steel and 800 lb. per square inch in concrete. The stress in concrete was taken as 37½% of an ultimate strength of 3000 lb. Tests made by the



DETAILS OF THE DESIGN OF NAVY OIL BARGES BUILT BY L. L. BROWN COMPANY

made with the horizontal did not increase.

In order to carry on the work economically, a two-level gantry was erected across the upper end of the barges and a concrete tower was provided to deliver concrete to these levels. This gantry connected with platforms down the center of the barge. A concrete water tank was built and water was piped to all parts of the work, so that an ample supply was available for wetting down the concrete. In the actual placing of the concrete the manner of placing was considered of greater importance than the quantity placed. The pouring of a complete barge in one operation was not attempted. Joints were foreseen; their locations were chosen and the bonding of new concrete to old was provided for. For instance, a horizontal joint was made at the level of the intermediate deck. At this point a large area of bonding was obtained, together with a maximum of reinforcement with the condition of no shears, since the slab support is here vertical.

In building the barges the bottom forms were first laid on the ways, extending up both rakes, and on this form were placed the two layers of mesh and the longi-

United States Navy showed the concrete to have a strength uniformly greater than the 3000 lb. assumed above. The average of these tests was 4000 lb. per square inch, with a maximum of 5400 lb. per square inch. The test specimens were cylinders 6 in. in diameter by 12 in. long, made by the resident inspector from concrete taken from the mixer during the actual pouring of the barges.

The layout of the yard and installation essential to construction is shown in one of the drawings. The berths are 50 ft. c. to c., and each berth has two ways 25 ft. c. to c. Each way consists of a concrete wall 18 in. thick, extending from the shore line back 150 ft. on a slope of ¾ in. to 1 ft., or 1 to 16. On top of the wall was placed an 8 x 16-in. timber secured to the concrete, as the fixed or permanent way on which the traveling shoe found bearing. Each berth also has concrete slabs in the ground between the ways, and on these foundations timber blocking was built up to a height 6 in. above the top of the permanent way timber. On this blocking were placed transversely building ways of 12 x 12-in. timber and of such length that they exceed the width of the barge by 2 or 3 ft. On these building ways the bottom forms were built, the entire structure being supported on the ways until within a week of launching.

After the concreting of the barge has attained sufficient strength, the building ways are removed and blocks substituted. On the day of the launching the 6 x 12-in. shoe was placed on the permanent way, well greased, the space between the shoe and the hull was well packed with timber, and the blocks were removed. With all blocks removed and the boat resting on the shoes, the component of gravity along the way was resisted by anchorage of the 6 x 12-in. shoes at the offshore end. The sawing of the two shoes simultaneously effected the release of the barge at the time desired and insured an equal start on the two ways. The ways were extended into the water sufficiently to satisfy the condition that at all times during the launching the moment of buoyancy about the end of the ways was greater than the moment of the weight of the barge about that point. In other words, the angle which the bottom of the barge

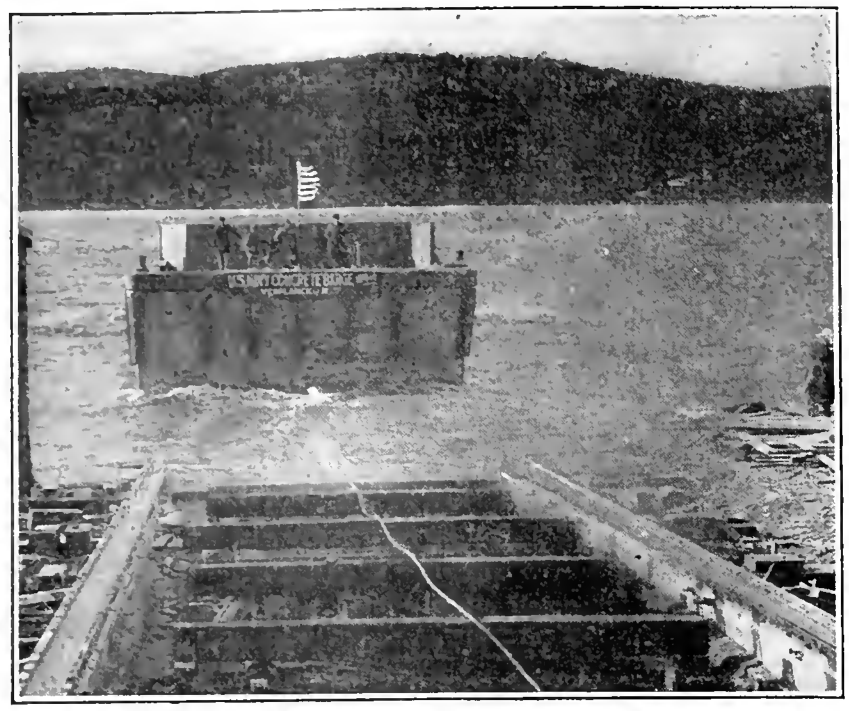
LOOKING DOWN ON OIL BARGE DURING CONSTRUCTION

tudinal rods. The mesh was placed transversely and was cut in lengths which extended above the joint in the sides of the hull. Posts were then erected and inverted trusses, framed of light lumber, were placed so that the upper chord spanned 40 ft. clear—that is, 2½ ft. each side of the outside skin of the boat. The lower chord was 30 ft. long and was included within the outside forms. This lower chord supported the reinforcement and the working platforms and runways. The chords were spliced, the framing was simple, and the erection by means of a gin-pole was easily effected. The lower chord was placed high enough to clear the intermediate deck by 2 ft. and the lower level of the gantry connected with the platform on the lower chord of the trusses.

The bottom of the barge was first concreted, the concrete being conveyed to the panels by buggies. Tied to the bottom reinforcement, stubs were placed to extend up into the bulkheads, longitudinal and transverse. The next step was the placing of reinforcement and forms for the longitudinal bulkheads and the intermediate deck. The forms were in 8-ft. lengths and in three parts forming the two sides and the top of the square, or, as it was called on the work, the tunnel. The stubs tied to the bottom reinforcement were hooked into the strands of the reinforcement of the bulkheads, such engagement giving a positive connection of the reinforcement of the two parts. This scheme of bonding was followed throughout the construction.

INTERMEDIATE DECK OF NAVY OIL BARGE CONCRETED FROM SUSPENDED RUNWAY

The bulkheads and the hull were poured to the level of the intermediate deck, and the intermediate deck was then poured. The webbing and the lower chord of the trusses were then removed, and the platform was shifted to the upper chord. This chord was posted in the center. The forms for the bulkheads above the intermediate deck were then set, the panel forms on the sides on which there were no beams being placed first. Against this the mesh was placed and then the 4-ft. panels forming the slabs and beams were set. These bulkheads and the hull were concreted to the deck level in two lifts. With these forms removed, supports were provided and the panels of the deck forms were placed. In concreting the deck the methods used in pouring were similar to those used in pouring floors.



BARGE LAUNCHED ENDWISE FROM CONCRETE WAYS

Additional reinforcement was provided where the deck fittings were placed, and holes were left in the deck for the fitting bolts. The fittings placed were standard Navy fittings. Under each was placed an oak seating 3 in. thick to protect the concrete deck. A 2-in. oak washer was provided below deck for each of these bolts, and the bolts were grommeted to make them water-tight. A waist for the deck cargo consists of brackets of structural steel bolted to the deck on 8-ft. centers and supporting 5 ft. of 3-in. pine plank. The fenders are 6 x 12-in. oak cut from local timber, bolted to the sides of the vessel by ¾-in. bolts 2 ft. on centers. Inside, a 2-in. plank was framed between the vertical beams to act as a washer for two bolts.

One of the essential features in the construction was the curing of the concrete. Concreting in extremely hot weather was avoided, and at all times the concrete was shaded from the sun for at least two weeks after placing. The surface of the concrete during this time was constantly kept wet, being sprinkled as often as was necessary. After the removal of the forms the exterior skin of the barge was carefully gone over, and all projections were rubbed down by a carborundum brick. The surface of the concrete was then rubbed with a cement brick, directly following a brush of thin mortar. Consideration was given to the painting of this hull with a paint other than a cement product, but the Navy gave instructions that this be omitted, in order to test the water-tightness of the slab. The barges proved to be dry—dusty dry. However, it is probable that an application of some waterproof coating on the skin of barges would be desirable in that it would assist in preventing water from attacking the steel reinforcement of the barge.

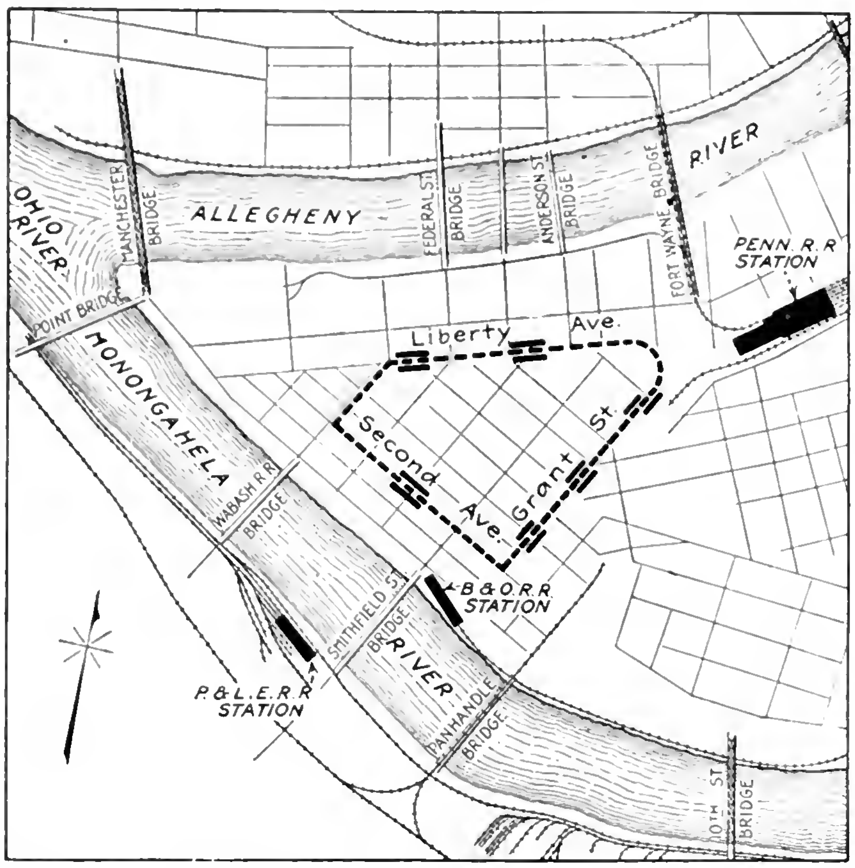
England Has Built Twenty-Two Concrete Barges

Up to Mar. 25 Great Britain had launched 22 concrete barges, according to a statement recently made in the House of Commons. Of these, nine had been completed and five actually delivered. Twenty-two more barges are under construction, as well as six concrete tugs. It is stated that as the Government does not require such vessels now, it is not the intention to build more, because in the opinion of the Admiralty there has not yet been sufficient experience to justify opinion concerning their success.

Street-Car Loop Subway Proposed by Pittsburgh

Six-Million-Dollar Municipal Project, to Relieve Downtown Traffic Congestion, Advocated by City Authorities

ISSUE of city bonds for $6,000,000 to build a street-car subway loop in downtown Pittsburgh has been proposed by the mayor and public works department to the voters of the city. Following several prior studies for transit improvement in the city, a report recommending two rapid-transit lines from the heart of the city to the eastern suburbs was rendered a year ago by E. K. Morse, appointed as city transit commissioner to investigate the situation and work out a solution. This



PROPOSED STREET-CAR LOOP SUBWAY IN PITTSBURGH

recommendation, which contemplated an expenditure of something over $12,000,000 for the two lines, did not meet with the favor of the city officials, however, partly for the reason that it would not relieve the downtown congestion of traffic. On account of the topographical limitations to the development of the Pittsburgh business district, the narrowness of the downtown streets, and the very great density of street-car traffic morning and evening, it has been concluded that relief of the surface-car congestion must be the first line of attack on the transit problem. The present project has been developed from this point of view.

In the accompanying sketch map of the "Point" district of Pittsburgh, taken from a recent pamphlet by N. S. Sprague, chief engineer of the city's department of public works, the proposed loop subway is indicated by a broken line. The route extends through Liberty Ave., Ferry St., Second Ave. and Grant St., passing the Pennsylvania Railroad station at the turn from Grant St. into Liberty Ave. The structure i. to be 8400 ft. long and is to be a two-track subway in which all cars will operate in the same direction around the circuit. Passengers will enter and leave by way of six stations, three of them being located on Grant St. (at Fourth Ave., Fifth Ave and Seventh Ave.), two on Liberty Ave. (at Wood St. and at Fifth Ave.), and one on Second Ave. (at Wood St.), the station intervals ranging from 760 to 1860 ft. Cars will enter and leave the subway by way of portals located above high-water level.

It is intended that all surface cars in the city shall loop through the subway except the North Side, West End, and Lincoln Ave. cars, which will extend only to the outer edge of the business district and will turn back by way of surface loops on Liberty Ave. (between Federal and Stanwix Sts.) and around the court house at Grant and Diamond Streets.

Referring to present traffic conditions and the proposed subway service, Mr. Sprague reports that at present 573 cars per hour enter the downtown district during the rush hours. Of these about 60%, or 335 cars per hour, would use the subway loop, the others using the two surface loops mentioned.

No definite plans for operation have been formulated, but the city officials believe that the subway can be leased to the street-railway company for operation. Inasmuch as the use of the subway would probably not increase the revenues of the street-car system very greatly, it is anticipated that part of the cost of the subway will have to be borne by the city. This is regarded as a proper offset against the cost of street widenings and other improvements which would have to be made for relief of street traffic if the subway were not built and the street cars thus were not taken from the street surface.

Development of the loop into the downtown portion of a true rapid-transit system is thought to be quite practicable at a later time. No suggestions have been made for future provision for the surface cars when the loop is thus taken over for rapid-transit service.

Engine Terminals and Roundhouse Cost

AN engine terminal capable of handling 100 locomotives daily will cost about $660,000, at present prices, for construction and equipment, according to a paper on "Modern Tendencies in Roundhouse Design," read before the Western Society of Engineers by E. M. Haas, railway specialist of the Austin Co. This would give annual fixed charges of about $69,300 at 10½% for interest and depreciation, or about $2 per engine per day. About 33% of the total first cost would be represented by the roundhouse and its equipment, the building of reinforced concrete. The cost per roundhouse stall at 1918 prices has ranged from $6000 to $22,000 for the building, with light, heat and plumbing; while for the entire terminal it has ranged from $25,000 to $50,000 per stall. The higher costs imply permanent construction and ample labor-saving facilities. The distribution of cost of such a terminal is shown in the accompanying table.

Fire-resisting construction is highly desirable, for,

COST OF ENGINE TERMINAL TO HANDLE 100 LOCOMOTIVES DAILY

24-stall roundhouse	$220,000
Grading, drainage and tracks	70,000
Two inspection pits and service building	16,000
Coaling and sand station, water-supply	74,000
Two water-type ashpits with a gantry crane	36,000
100-ft. turntable and pit	20,000
Oil house and equipment	10,000
Machine shop and power house	64,000
Boiler-washing plant, 10-ton crane, electric hoist for engines, shop and power house equipment	120,000
Miscellaneous	30,000
	$660,000

although roundhouse fires are not frequent, they may cause great loss to expensive locomotives, besides putting engines out of commission. This may be the case even if only the roof is of wood. Timber frame and roof with brick walls has been a very general type, but involves high cost for depreciation and maintenance. Both steel and concrete construction were noted by Mr. Haas, but he favored the latter, and also preferred monolithic concrete construction to the unit system. He referred to the desirability of long span between the posts, in order to avoid interference with the work on the engines. For this reason a design used by the New York Cenetral R.R. has a 64-ft. truss span over the main space. Incidentally, these trusses were originally made of heavy timbers, but they are now built up of planks, in order to cheapen the construction.

Overhead cranes have been applied in a number of roundhouses and an investigation made on the Pennsylvania R. R. showed that the maximum load to be handled was about 8½ tons, so that a 10-ton crane would be adequate for this service. In Mr. Haas' opinion there is a tendency to substitute the engine hoist for the drop pit for handling wheels and axles, owing to the greater liability of danger in jacking up the engines on the pits, due to weight of modern engines and the use of inexperienced labor. For heating, the hot-blast system is considered preferable, as it costs little more than the direct system and has the advantage of providing forced ventilation.

Daily Code Letter Shows Status of All Highway Work

Texas State Highway Department Condenses All Daily Progress Reports Into One Page by Means of Alphabetical Symbols

By Julian Montgomery
Division Engineer, Texas State Highway Department

Using alphabetical symbols, the Texas State Highway Department, which has 189 state-aid projects and 190 Federal-aid projects, has found it possible to make on one sheet of letter paper a combined daily progress report of the status of all jobs. The key for the code letter, which is sent to each recipient of the report, makes it possible to tell at once the condition of each job in the state, while the job number and county indices give a complete description of the project. These reports have been found very useful in conveying accurate information to commissioners and engineers who are constantly being questioned as to the status of the various jobs.

Due to the recent war, most state-aid and Federal-aid projects have been inactive. The majority of the counties in which they are located have not finally completed their applications for aid, one of the main reasons being that they had no available funds at the time of making application. In order to complete their applications they must show the source from which the county's share of the cost of construction is to come —usually bond issues.

Whenever aid is allotted to a county on a state highway, this allotment is given a job number for filing reference, and when the job has reached the stage for the execution of the project agreement it is then given a project number. Work other than road construction, such as the preparation of county road maps (specified by law to be done by the highway department in certain instances), involving the expenditure of money by the department, also receives a job number. The projects are in various stages of progress, ranging from 195 which have not finally completed their applications for aid, to 81 which are now under construction.

The state highway engineer, the highway commissioners, and the division engineers, located in different parts of the state, every day receive numerous inquiries concerning the present status of these state- and Federal-aid projects. In order to be able to answer these numerous inquiries, and to have the present status of each job for available information, the state highway engineer found it necessary to have a comprehensive daily progress report of all jobs. To serve its intended purpose, it was necessary for this daily report to be very brief, easily digested and thorough.

To the writer was entrusted the task of designing such a report. It is easily seen that an ordinary written report covering about 400 jobs, if intelligently prepared, would cover 10 to 12 pages. To issue such a report daily would entail a great deal of printing and consume a large quantity of paper. It was found that a status key combined with a job number key enabled the daily status of every job to be given on one sheet of paper.

CODE LETTER, JOB AND COUNTY INDEXES AND CODE KEY USED BY TEXAS STATE HIGHWAY DEPARTMENT

Daily Report on Jobs, March 8, 1919

Job Number Index (Sample)

Job No.	County	Estimated Cost	State Aid	Federal Aid
150	Travis	$100,436 00	$25,109 00	
151	Guadalupe	12,316 25		$5,000 00
152	Camp	65,644 52		17,454 00

County Index (Sample)

County	Local Name of Road	Job No.	Highway No.	—Project No.— State Aid	Federal Aid
Taylor	Texarkana-El Paso	297	1	61	..
Titus	Texarkana-El Paso	54	1	13	26
Travis	Austin-Lockhart	150	29	33	..

A reproduction of the code portion of one of these sheets, together with the key, is given in the table. The code in this case covered only about one-third of a sheet and the remainder was used for a summary of the various information and an announcement of coming lettings and jobs under construction.

It will be noticed that the code letters in the daily report are arranged in groups of 10. This is for convenience in locating the job numbers. Beginning in the upper left-hand corner, the first capital letter denotes the present status of Job No. 1, the second capital letter that of Job No. 2, etc. Fifty jobs are on each line, arranged in groups of ten. To expedite the location of job numbers on the report, the numbers of the first and last job on each line are placed at the beginning and end.

The "present-status" key is self-explanatory. Each capital letter represents a step in the process of the completion of the project, from the time when aid is granted to the acceptance of the completed work and payment of the final estimate. Some of the job numbers refer to other things besides state- and Federal-aid projects, such as the preparation of country road maps. The letter "Z" is supplied for such jobs.

Each person to whom the daily report is sent is supplied with a job number index showing the job number, county, estimated cost, state aid and Federal aid. In addition, an alphabetical index by counties is furnished showing county, local name of road, job number, highway number, state project number and Federal project number. Samples of these indexes are also given in the table.

Example

It is seen that the last letter in the third line of the daily report is "O." This is the 150th letter and therefore gives the present status of Job 150. Referring to the "present-status" key, the letter "O" shows that the project has reached the stage where the contract for Job No. 150 has been let and executed between the contractor and the department. Knowing that the project has reached this stage, it is known also that all the stages preliminary to this have been completed.

Referring to the job number and county indexes, it is noticed that Job No. 150 is a state-aid project, No. 33, on the Austin-Lockhart section of state highway number 29, Travis County, and that $25,109, state aid, has been allotted to this road.

This daily report is printed by multigraph which is kept set all the time. Only such daily changes are made in the capital letters as are dictated by the changes in the present-day status of each job.

Maintaining Traffic During Erection of Louisville Bridge

Floods and Washouts Caused by Swift Current of Ohio River Force Revision of Methods—Timber Towers Support Longitudinal Steel Girders

The erection of the new double-track riveted-truss spans outside of the historic Fink trusses of the Louisville bridge practically without interruption of traffic was completed last year in spite of many difficulties caused by the swift current of the Ohio River and unusual flood conditions which at one time resulted in the loss of some steel lower chords and floor material by the washing out of the falsework. By bunching the trains to pass over the bridge at the noon hour or about 4 p. m., and diverting some trains to other bridges at the critical stages in the work, operation was maintained throughout the two years from June, 1916, to October, 1918, during which time about one mile of steel superstructure was erected, including the long 644-ft. riveted span and a 260-ft. lift span. The old masonry piers were built by removing the upper courses and capping with steel grillages surrounded by concrete. The principal design features of this bridge were de-

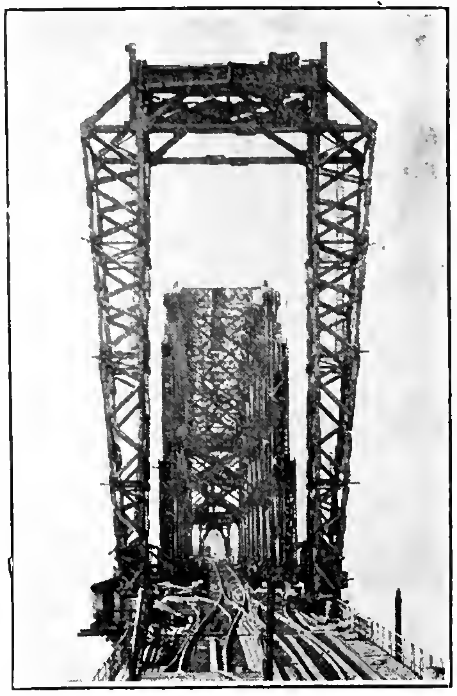
scribed in *Engineering News-Record* of May 22, 1919, p. 1007.

Erection of the 644-ft. span was carried out by the use of timber bents built in groups of four and supporting longitudinal steel girders for the tracks of a gantry traveler. Many difficulties had to be overcome in placing these bents on the rough rock bottom of the river. In general, the principle adopted to avoid flood danger was the use of longitudinal steel girders on timber towers spaced to conform to the lengths of the available girders. This resulted in greater clear waterway for the swift current, which averaged about 10 miles per hour, and a less number of bents to be set on the river bottom.

Erection Progress—Erection work started in June, 1916, on the deck spans at the north end, working from the abutment to the Indiana channel span. By Oct. 1, 823 ft. had been erected, consisting of three 180-ft. deck spans, one 150-ft. deck span, and two small girder spans. Between Sept. 1 and Sept. 15 of the same year, five 245-ft. deck spans, connecting the two through-truss spans, were completed. The next year the 370-ft. through span was constructed between Apr. 25 and July 10, followed by the remaining nine deck trusses on the Louisville side, which were completed by Jan. 20, 1918. The lift span, with its approach girder spans, was erected in the spring of 1918. Work began on the 644-ft. through span on Apr. 20, 1918, and it was swung on Oct. 15, 1918, about six months later.

Deck Span Erection—A regular sequence in the erection of the series of 245-ft. deck truss spans was followed. In each case the first operation was the construction of the double-bent timber towers. These were placed on concrete pedestals anchored to rock by 1½-in. gaspipe set in cement grout, similar concrete foundations also being used for the pedestals of the 370-ft. Kentucky channel span.



GANTRY ERECTION OF 644-FOOT SPAN

The timber towers, which supported steel girders at a level just below the lower chords of the old trusses, were spaced according to the length of the girders available—in the case of the deck spans these girders were 70 ft. long and were obtained from the contractor. They were placed by a derrick car from the old Fink-truss spans. Timber pony bents were then erected on these girders, one on each side of the panel points of the old truss, blocking up under the old stringers to support the floor. Except for the first group of spans erected, these pony bents, as shown in one of the drawings, were supported by floor-beams removed from the old trusses.

As soon as this falsework had been constructed and

THROUGH MULE TRAVELER AND DERRICK CAR WHICH ERECTED DECK TRUSS SPANS OF LOUISVILLE BRIDGE

the floor supported in two adjacent spans, the old intermediate masonry pier was cut down by carefully removing the stones to a level far enough below the desired pedestal support of the new deck girders to allow the steel grillages to be placed on top of the pier, and concreted.
